De conformidad con el artículo 4 de la DAS, una masa de agua subterránea está en buen estado cuando no se superan las normas de calidad o los valores umbral en ninguna de las estaciones de control. En el caso de que se haya excedido una norma de calidad o valor umbral en una o varias estaciones de control, es necesaria una investigación adecuada que integre de manera apropiada los datos de control, para efectuar una estimación del alcance en la MAS -en términos de volumen o porción de territorio- cuya concentración media aritmética de un contaminante supera la norma de calidad o el valor umbral. Se trata de evaluar:

- los riesgos medioambientales significativos producidos por los contaminantes presentes en toda la masa de agua subterránea
- que no exista un deterioro significativo de los usos humanos,
- la salinización y otras intrusiones.

Para que la investigación o investigaciones adecuadas se desarrollen satisfactoriamente, podrán utilizarse datos adicionales, para afinar el modelo conceptual y/o valorar el alcance del citado incumplimiento.

4.2.3 Situación de los puntos donde se han superado las normas de calidad o los valores umbral

Algunos de los criterios para la evaluación del estado también se basan en la evaluación del impacto a escala local, que puede no ser representativo de las condiciones que se dan en toda la masa de agua subterránea. En esos casos, la ubicación de los puntos donde se han excedido las normas de calidad o los valores umbral será pertinente para determinar si se han cumplido las condiciones para un buen estado. Esto hace referencia a la evaluación de:

- la disminución de la calidad ecológica y química de las masas de agua superficial asociadas,
- los daños a los ETDAS,
- la salinización y otras intrusiones,
- el que no exista deterioro del agua para consumo humano.

En lo relativo a la protección de los ecosistemas terrestres y acuáticos dependientes, los Estados miembros evaluarán, cuando sea necesario y pertinente, las cantidades y las concentraciones de los contaminantes que se estén transfiriendo o puedan transferirse desde la masa de agua subterránea a las aguas superficiales asociadas o ETDAS [anexo III, 4 b)] y el posible impacto de los contaminantes transferidos [anexo III, 4 c)].

La evaluación de toda salinización o intrusión de otro tipo en la masa de agua subterránea está vinculada a la identificación de las zonas en las que existe presión producida por la captación de agua, y con los efectos que aparecen en los puntos de control, en relación con las tendencias al aumento de las concentraciones de contaminantes pertinentes y los impactos significativos en los puntos de captación.

4.3 Normas de calidad y valores umbral de las aguas subterráneas

4.3.1 Fundamentos y requisitos específicos

El artículo 3 de la DAS establece los criterios para la evaluación del estado químico de las aguas subterráneas:

“1. A efectos de la evaluación del estado químico de una masa de agua subterránea [….] los Estados miembros utilizarán los criterios siguientes:

(a) las *normas de calidad de las aguas subterráneas recogidas en el Anexo I;*

(b) Los valores umbral que establezcan los Estados miembros de conformidad con el procedimiento descrito en la parte A del Anexo II […]”.

Además, entre los criterios de evaluación del estado químico se incluye una investigación adecuada cada vez que se haya excedido una norma de calidad de las aguas subterráneas o un valor umbral, tal como se establece en el Anexo III de la Directiva de aguas subterráneas.

Las normas de calidad de las aguas subterráneas se refieren a nitratos y plaguicidas. Los valores para las normas citadas se muestran en la tabla 1.

Tabla 1. Normas de calidad de las aguas subterráneas (DAS, anexo I).

Contaminante	***Norma de calidad***
Nitratos	50 mg/L
Sustancias activas de los plaguicidas, incluyendo los metabolitos relevantes y los productos de degradación y de reacción	0.1µg/L 0.5 µg/L (total)

No obstante, si estas normas no son adecuadas para el logro de los objetivos medioambientales enunciados en el artículo 4 de la DMA, es decir, si se observa que el estado químico y/o el estado ecológico de las aguas superficiales asociadas y/o los ecosistemas terrestres asociados han sufrido algún daño real o potencial, deben aplicarse valores más exigentes[18]. Estos nuevos valores se transforman en valores umbral y el procedimiento para su definición se atiene a los requisitos del artículo 3 y del Anexo II de la DAS y a las especificaciones descritas en este documento.

El artículo 3.1.b de la DAS exige a los Estados miembros la determinación de valores umbral con respecto a otros parámetros pertinentes que están generando un riesgo de incumplimiento de los objetivos del artículo 4 de la DMA. Tal como se define en el artículo 2.2, los valores umbral en cuestión se convertirán en normas de calidad definidas por los Estados miembros. Estas normas deben fijarse a la escala más adecuada -nacional, por demarcación hidrográfica, o por masa de agua subterránea- y deben utilizarse en la evaluación del buen estado químico. Los Estados miembros deben tener en cuenta como mínimo la lista de sustancias del anexo II.B que son:

- Sustancias, o iones, o indicadores, que pueden estar presentes de modo natural y/o como resultado de las actividades humanas: As, Cd, Pb, Hg, NH_4^+, Cl^-, SO_4^{2-}
- Sustancias sintéticas artificiales: tricloroetileno, tetracloroetileno
- Parámetros indicativos de salinización o de otras intrusiones: conductividad o Cl^- y SO_4^{2-}, a elección de los Estados miembros.

Nota*:* "Teniendo en cuenta…" no significa que la determinación de valores umbral para todos los parámetros del anexo II.B sea obligatoria. Es obligatorio asignar valores umbral para otras sustancias/parámetros que no están en la lista, pero que contribuyen a que la masa de agua subterránea esté en riesgo.

Criterios para la determinación de valores umbral

Según el Anexo II.A de la DAS, *"la determinación de valores umbral debería basarse en:*

a) el alcance de las interacciones entre las aguas subterráneas y los ecosistemas acuáticos y ecosistemas terrestres dependientes;

b) la interferencia con usos o funciones existentes o futuros de las aguas subterráneas;

[…]

c) Las características hidrogeológicas, incluida la información sobre niveles de referencia".

Asimismo, según el Anexo II.A de la DAS *"se establecerán valores umbral de tal modo que […] ello indique el riesgo de que no se estén cumpliendo algunas de las condiciones para el buen estado químico del agua subterránea mencionadas en los incisos ii), iii) y iv) de la letra c) del apartado 2 del artículo 4".* Este requisito se refiere a los aspectos siguientes:

- la definición de buen estado químico del agua subterránea (DMA, anexo V, sección 2.3.2). Véase la sección 4.1 de este documento.

- las áreas protegidas utilizadas para la captación de agua potable (artículo 7 de la DMA),

- la capacidad de la masa de agua subterránea de soportar usos humanos.

Basándose en estos elementos, la determinación de valores umbral debe considerar dos tipos de criterios:

[18] Un ejemplo típico es cuando se demuestra que la existencia de nitratos en valores inferiores a 50 mg/L en las aguas subterráneas es causa de eutrofización en una masa de agua superficial asociada, lo cual justifica el establecimiento de un valor umbral más bajo para los nitratos.

- *criterios medioambientales*
  - valores umbral cuyo fin es la protección de los ecosistemas acuáticos asociados y de los ecosistemas terrestres dependientes,
- *criterios de uso*
  - valores umbral cuyo fin es la protección de las zonas protegidas para la captación de agua potable (ZPAP), y
  - otros usos legítimos de las aguas subterráneas: cultivos, regadío, industria, etc. Solamente deben tenerse en cuenta los usos localizados en una porción significativa de la masa de agua subterránea en relación a la superficie total o al volumen total de la misma.

Nota: Estos criterios consideran el nivel mínimo de protección del receptor de conformidad con los requisitos de la DAS. Los Estados miembros pueden optar adicionalmente por considerar que "las aguas subterráneas" son una función legítima a proteger por derecho propio y establecer valores umbral con este fin. No obstante, es obvio que no están obligados a hacerlo.

Escala para el establecimiento de valores umbral

Dependiendo del tipo de contaminante y de las concentraciones registradas, los Estados miembros pueden establecer valores umbral a distintas escalas: masa de agua subterránea o grupo de masas de agua subterránea, demarcación hidrográfica, o a escala estatal (articulo 3.2). La masa de agua subterránea es la escala más pequeña permitida para la determinación de valores umbral.

Por ejemplo, cuando un contaminante tal como el tricloroetileno se detecta con mucha frecuencia en valores muy bajos, los Estados miembros pueden establecer un valor umbral de ámbito estatal, a condición de no poner en peligro el logro de los objetivos medioambientales. Alternativamente, cuando se trata de parámetros para los cuales las concentraciones naturales varían de un tipo de masa de agua subterránea a otro -As, Cl, SO_4^{2-}, NH_4^+ y metales[19] -, se recomienda encarecidamente que los valores umbral se definan en el ámbito de la masa de agua subterránea.

Aspectos transfronterizos

Los Estados miembros que comparten masas de agua transfronterizas velarán por que la determinación de valores umbral se someta a la coordinación entre los Estados miembros afectados (artículo 3.3 de la DAS).

Para las masas de aguas subterráneas compartidas entre uno o más Estados miembros y uno o más Estados que no son miembros, el Estado(s) afectado(s) se comprometerán a que los valores umbral se determinen de modo coordinado con los Estados afectados que no sean miembros (artículo 3.4 de la DAS).

Calendario y revisión

Los Estados miembros deben establecer valores umbral por primera vez el 22 de diciembre de 2008 (artículo 3.5 de la DAS), y publicarlos en el primer PHC a más tardar el 22 de diciembre de 2009 (artículo 13 de la DMA).

No obstante, la determinación de valores umbral es un proceso abierto, y los Estados miembros podrán añadir, retirar o reintroducir valores umbral para cualquier sustancia siempre que sea necesario (artículo 3.6 de la DAS). Los cambios estarán en función de la disponibilidad de "nueva información" sobre los parámetros basada en los nuevos conocimientos y comprensión científica. Estos cambios deben comunicarse en el contexto de la revisión periódica de los PHC.

Asimismo, los Estados miembros podrán retirar un valor umbral de la lista cuando la masa de agua subterránea afectada deje de estar en riesgo para el parámetro en cuestión.

4.3.2 Relación entre los valores umbral (artículo 3) y el objetivo de "evitar o limitar" (artículo 6)

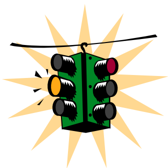
El objetivo de 'evitar o limitar' presente en la DMA y la DAS, protege a todas las aguas subterráneas frente a entradas inaceptables de contaminantes. Evitar o limitar la entrada de contaminantes en las

[19] Pauwels *et al* (2006)

aguas subterráneas protege a una gama amplia de receptores y preserva a las aguas subterráneas de la contaminación de ámbito local.

Los requisitos en materia de buen estado químico son diferentes. La evaluación del buen estado químico se lleva a cabo sobre **toda la masa de agua subterránea,** lo que en muchos casos implica una zona extensa. La evaluación se lleva a cabo una vez en cada periodo del PHC, es decir, cada seis años, y aporta información sobre el estado actual de las masas de agua subterránea. Esta evaluación nos dice si esa masa de agua subterránea se atiene a la definición de buen estado químico formulada en la DMA/DAS. Esta definición se limita únicamente a unos pocos receptores y a circunstancias específicas. Alcanzar un buen estado químico no siempre protege la calidad de las aguas subterráneas en el ámbito local.

La entrada de un contaminante debe desplazarse físicamente a lo largo del sistema de agua subterránea para afectar a un receptor. Este movimiento varía dependiendo de las características físicas y químicas de los estratos geológicos. Y, lo que es más importante, el contaminante puede estar sometido a dilución y atenuación durante el tránsito en el acuífero hacia un receptor. Por este motivo, muchas entradas sólo tienen efectos localizados. Estas entradas pueden desencadenar una contaminación localizada de las aguas subterráneas, aunque no afectan al estado de la masa de agua subterránea cuando su impacto sobre los receptores recogidos en la definición de buen estado químico de las aguas subterráneas es leve o nulo. De conformidad con la DMA/DAS, una masa de agua subterránea que se encuentre en un buen estado químico puede sufrir contaminación localizada. **No obstante, cuanto más extendida está la contaminación, más aumenta la posibilidad de que la masa de agua subterránea no se encuentre en buen estado. En caso de que exista una contaminación localizada de este tipo, los Estados miembros deben llevar a cabo investigaciones y adoptar medidas para limitar la contaminación, aunque el estado global de la masa de agua subterránea sea bueno. Estas medidas deberán adaptarse a lo dispuesto en el artículo 6 de la DAS (evitar y limitar entradas).**



¡Atención! En principio, las medidas para evitar o limitar son la primera línea de defensa para impedir entradas inaceptables de contaminantes a todas las aguas subterráneas y evitar con ello la contaminación. La aplicación efectiva del objetivo de ‘evitar o limitar’ por medio de la reglamentación existente debería garantizar la protección de la calidad de las aguas subterráneas. Esta reglamentación puede consistir en permisos, normas generales vinculantes o códigos de buenas prácticas para el control de actividades específicas en la superficie. Las condiciones de las permisos y/o los “valores límite” pueden utilizarse para garantizar que no se produzca ninguna entrada inaceptable de contaminantes en las aguas subterráneas. Es necesario un cierto tiempo para permitir que se degrade o se disperse el legado histórico de vertidos anteriores. Pero aparte de este hecho, si en todos los puntos de una masa de agua se cumplieran todos los requisitos de evitar y limitar, su estado químico sería bueno. **Así pues, los requisitos de ‘evitar o limitar’ y los requisitos de estado son complementarios, y utilizados conjuntamente proporcionan un marco efectivo para la protección de las aguas subterráneas en toda la Unión Europea. (ver la Guía CIS N°17[20]).**

Los valores umbral que se describen en esta guía ayudarán a evaluar el buen estado químico, aunque muchas veces estos valores -y el régimen de cumplimiento que va a asociado a ellos- no serán apropiados para cumplir los requisitos del objetivo de evitar o limitar. Esto se debe a que no protegen las aguas subterráneas de la contaminación a escala local.

El Documento guía sobre “Entradas directas e indirectas” (“*Direct and Indirect Inputs”*) contiene más información sobre el modo de aplicar el objetivo de ‘evitar o limitar’; no obstante, parece conveniente resumir aquí los distintos fines y funciones de los valores límite y los valores umbral en la protección de las aguas subterráneas:

[20] Guidance Document No. 17 Preventing or Limiting Direct and Indirect Inputs (2007)

1. Definiciones

   Valor Umbral. Definido previamente en este documento. Los valores umbral se fijan para la protección de los receptores y para garantizar que se cumple con los requisitos de buen estado químico.

   Valor Criterio. Es la concentración de un contaminante, sin tomar en consideración concentraciones naturales de referencia, que, en caso de que sea superada, puede resultar en el incumplimiento del respectivo criterio de buen estado.

   Valor Límite. Es un valor de concentración y su régimen de cumplimiento asociado que, si no se exceden en la fuente, evitarán un vertido inaceptable a las aguas subterráneas. Son ejemplos de valores límite una concentración o carga inaceptables incorporadas como condición en una autorización o un objetivo de recuperación para suelos contaminados. Se mide en la fuente, es decir en el punto de vertido.

   Valor de Cumplimiento. Es la concentración y el régimen de cumplimiento asociado que impiden la contaminación siempre que no se superen en el punto de cumplimiento (PC). Se mide en el punto de control de prevención/limitación.

   Tanto los valores límite como los valores de cumplimiento se fijan para proteger la calidad de las aguas subterráneas en el ámbito local, en el contexto del objetivo de "evitar o limitar".

2. Escala de aplicación

   Los valores umbral que se determinan para cumplir los requisitos de los artículos 3 y 4 de la DAS no se aplican necesariamente en los mismos puntos de cumplimiento como valores de cumplimiento, que se describen en el Documento guía respectivo[20]. La evaluación del estado se lleva a cabo en estaciones de control de la red de control operativo, que están distribuidos por la masa de agua subterránea. Las entradas se evalúan localmente en la fuente de entrada de los puntos de control de evitar/limitar, que pueden ser reales o virtuales. Esto aporta una protección más inmediata y global de las "aguas subterráneas propiamente dichas" como receptor. Cabe destacar que, en algunos casos, el punto de control de evitar/limitar utilizado para evaluar el grado de aceptabilidad de la entrada, puede ser también un punto de control operativo que permite evaluar el estado, en cuyo caso el valor umbral será un valor de cumplimiento apropiado.

3. Localización de la aplicación

   Los valores umbral se aplican sólo a las masas de agua subterránea, mientras que los "valores de cumplimiento" establecidos para apoyar los objetivos de "evitar o limitar" se aplican a todas las aguas subterráneas. Pueden aplicarse valores de cumplimiento diferentes en diferentes puntos de cumplimiento. Por ejemplo, tanto el agua de depósitos de gravas de terrazas fluviales discontinuas, como el agua colgada sobre niveles de arcillas glaciares, es agua subterránea, y deben evitarse o limitarse las entradas de contaminantes para garantizar que no se produzca contaminación en ninguno de los receptores. No obstante, ninguno de estos depósitos geológicos son unidades de gestión y por ello tampoco son masas de agua subterránea. Por ello, su estado no tiene que clasificarse como bueno o malo, y no tienen que establecerse valores umbral para ellos.

4.3.3 Metodología general para la determinación de valores umbral

La metodología general para la determinación de los valores umbral en una masa de agua subterránea se resume en la figura 3.

Como se señala en la sección 4.3.1, cuando se determinen los valores umbral, deberán considerarse dos tipos de criterios: criterios medioambientales y criterios de uso.

Los Estados miembros establecerán el valor umbral medioambiental utilizando una comparación entre los niveles de referencia (NR) y el valor criterio (VC). El valor criterio es una concentración de un contaminante, que sin tener en cuenta ninguna concentración natural de referencia, en caso de ser superada puede resultar en el incumplimiento de uno o más de los criterios de buen estado. Los VC deben tener en cuenta la evaluación de riesgo y las funciones de las aguas subterráneas.

Cuando se comparan los niveles de referencia con los valores criterio pueden surgir dos situaciones:

- Caso 1: El NR es menor que el VCi. En ese caso, los Estados miembros definirán los valores umbral según sus estrategias nacionales y una evaluación de riesgo, permitiendo que se establezca un valor umbral por encima del nivel de referencia, siempre que pueda justificarse claramente.

- Caso 2: El NR es mayor que el VCi. En ese caso, el valor umbral debe ser igual al nivel de referencia.

No obstante, para integrar el concepto de desarrollo sostenible y permitir el desarrollo de actividades económicas -especialmente las actividades existentes-, los Estados miembros pueden considerar un *pequeño* añadido a los niveles de referencia que representa un grado aceptable de influencia humana, siempre que se considere que no daña la protección de los receptores pertinentes. Una concentración admisible de este tipo consideraría el requisito de "limitar las entradas" de contaminantes no peligrosos de conformidad con el artículo 6 de la DAS y también persigue evitar problemas no deseados en la verificación de cumplimiento, provocados por un gran número de pozos que presentan pequeñas desviaciones sin importancia de los valores umbral. Considerando que a menudo el criterio para la evaluación de los niveles de referencia será el percentil 90, se supone que al menos el 10% de los pozos de observación superarían lo permitido si el valor umbral se fijara exactamente en la concentración del nivel de referencia. Esto conduciría obligatoriamente a una 'investigación adecuada' de todas las masas de agua subterránea que se encontraran en el caso 2, algo que se ha considerado imposible de gestionar.

Los Estados miembros deben definir la concentración adicional admisible utilizando un procedimiento de evaluación de riesgos. En particular se recomienda que se tenga en cuenta la vulnerabilidad o susceptibilidad de la MAS, incluyendo las propiedades biogeoquímicas del suelo y las propiedades de los contaminantes. Una evaluación de este tipo dependerá del nivel de conocimiento y de la confianza en los modelos conceptuales. Cabe señalar que los Estados miembros pueden actualizar los valores umbral, de conformidad con las indicaciones formuladas en el capítulo 4.3.1 de esta guía. Así pues, puede que sea necesario ajustar la "concentración adicional admisible" como consecuencia de los cambios en los valores umbral teniendo en cuenta la información nueva, es decir, como resultado de los proyectos de investigación.

Además de consideraciones de tipo socio-económico, un valor umbral que contenga una cierta concentración que excede del nivel de referencia puede ser aceptable por motivos prácticos, entre otros la armonización con otras directivas, como la directiva sobre nitratos, la directiva de aguas potables o la directiva relativa a normas de calidad ambiental (2008/105/CE). No obstante, en todos los casos el valor umbral final **debe** proteger a todos los receptores, tanto los diferentes usos humanos como el estado ecológico de las aguas superficiales y los ETDAS. Además, la protección de las aguas subterráneas está garantizada también por la consecución de los objetivos del artículo 5 y 6 de la DAS. Estos exigen que los Estados miembros inviertan las tendencias significativas al aumento de los contaminantes y que limiten o impidan las entradas de contaminantes en las aguas subterráneas[21].

[21] Guidance Document No. 17 Preventing or Limiting Direct and Indirect Inputs (2007)

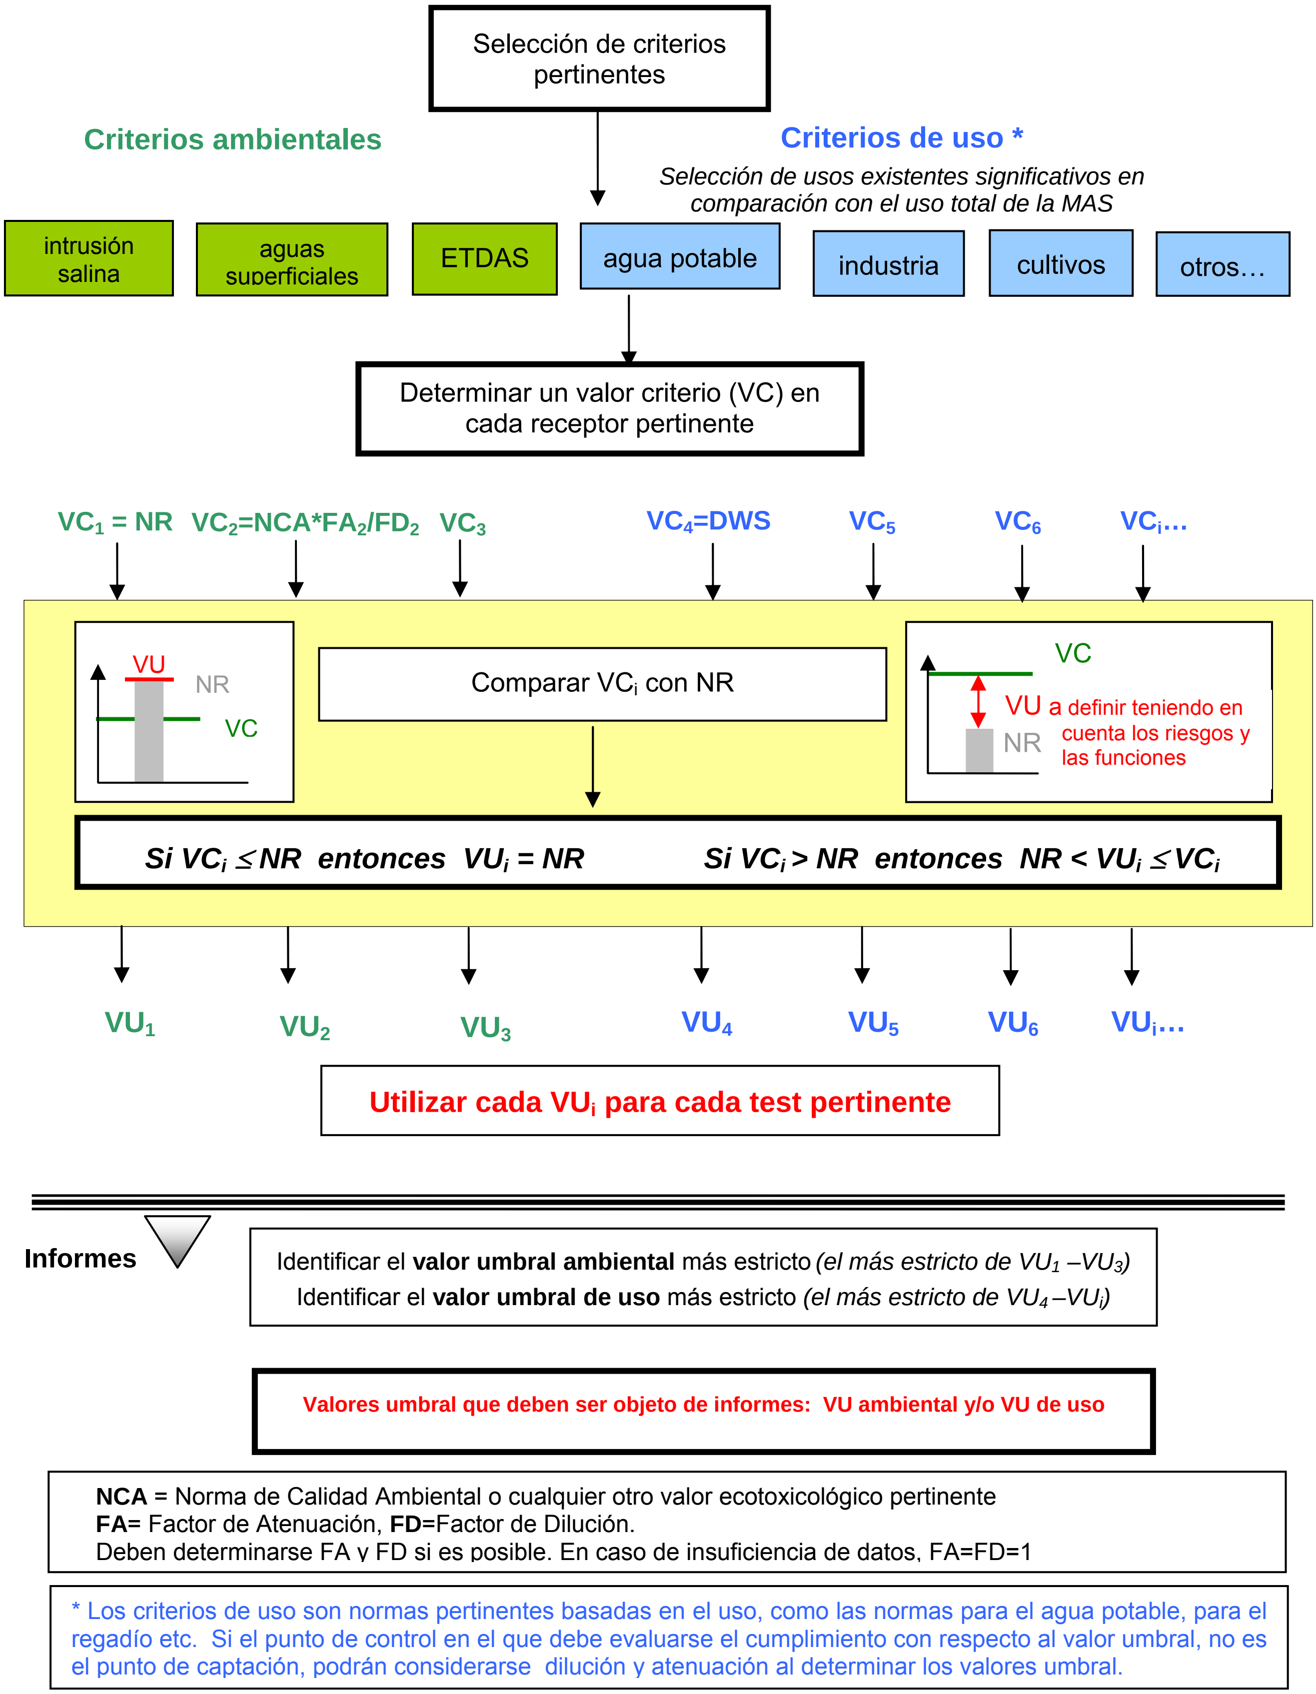


Figura 3: Metodología general para la determinación de valores umbral para las aguas subterráneas.

Determinación de los valores umbral para ecosistemas acuáticos asociados y ecosistemas terrestres dependientes

Cuando existe interrelación entre las aguas subterráneas y las aguas superficiales, y especialmente cuando las aguas superficiales o los ecosistemas terrestres dependientes son alimentados por agua subterránea, los valores criterio que sean relevantes para la protección de las aguas superficiales asociadas o los ETDAS se determinarán utilizando normas de calidad medioambiental (NCA) para las aguas superficiales o cualquier otro valor eco-toxicológico pertinente. Para las sustancias prioritarias y demás contaminantes reseñados en la directiva relativa a las “Normas de Calidad Medioambiental en el ámbito de la política de aguas” (Directiva 2008/105/CE) pueden utilizarse los valores establecidos en este texto. Puede aplicarse asimismo cualquier otra NCA establecida por un Estado miembro a escala local o estatal, por ejemplo, a partir de los resultados de tests de ecotoxicidad de organismos acuáticos.

La concentración de un parámetro varía según se trate de un acuífero o de un río. Por ello, puede aplicarse un factor de dilución (FD) o un factor de atenuación (FA) para determinar el valor adecuado para ese criterio.

Los factores de atenuación y dilución se calcularán dependiendo del nivel de conocimiento de la interacción entre el agua subterránea y el agua superficial, el modelo conceptual, y considerando la situación de los puntos de control en el sistema de aguas subterráneas en relación al receptor. (Véanse, en el anexo 1, principios generales de aplicación de los factores de dilución y de atenuación). Los Estados miembros podrán establecer libremente los valores de FD y de FA para cada masa de agua subterránea de acuerdo con su propio enfoque y conocimientos. Pueden utilizarse asimismo las propuestas del proyecto BRIDGE para el cálculo de FD y FA.[22]

Por lo tanto, el valor adecuado asignado a este criterio es igual a:

VC = NCA* FA/ FD.

La dilución y la atenuación **no** deberán incluirse cuando el control tiene lugar en el receptor.

En este caso:

$FD=FA=1 * NCA_{agua\ superficial}$.

Nota: El cálculo del factor de dilución y el factor de atenuación exige una buena comprensión del sistema de aguas subterráneas y de la interacción entre agua subterránea y agua superficial. Cuando no exista un conocimiento suficiente, puede ocurrir que los factores de dilución y/o de atenuación no puedan utilizarse. En este caso, puede recurrirse en primera instancia al enfoque de precaución; a saber, VC=NCA.

En las recomendaciones anteriores, basadas en los resultados del proyecto BRIDGE, se considera que el factor de atenuación FA es <1. Si un Estado miembro ya ha definido algunas masas de agua subterránea, y si la definición de esos factores de atenuación difiere ligeramente -por ej. FA>1-, la ecuación citada puede adaptarse. Ciertamente, la determinación del valor umbral debería basarse en los conocimientos existentes a escala nacional.

Determinación de los valores umbral para usos existentes

Cuando la masa de agua subterránea tiene otros usos aparte de apoyar la química y la ecología de las aguas superficiales, como por ejemplo, el abastecimiento de agua potable, el riego de cultivos o el apoyo a la industria alimenticia, entonces deben apoyarse dichos “usos existentes” de conformidad con las DMA y DAS. Para hacer efectivo este apoyo, deberán definirse los valores criterio según proceda. Por ejemplo, solo tendrán que determinarse y considerarse los VU si la superficie o volumen total de la zona contaminada está poniendo dichos “usos existentes” en riesgo, y si se trata de un riesgo “significativo” comparado con la superficie o volumen total de la masa de agua subterránea. En el caso del abastecimiento de agua potable, deberán considerarse las normas sobre el agua potable –VP, valor paramétrico, norma de calidad para aguas potables, DWS en las siglas en inglés- cuando se establezcan los valores para el criterio en cuestión. Para otros usos como regadíos e industria se recomienda un enfoque caso por caso.

Si el punto de control donde debe evaluarse el cumplimiento del valor umbral no es el punto de captación, puede ser conveniente tener en cuenta también la dilución y la atenuación cuando se

[22] (Müller *et al*., 2006).

efectúa la determinación de los valores umbral y los valores criterio para los usos del agua (véase el anexo 1), decisión que deben tomar los Estados miembros.

No obstante, es conveniente reiterar que el régimen de cumplimiento para las ZPAP no sólo consiste en comprobar si se han excedido los valores umbral, sino que también se basa en verificar que no será necesario un mayor aumento de las medidas de tratamiento del agua, tal como exige el artículo 7.3 de la DMA.

Determinación del valor para "salinización u otras intrusiones"

El valor umbral pertinente para la salinización u otras intrusiones será el nivel de referencia para los parámetros clave, puesto que es el valor medioambiental más adecuado que se puede usar cuando se examina si se ha producido alguna intrusión provocada por las actividades humanas.

4.4 Procedimiento para evaluar el buen estado químico

Dependiendo de los resultados de la evaluación de riesgo, deberán llevarse a cabo varios tests para evaluar el estado químico de las aguas subterráneas. Según los objetivos de las Directivas DMA y DAS, los criterios principales que deben considerarse en los tests son:

- Criterios medioambientales. Entre ellos se encuentran:
  – protección de las aguas superficiales asociadas (relacionadas)
  – protección de los ecosistemas terrestres dependientes de las aguas subterráneas
  – protección de las masas de agua subterránea frente a la salinización u otras intrusiones
- Criterios de uso. Entre ellos están:
  – protección del agua potable en las ZPAP
  – protección de otros usos existentes: regadío de cultivos, industria….

Cada test de clasificación considera elementos específicos del estado químico tal como se ha descrito en el capítulo 4.2. y se resume en la tabla 2. En cada uno de los apartados siguientes se describe en detalle cada test de clasificación y se hace referencia a los elementos individuales de los tests.

Tabla 2: Resumen de los tests de clasificación y de los elementos de verificación de estado

Elemento para la clasificación	Test de clasificación	Elementos del test			
		Agregación de los datos	Alcance	Localización	Confianza
No hay deterioro significativo de los usos humanos. Artículo 4(2)(c) (iv) DAS	Evaluación general del estado químico de toda la masa de agua subterránea.	✓	✓		✓
Los contaminantes presentes en toda la extensión de la masa de agua subterránea no suponen un riesgo ambiental significativo. Artículo 4(2)(c) (i) y Anexo III 3 de la DAS.	Evaluación general del estado químico de toda la masa de agua subterránea.	✓	✓		✓
Ausencia de salinización u otras Intrusiones. Anexo V 2.3.2 de la DMA.	Salinización u otras intrusiones	✓	✓	✓	✓
Ausencia de disminución significativa de las condiciones ecológicas de las aguas superficiales. Anexo V 2.3.2 de la DMA.	Ausencia de afección significativa a las condiciones químicas y ecológicas del agua superficial por transferencia de contaminantes desde la MAS.	✓		✓	✓
Ausencia de afección significativa a las características químicas de las aguas superficiales. Anexo V 2.3.2 de la DMA.	Ausencia de afección significativa a las condiciones químicas y ecológicas del agua superficial por transferencia de contaminantes desde la MAS.	✓		✓	✓
Ausencia de daño significativo a ETDAS. (Anexo V 2.3.2 de la DMA)	Ausencia de daño significativo a ETDAS por transferencia de contaminantes de la MAS	✓		✓	✓

Ausencia de deterioro de la calidad de las aguas para el consumo humano (Artículo 4(2)(c) (iii)) y Anexo III 4 de la DAS)	Cumple las exigencias del articulo 7(3) de la DMA (ZPAP)	✓		✓	✓

4.4.1 Procedimiento práctico

La evaluación del estado químico de las masas de agua subterránea se lleva a cabo en dos fases:

- fase 1: Verificar si se ha excedido alguno de los valores umbral o normas de calidad. Si no se han producido excesos en ninguno de los puntos de control, el estado de la masa de agua subterránea será bueno.

Nota: El valor umbral que se utilizará en el paso 1 será el valor más estricto que se determine usando la metodología que se describe en el capítulo 4.3. Este enfoque es consecuente con el principio de precaución.

- fase 2: En caso de que se haya superado una o más veces una norma de calidad o valor umbral, debe llevarse a cabo una "investigación adecuada". Esto implicará ir avanzando en los tests de clasificación pertinentes para determinar si el exceso está impidiendo el cumplimiento del buen estado químico.

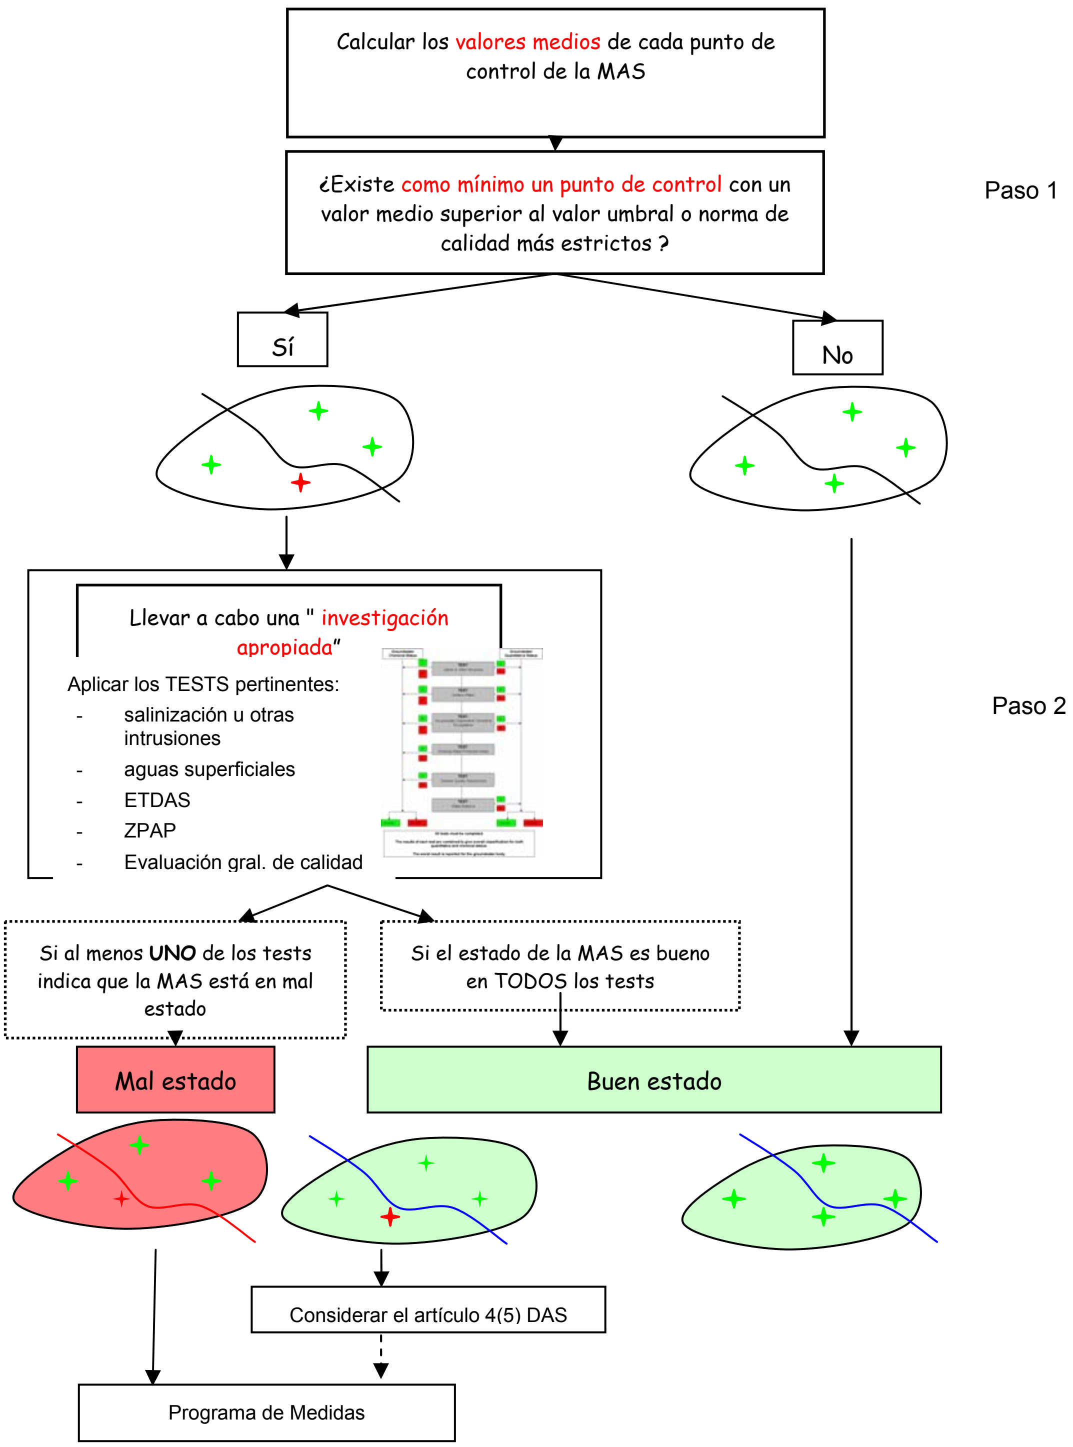

Figura 4. Procedimiento general para la evaluación del estado químico de una masa de agua subterránea (MAS).

4.4.2 Test: Evaluación general del estado químico de la totalidad de la masa de agua subterránea

Este test considera la evaluación de:

- un riesgo medioambiental significativo derivado de los contaminantes presentes en la totalidad de la masa de agua subterránea (artículo 4(2)(b) (i) y anexo III 3 de la DAS), y
- un deterioro significativo de la capacidad de soportar los usos humanos (artículo 4(2)(b) (iv) de la DAS).

Basándose en las exigencias legales, la evaluación general del estado químico de las aguas subterráneas se centra en la totalidad de la masa de agua subterránea y considera los elementos siguientes:

- **criterios** para la evaluación del estado químico de las aguas subterráneas para este test *(normas de calidad de las aguas subterráneas y valores umbral)*
- **agregación de los datos**
- **alcance del incumplimiento**
- **confianza** en la evaluación, considerando el valor de las concentraciones.

En el marco de la evaluación, los grupos de masas de agua subterránea merecerían una atención y tratamiento especial. Las MAS pueden agruparse con fines de control siempre que se garantice que pueden lograrse eficazmente el seguimiento y los objetivos medioambientales de cada una de ellas[23]. El documento guía sobre seguimiento de las aguas subterráneas distingue entre la agrupación de MAS que están en riesgo y las que no están en riesgo. Cuando las masas de agua subterránea se encuentran en riesgo, se recomienda disponer como mínimo de un punto de control por cada masa; en las masas que no están en riesgo no se necesita un punto de control por cada uno de sus componentes.

Cuando los resultados del control muestren que se han superados las normas de calidad o los valores umbral en uno o más puntos de control, debería confirmarse si las masas que los componen se encuentran en el mismo estado químico. Así pues, se recomienda dividir el grupo de masas de agua subterránea en las masas que lo componen y mejorar el modelo conceptual y la delimitación de las masas en caso de que uno de los puntos de control exceda las normas de calidad de las aguas subterráneas o los valores umbral. Cada masa de agua subterránea que compone el grupo debería tratarse como una masa de agua subterránea individual y los tests propuestos deberían aplicarse en consecuencia.

Procedimiento propuesto (véase la figura 5):

- Paso 1 (agregación): Verificar si la concentración media en algún punto de control excede una norma de calidad o valor umbral. En caso negativo, se recomienda que la masa de agua subterránea está en un buen estado químico con respecto al parámetro pertinente. No se precisa investigación ni evaluación posterior. En caso de exceso, debe seguirse el paso 2 del procedimiento.
- Paso 2 (grupos de masas de agua subterránea): En el caso de MAS agrupadas, el grupo debe dividirse y deben delimitarse adecuadamente los componentes individuales en los que se haya registrado un exceso, tomando como base un modelo conceptual mejorado y tratando las masas de agua en el test como masas de agua subterránea separadas.
- Paso 3 (superación de norma de calidad o valor umbral): Calcular el alcance espacial del incumplimiento referido a los valores medios, para cada sustancia y compararlo con un grado de incumplimiento aceptable para que el estado químico de una MAS sea bueno. Se propone aplicar una metodología sencilla, que considera la porción del área o volumen de la masa de agua subterránea representado por los puntos de control donde se han superado las normas de calidad o los valores umbral, en comparación con el área o volumen total de la MAS. Para que pudiera aceptarse, dicha porción no debería superar el 20 %[24] del total de la MAS.

---

[23] Guidance Document No. 15: Groundwater Monitoring (2007)

[24] El criterio del 20% se sugiere como criterio por defecto; en función de la situación específica en la masa de agua subterránea y en la red de control, puede seleccionarse un porcentaje diferente o un enfoque alternativo para determinar el alcance del exceso utilizado. Debe incluirse en el PHC una explicación y descripción resumida de la metodología que se haya aplicado.

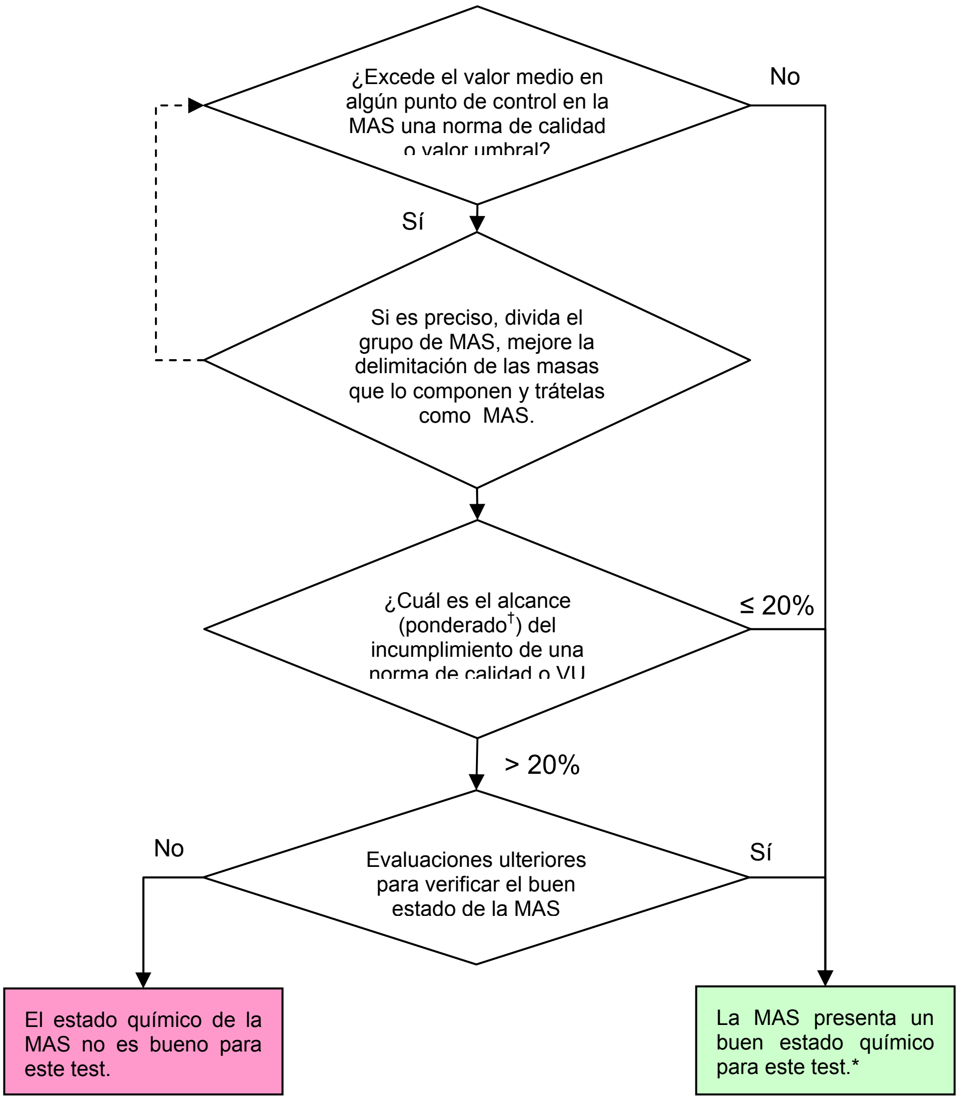
- Paso 4 (confianza): Si la porción afectada es superior al 20 % del total o si se cumplen otros criterios relevantes, una evaluación ulterior debería detectar si la masa de agua subterránea está o no en buen estado. La evaluación en cuestión podría apoyarse en un análisis de la fiabilidad, de modo que pudiera distinguir si el alcance del exceso identificado es aceptable. Una evaluación de fiabilidad de este tipo podría tener en cuenta la incertidumbre analítica, la incertidumbre producida por la red de control y la incertidumbre producida por la variación de las concentraciones, En caso de que los datos sean insuficientes, podría adoptarse un enfoque determinista, evaluando las presiones y los impactos con más detalle.

Algunos métodos estadísticos apuntan a aspectos del diseño de las redes de control -por ej. la distribución de los puntos de control- que hay que considerar de antemano. Algunos métodos de integración -por ej. kriging- ya toman en consideración una distribución heterogénea de los emplazamientos usando índices ponderados.

Si no se cumplen las precondiciones sobre diseño de la red en la totalidad de la masa de agua subterránea, puede ser de ayuda el procedimiento de agregación, la delimitación de las sub-masas de agua subterránea y/o la ponderación de los puntos de control individuales.

Cuando se trate de sub-masas de agua subterránea adecuadamente delimitadas, se propone que la evaluación se lleve a cabo para cada sub- masa de agua subterránea, procediendo a la agregación de cada uno de los resultados de cada sub-masa para dar un resultado relativo a la totalidad de la masa de agua subterránea.

Una aproximación de ponderación de este tipo puede servir para considerar la variabilidad en el seno de la masa de agua subterránea que se ha identificado a través del modelo conceptual –presiones, vulnerabilidad, impacto- así como en el diseño de la red de seguimiento. El método de ponderación debería adecuarse a los principios del método de clasificación.



† Un método de ponderación puede ayudar a tomar en consideración el modelo conceptual -por ej. presión, vulnerabilidad, situación del impacto- dentro de la masa de agua subterránea, así como el diseño de la red de seguimiento.

*…Actuar de conformidad con el artículo 4(5) de la DAS

Figura 5. Procedimiento propuesto para la evaluación general del estado químico de una masa de agua subterránea (MAS) considerada globalmente.

4.4.3 Test: Salinización u otras intrusiones

Este test considera la evaluación de la salinización u otras intrusiones de conformidad con el anexo V.2.3.2. de la DMA.

Los distintos tipos de intrusiones que se consideran en esta evaluación aparecen ilustrados en la figura 6 (Fuente: UKTAG). Entre ellos se encuentran:

- la intrusión marina detectada frecuentemente en los acuíferos costeros, particularmente en la cuenca Mediterránea, y
- la intrusión salina de origen natural, resultante de la influencia de aguas de formación o de una pérdida de capas salinas –caso de las evaporitas- en la masa de agua subterránea.

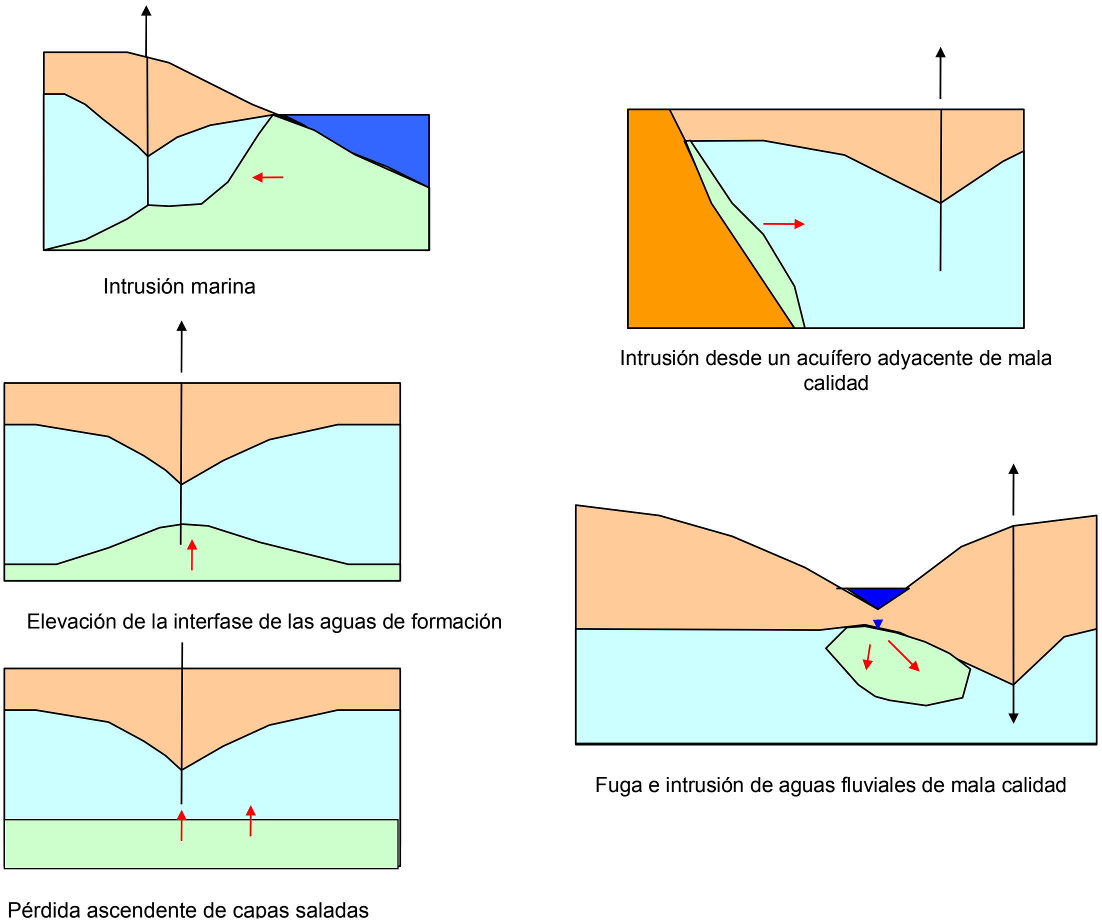


Figura 6. Diferentes tipos de intrusión

Basándose en los requisitos legales, la evaluación de la salinización u otras intrusiones considera los elementos siguientes:

- **criterios** para la evaluación del estado químico de las aguas subterráneas para este test *(normas de calidad del agua subterránea y valores umbral)*
- **agregación de datos**
- **alcance** del incumplimiento de las normas de calidad o valores umbral
- **localización** de los puntos donde se superan las normas de calidad o los valores umbral
- **confianza** en la evaluación.

Además, el test está vinculado con la evaluación del estado cuantitativo de la MAS, y con la evaluación de las tendencias significativas o sostenidas al aumento de la contaminación.

La evaluación del estado cuantitativo debe llevarse a cabo con carácter previo al test sobre el estado químico, que habrá identificado aquellos ámbitos en los que existe presión debida al bombeo y con ello un riesgo de salinización o de otras intrusiones.

No se alcanza un buen estado químico del agua subterránea si:

- el valor medio en un punto de control relevante supera un valor umbral **y**
- existe una tendencia significativa y sostenida al aumento en uno o más parámetros clave en uno o varios puntos de control relevantes, o
- hay un impacto significativo en un punto de captación como consecuencia de la intrusión.

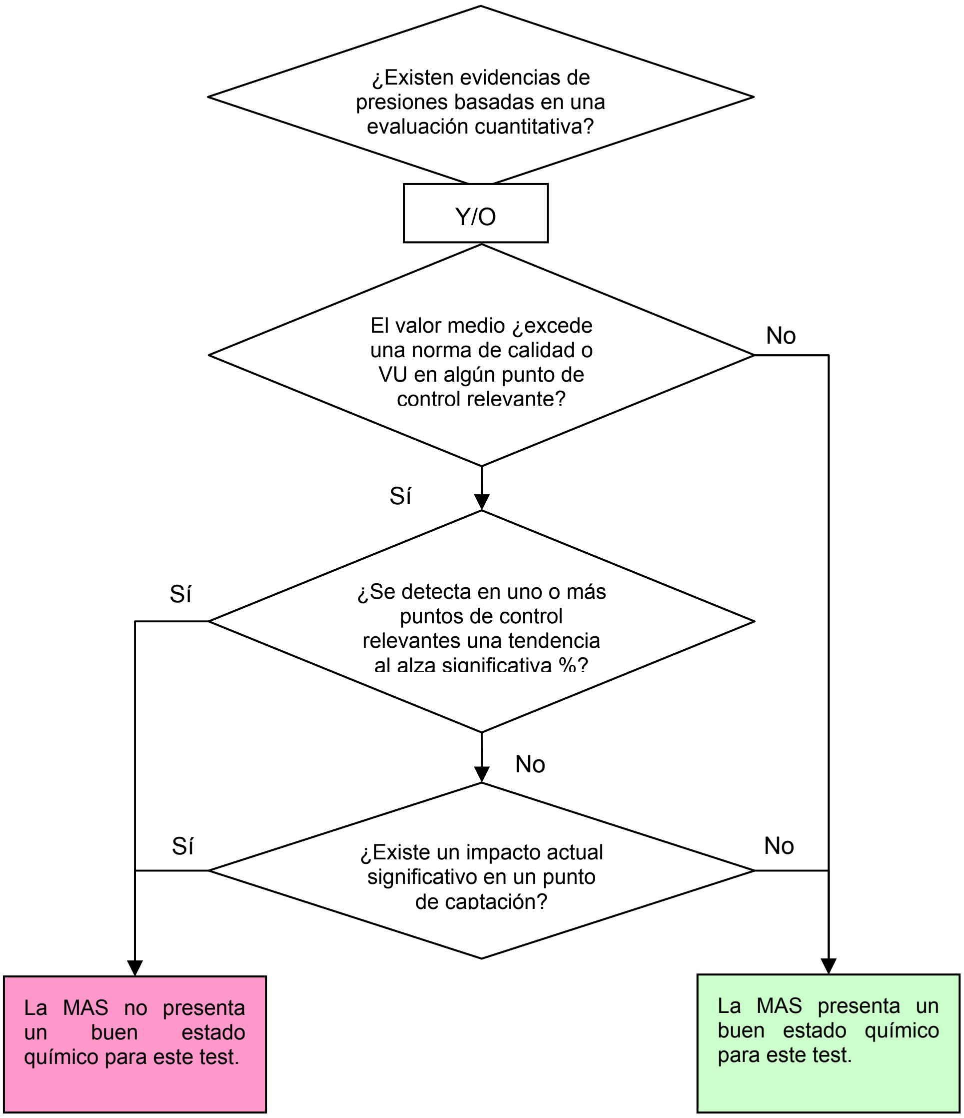
Los valores umbral pertinentes serán el nivel de referencia para parámetros clave, es decir, Cl^- y SO_4^{2-} o conductividad eléctrica.

Algunas masas de agua subterránea tienen elevados niveles naturales de salinidad, debido a la geoquímica del acuífero o las unidades estratigráficas adyacentes que actúan como fuente. Para este test, debido a la compleja fluctuación de la calidad del agua subterránea adyacente a la interfase entre agua dulce y salada, los valores umbral numéricos no serían determinantes por sí solos. Se propone un enfoque basado en "líneas de evidencia" para confirmar la existencia de una intrusión como la citada.

Con respecto a la intrusión de agua marina salada en una masa de agua subterránea y la situación especial del abastecimiento de agua potable en las islas, puede ser apropiado diferenciar entre la intrusión horizontal, que refleja un problema regional, y la intrusión vertical, que tiene una importancia más local y un alcance limitado. La base principal para esta diferenciación es la comprensión conceptual de la masa de agua subterránea.

Procedimiento propuesto (véase la figura 7):

- Paso 1 (evidencias):
  - identificar las zonas en las que se producen altas concentraciones salinas naturales (de procedencia marina o geológica)
  - identificar las zonas en las que existe presión provocada por el bombeo y riesgo de salinización o de otras intrusiones (*ver el capítulo 5.3.4*)
- Paso 2 (agregación y localización):
  - identificar puntos de control pertinentes donde los valores medios superan las normas de calidad relevantes y los valores umbral
  - considerar la localización de dichos puntos junto con las zonas donde se generan presiones provocadas por los bombeos y los riesgos de salinización o de otras intrusiones (identificados en el test de estado cuantitativo del agua subterránea, ver el cap. 5.3.4).
  - considerar el modelo conceptual de la masa de agua subterránea. La intrusión horizontal está produciendo sobre todo un problema regional, mientras que la intrusión vertical puede ser representativa de un problema puntual localizado.
- Paso 3 (tendencia): Calcular las tendencias en parámetros clave, como Cl^- y SO_4^{2-} o conductividad eléctrica, así como cualquier otra sustancia significativa que indique una expansión de las intrusiones (*véase la sección 6.3.4*).
- Paso 4 (impactos): Identificar cualquier impacto significativo en puntos de captación como consecuencia de la intrusión.



Considere el modelo conceptual -presiones, vulnerabilidad, situación de impacto- de la MAS en cada uno de los pasos que conforman la evaluación.

Figura 7. Procedimiento propuesto para evaluar la salinización y otras intrusiones

4.4.4 Test: Disminución significativa de la calidad química y ecológica de las masas asociadas de aguas superficiales, producida por la transferencia de contaminantes procedentes de la masa de agua subterránea

Este test considera la evaluación de:

- una disminución significativa de las condiciones ecológicas de las aguas superficiales, y
- una disminución significativa de la calidad química de las aguas superficiales.

Basándose en las exigencias legales, la evaluación considera los elementos siguientes:

- **Criterios** para la evaluación del estado químico del agua subterránea para este test *(normas de calidad de las aguas subterráneas y valores umbral) -*
- **Agregación de datos**
- **Situación** de los puntos donde se superan las normas de calidad o los valores umbral
- **Confianza** en la evaluación.

El estado se determina a través de una combinación de resultados de clasificación de las aguas superficiales y de una evaluación de las entradas de compuestos químicos (transferencia de contaminantes) procedentes de las masas de agua subterránea y que penetran en las masas de agua superficial. El test se diseñó para determinar en qué medida la transferencia de contaminantes procedentes de las aguas subterráneas hacia las aguas superficiales o cualquier otro impacto consecuente en la ecología de las aguas superficiales es suficiente para amenazar los objetivos de la DMA para las masas de aguas superficiales asociadas citadas.

El test debe llevarse a cabo en todas las masas de agua subterránea que estén vinculadas a masas de agua superficial en riesgo, considerando el modelo conceptual de cada masa de agua subterránea.

Procedimiento propuesto (véase la figura 8):

- Paso 1 (agua superficial en riesgo): ¿La masa de agua superficial no consigue alcanzar los objetivos medioambientales (está en un estado peor que bueno) y la masa de agua subterránea contribuye a ello?
- Paso 2 (Agregación de datos y localización):
  - Identificar toda superación de un valor umbral pertinente en la masa de agua subterránea en alguna de las concentraciones medias calculadas en cada punto de control pertinente.
  - Considerar si alguno de los casos en que se ha excedido un valor umbral pertinente se ha producido en una zona en la que puedan transferirse contaminantes a las aguas superficiales.

  Paso 3 (transferencia de contaminantes): Efectuar una estimación de la cantidad y concentración de contaminantes que está siendo o puede ser transferida al receptor agua superficial y los posibles impactos. La carga contaminante global en las aguas superficiales procedente de las aguas subterráneas puede calcularse a partir de los factores de dilución agua subterránea-agua superficial y de los índices de atenuación. Cuando la contribución de la carga contaminante que procede de las aguas subterráneas en las aguas superficiales es significativa -mayor del 50% de la carga-, la masa de agua subterránea está en mal estado.

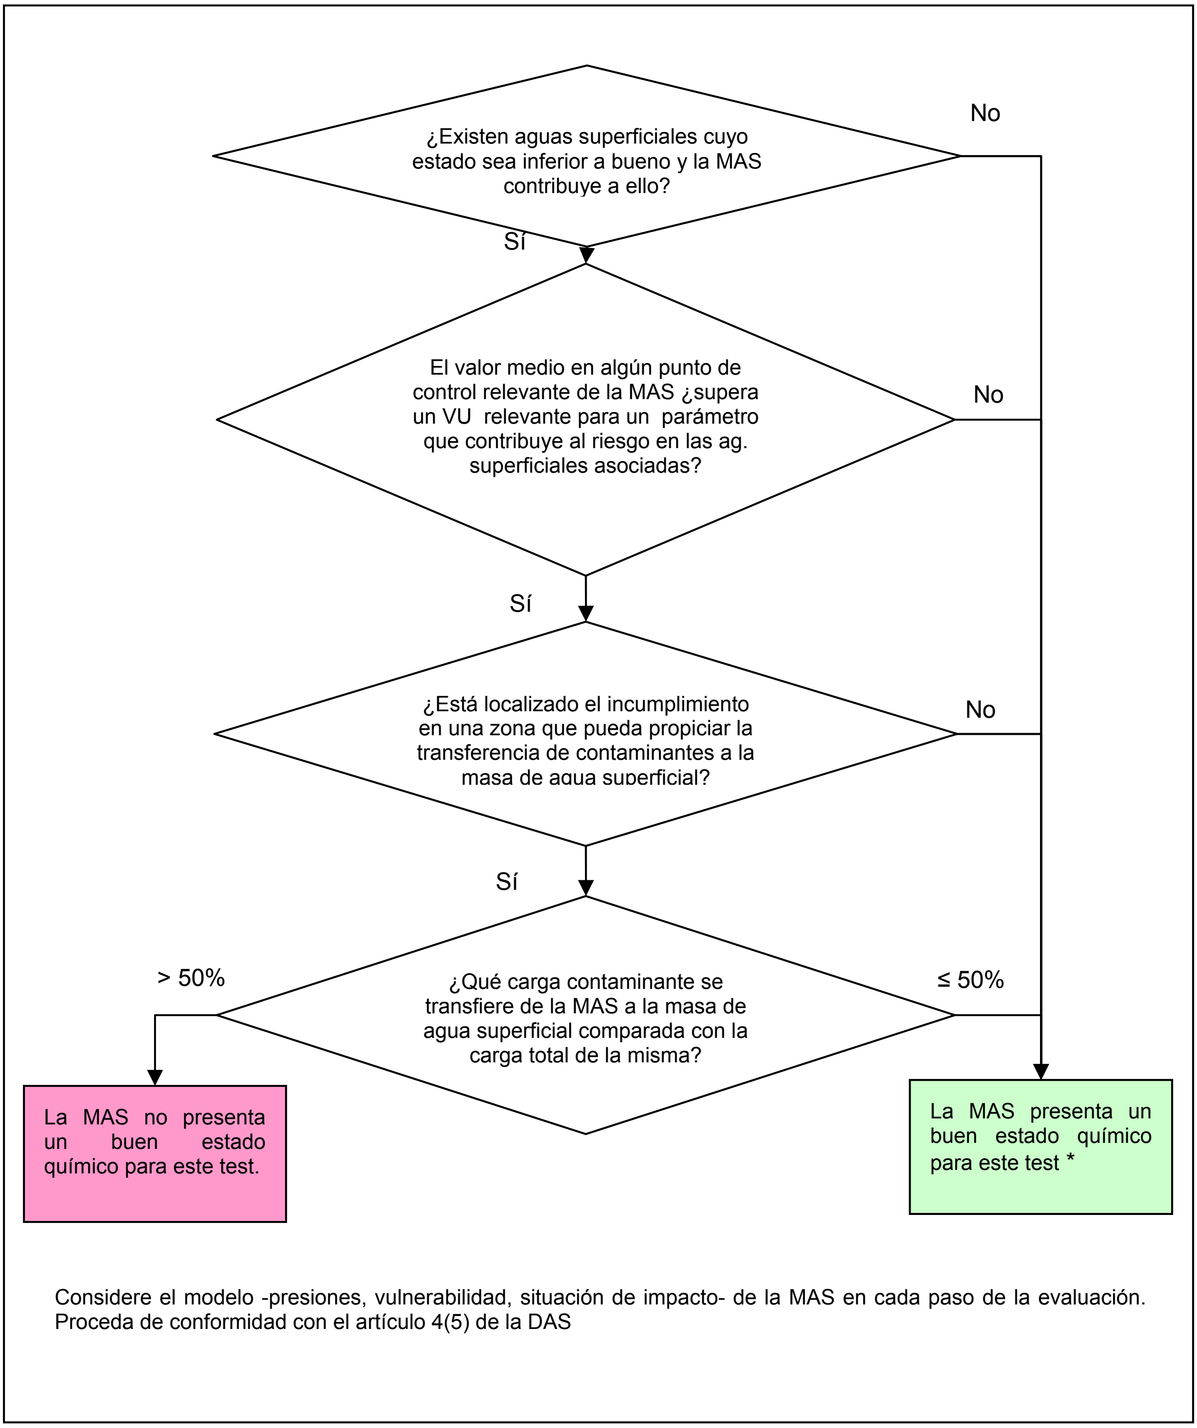


Figura 8. Procedimiento propuesto para verificar la disminución significativa de la calidad ecológica o química de las masas de agua superficial asociadas

4.4.5 Test: Daño significativo a los ecosistemas terrestres dependientes de las aguas subterráneas (ETDAS) producido por la transferencia de contaminantes procedentes de la masa de agua subterránea

Este test considera la evaluación de un daño significativo a los ETDAS (DMA, anexo V 2.3.2)

Basándose en los requisitos legales, la evaluación considera los elementos siguientes:

- **Criterios** para la evaluación del estado químico de las aguas subterráneas para este test *(normas de calidad y valores umbral del agua subterránea)*

- **agregación de datos**
- **situación** de los puntos en los que se hayan superado las normas de calidad o los valores umbral
- **confianza** en la evaluación.

El test debería determinar la posibilidad de que las concentraciones de contaminantes en una masa de agua subterránea conduzcan a un impacto sobre un ETDAS que sea suficiente para amenazar los objetivos de la DMA u otros objetivos relevantes para las zonas protegidas.

El test debería llevarse a cabo en todas las masas de agua subterránea que estén vinculadas a un ETDAS que haya sufrido -o esté en riesgo de sufrir- un daño significativo, considerando el modelo conceptual de cada masa de agua subterránea durante cada etapa de la evaluación.

Procedimiento propuesto (véase la figura 9):

- Paso 1 (ETDAS afectado): ¿Existe algún ETDAS afectado -o que esté en riesgo- que sea directamente dependiente de la masa de agua subterránea que está siendo evaluada?
- Paso 2 (Agregación de datos y localización):
  - identificar los casos en que se hayan superado los valores umbral pertinentes en el agua subterránea usando las concentraciones medias calculadas en cada punto de control pertinente.
  - determinar la ubicación de los puntos en los que se hayan superado los valores umbral relevantes para determinar si existe una zona en la que puedan transferirse contaminantes al ETDAS.
  - paso 3 (transferencia de contaminantes): efectuar una estimación de la cantidad y concentración de los contaminantes que se están transfiriendo -o pueden transferirse- al receptor (ETDAS) y los posibles impactos. La carga contaminante global procedente de las aguas subterráneas que desemboca en los ecosistemas terrestres dependientes puede estimarse a partir de una comprensión de los factores de dilución agua subterránea-ETDAS y de los índices de atenuación.

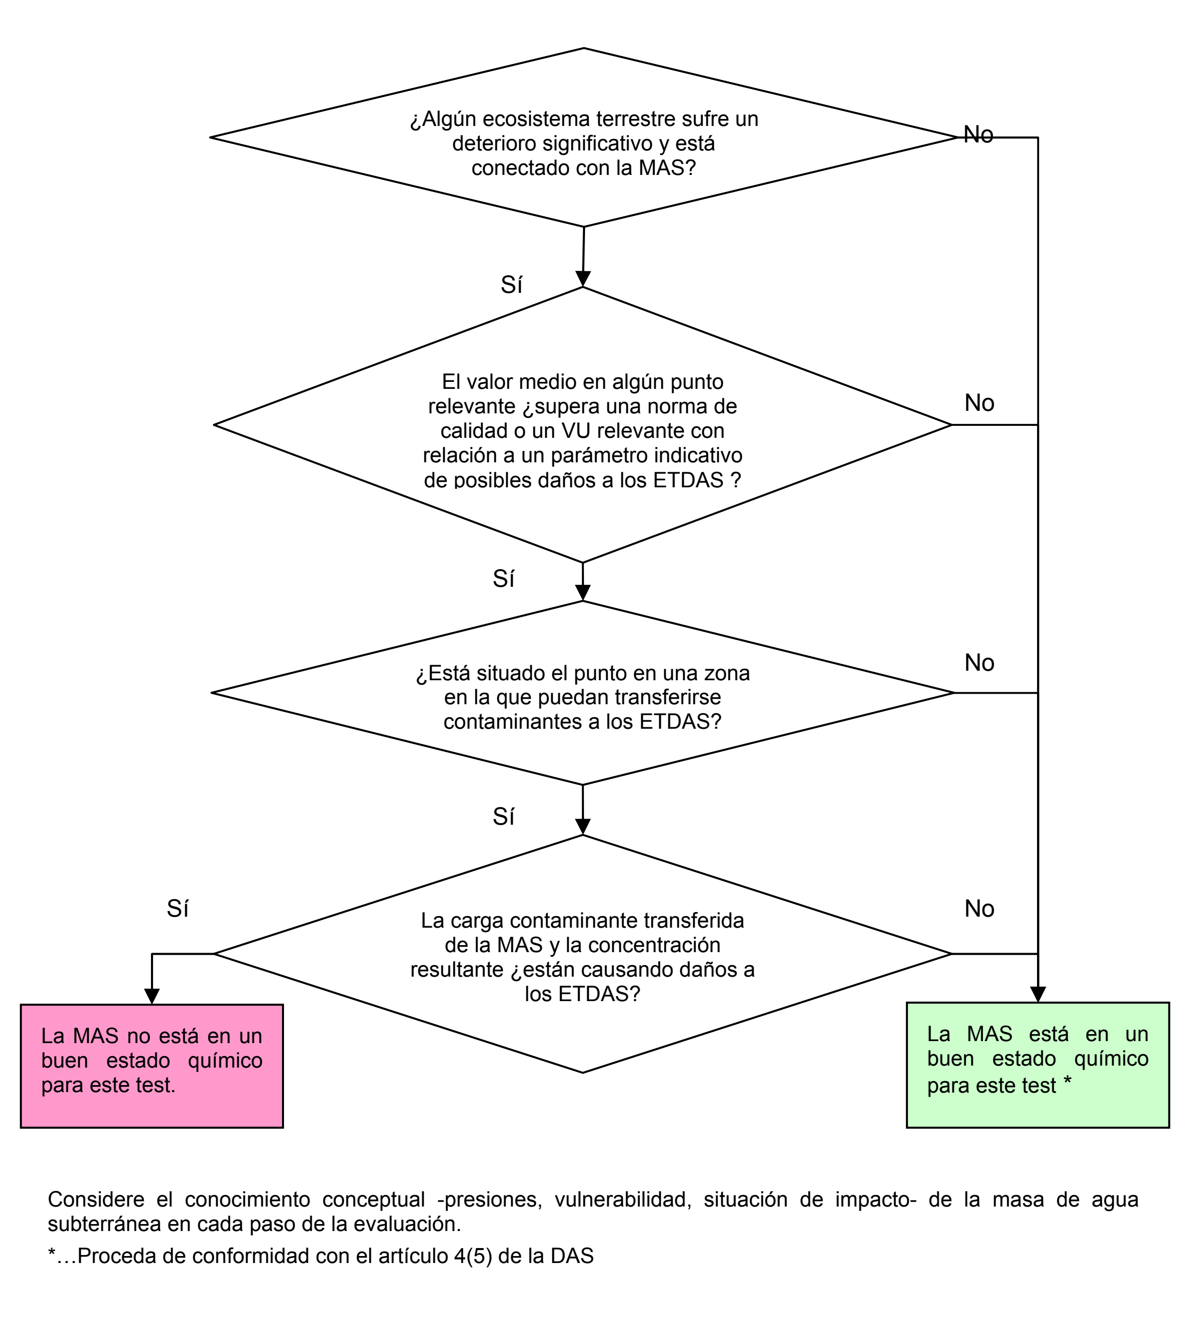

Figura 9. Procedimiento propuesto para la evaluación del daño significativo a los ecosistemas terrestres directamente dependientes de la masa de agua subterránea

4.4.6 Test: Cumplimiento de las disposiciones del artículo 7(3) de la DMA (zonas protegidas para la captación de agua potable).

Este test evalúa el deterioro de la calidad de las aguas para el consumo humano (Artículo 4(2)(c) (iii)) y Anexo III 4 de la DAS). Este capítulo debería leerse conjuntamente con las guías anteriormente publicadas, en particular la de seguimiento de las aguas subterráneas[25] y la relativa a las aguas subterráneas en zonas protegidas para la captación de agua potable[26]. De conformidad con ésta última, se consideran a las ZPAP como masas de agua subterránea y las medidas de protección se centran en perímetros de protección.

[25] Guidance Document No. 15 Groundwater Monitoring (2007)

[26] Guidance Document No. 16 Groundwater in Drinking Water Protected Areas (2007)

De conformidad con el artículo 7.3 de la DMA, los Estados miembros velarán por la necesaria protección de las masas de agua especificadas "*con objeto de evitar el deterioro de su calidad, contribuyendo así a reducir el nivel del tratamiento de purificación necesario para la producción de agua potable*" *[…]"*

Los elementos de la guía sobre las aguas subterráneas en zonas protegidas para la captación de agua potable[26] que ofrecen un mayor interés para la evaluación del estado de las aguas subterráneas son los siguientes:

- se recomienda que cuando una captación sea competencia de la directiva de aguas potables[27], el control del agua no depurada se lleve a cabo de conformidad con los principios de vigilancia y control operativo en lo relativo a la frecuencia de las mediciones. Los Estados miembros deben garantizar previamente que el control sea representativo y suficiente para detectar los cambios significativos y sostenidos en la calidad del agua subterránea producidos por actividad humana. La guía sobre el seguimiento de las aguas subterráneas contiene recomendaciones sobre la selección de los puntos de control y sobre su agrupación.
- la evaluación del riesgo de deterioro debería llevarse a cabo para todos los parámetros individuales que se controlan de conformidad con la directiva de agua potable. Esto incluye los parámetros químicos, radiológicos y microbiológicos.
- los puntos de cumplimiento deben situarse en el punto o cerca del punto donde se capta el agua potable y antes de que se lleve a cabo ningún tratamiento de depuración.
- los datos de referencia sobre la calidad actual de las aguas subterráneas son necesarios para aquellos contaminantes que pueden plantear un riesgo de deterioro, que pueden utilizarse como referencia para evaluar el riesgo de deterioro (tendencias futuras). Cuando existan suficientes datos disponibles de la supervisión de las aguas subterráneas para definir niveles básicos[28], se recomienda que los puntos de partida se basen en esos datos. De otro modo, la evaluación tendría que posponerse hasta que hubiera suficientes datos disponibles.
- para las captaciones futuras, los niveles básicos de las captaciones y los niveles de tratamiento deben determinarse en el momento en que se desarrolle y se empiece a aplicar la propuesta de captación de agua potable.
- el cierre de una captación de agua potable motivado por su deterioro se considera como un indicador de violación del artículo 7(3) si el deterioro se debe a efectos humanos.
- puede ser aceptable un cierto grado de mezcla para igualar la calidad del agua sin tratar dentro de un pozo, o incluso inevitable, por la naturaleza de la infraestructura utilizada para la captación. No obstante, la mezcla de agua procedente de distintos campos de pozos podría ocultar cambios significativos y sostenidos en la calidad del agua subterránea.
- la evaluación del estado de cumplimiento debería centrarse en si se han producido cambios significativos y sostenidos en la tendencia de la calidad del agua sin tratar en el punto de captación, tal como se determina en los programas de seguimiento. A falta de cambios como los expuestos, es razonable asumir que no se necesitan cambios en los niveles de tratamiento. Si las tendencias son significativas y sostenidas y ya se ha instaurado el tratamiento, en la mayoría de los casos cualquier deterioro tendrá implicaciones que se prolongarán en el tiempo en el nivel de tratamiento. En los casos en que no se hayan superado las normas para el agua potable y el tratamiento no esté aún instaurado, deben evaluarse el potencial de deterioro futuro y sus implicaciones en el tratamiento.
- sólo si existen evidencias de cambios significativos en la calidad del agua no tratada que puedan atribuirse a un impacto humano deberá evaluarse el impacto sobre el nivel de tratamiento donde tenga lugar la captación. De este modo puede minimizarse la recogida y evaluación de datos adicionales.
- para poder evaluar los cambios en el "nivel" del tratamiento de depuración, sería necesario un conocimiento del proceso de tratamiento, que incluiría los parámetros que tenía que tratar cuando se instaló, en qué grado debía tratarlos, y el uso de materiales consumibles como productos químicos.

---

[27] Directiva comunitaria 98/83/CE

[28] "*Nivel básico' es el valor medio medido por lo menos durante los años de referencia 2007 y 2008 sobre la base de los programas de control aplicados De conformidad con el artículo 8 de la DMA o, en el caso de sustancias identificadas después de los citados años de referencia, durante el primer período para el que se disponga de un período representativo de datos de control* [artículo 2(6) DAS]

- Resulta difícil orientar sobre qué constituye una modificación en el nivel de tratamiento, pero se insta a los Estados miembros a que tomen en consideración los factores que se enumeran a continuación, con un enfoque de caso por caso:
  – si se necesita aumentar durante un cierto tiempo el nivel del tratamiento, ¿se trata de un aumento temporal o de un aumento a largo plazo?
  – ¿cuál es la tendencia general en la aplicación del tratamiento en ese emplazamiento?
  – ¿se necesitan equipos nuevos?
  – el objetivo de alguno de los cambios en el equipo o en los productos químicos ¿es aumentar el tratamiento, o simplemente hacerlo más eficaz? Un cambio en el proceso de tratamiento puede reflejar cambios tecnológicos y no un aumento del nivel de tratamiento como tal.
  – si tiene lugar la mezcla de fuentes diferentes, ¿qué fin persigue? ¿Se trata de un indicador de que existe un cambio significativo y sostenido de la calidad del agua sin tratar dentro de la ZPAP?
- Deben reseñarse las alteraciones, la clausura y el abandono de las fuentes existentes de abastecimiento de agua potable por causa de contaminación, de modo que los datos obtenidos puedan utilizarse para reforzar el sistema de control que aún con todo el empeño, puede que no siempre detecte los incidentes de contaminación. Esos datos pueden utilizarse también para evaluar en qué medida están siendo eficaces las distintas medidas de protección necesarias.
- Debe resaltarse que los cambios en la calidad de las aguas subterráneas pueden ser inducidos no sólo por la liberación directa de contaminantes, sino también por los efectos de la captación. Estos efectos también deben tenerse en cuenta.

En el ámbito de la evaluación del estado químico, los perímetros de protección no tienen una función específica. Los perímetros de protección que pueden ser delimitados por los Estados miembros de conformidad con el artículo 7(3) de la DMA se relacionan con medidas que garanticen la protección necesaria con el fin de evitar el deterioro de la calidad. Además, los perímetros de protección pueden ser útiles cuando se agrupen las captaciones con fines de seguimiento y evaluación. En los casos en que varias captaciones individuales de aguas subterráneas forman parte de un grupo de fuentes de abastecimiento dentro de un perímetro de protección y el sistema de seguimiento es consistente y representativo, es posible que sólo sea necesario someter a seguimiento y evaluación una selección representativa de las captaciones.

Procedimiento propuesto (véase la figura 10):

Además de la evaluación del cumplimiento de las exigencias de la directiva de aguas potables, que es un proceso bastante sencillo, tal como establece el artículo 7(2), el artículo 7(3) requiere un examen más cuidadoso y la elaboración de un procedimiento de test.

El procedimiento propuesto para la evaluación del estado químico de las aguas subterráneas en lo relativo al artículo 7(3) considera los requisitos legales y las recomendaciones formuladas en las guías pertinentes y puede resumirse del siguiente modo:

- el test hace referencia a los puntos de control pertinentes (ZPAP) que recomienda la guía sobre seguimiento [29]:
- paso 1 (cambio en el nivel de tratamiento): no debe existir ninguna prueba de que se haya producido un aumento del tratamiento inducido por cambios en la calidad del agua -cantidad de agua- lo que incluye la consideración del cambio de la mezcla y el cierre de la captación.
- paso 2 (deterioro de la calidad del agua): la evaluación del deterioro de la calidad del agua se centra en la calidad del agua sin tratar en el punto de captación.
  – identificar el nivel básico con respecto a contaminantes pertinentes -químicos, radiológicos y microbiológicos- que planteen un riesgo de deterioro
  – identificar cambios significativos -evaluación de la tendencia considerando los niveles básicos y los valores medios anuales- que se atribuyan a un impacto humano
  – evaluar el impacto que tienen los cambios significativos aludidos en el nivel de tratamiento

[29] Guidance Document No. 15 Groundwater Monitoring (2007)

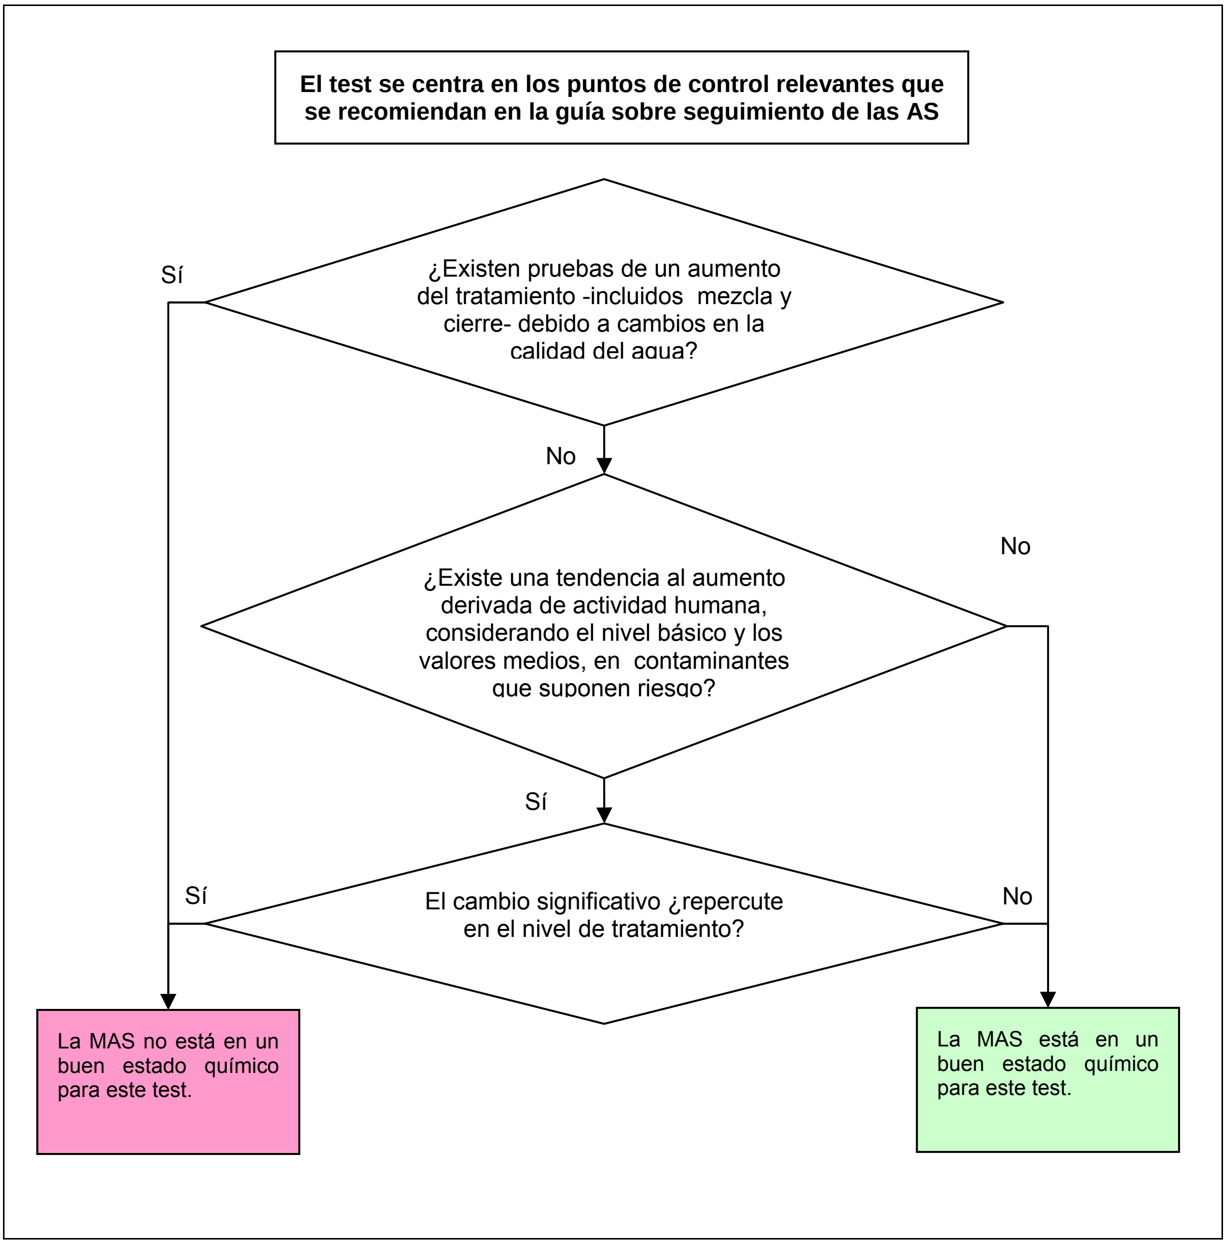

Figura 10. Procedimiento propuesto para el cumplimiento de los requisitos del artículo 7(3) de la DMA (ZPAP).

5 EVALUACIÓN DEL ESTADO CUANTITATIVO

5.1 Definición de buen estado cuantitativo

El buen estado cuantitativo se define en el anexo V 2.1.2 de la DMA. Tal como figura en este anexo, se logrará un buen estado cuantitativo de las aguas subterráneas cuando:

> “*El nivel del agua subterránea en la masa de agua subterránea es tal que la tasa media de extracción a largo plazo no excede del recurso disponible de agua subterránea.*
>
> *Del mismo modo, el nivel de las aguas subterráneas no es sometido a alteraciones antropogénicas como las que desembocarían en:*
>
> - incapacidad de lograr los objetivos medioambientales especificados en el artículo 4 para las aguas superficiales asociadas;
> - cualquier disminución significativa del estado de las aguas citadas; y
> - cualquier daño significativo a los ecosistemas terrestres que dependen directamente de la masa de agua subterránea[30].
>
> y alteraciones de la dirección del flujo que desembocan en posibles cambios temporales de nivel, o cambios continuos en una zona limitada espacialmente, pero cuando las inversiones citadas no causan la intrusión de agua salina ni de ningún otro tipo, y no indican una tendencia sostenida y claramente definida antropogénicamente en la dirección del flujo que pueda provocar las intrusiones citadas”.

5.2 Elementos de la evaluación del estado cuantitativo

Para que una masa de agua subterránea se encuentre en buen estado cuantitativo deberán cumplirse todos los criterios –objetivos- incluidos en la definición de buen estado (5.1). Estos objetivos son:

- la tasa media de captación a largo plazo no es superior al recurso hídrico disponible;
- no hay disminución significativa de las condiciones químicas y/o ecológicas de las aguas superficiales como resultado de una alteración antropogénica del nivel piezométrico o de un cambio de las condiciones del flujo, que conduciría a un incumplimiento de los objetivos pertinentes del artículo 4 de cualquiera de las masas de agua superficial asociadas;
- no se ha producido ningún daño significativo a los ecosistemas terrestres dependientes de las aguas subterráneas como resultado de una alteración antropogénica del nivel del agua;
- no existe intrusión salina ni otro tipo de intrusiones como resultado de cambios sostenidos de la dirección del flujo inducidos por la actividad humana.

Para verificar el cumplimiento de los objetivos expuestos puede adoptarse un sistema de clasificación del estado que desglose y compare uno por uno los distintos elementos de la definición de buen estado cuantitativo.

Todas las masas de agua subterránea -o grupos de masas- deberán ser sometidas a una evaluación del estado cuantitativo. No obstante, cuando existe un alto grado de confianza en que una masa de agua subterránea no está en riesgo de incumplir los objetivos de buen estado cualitativo, es razonable declarar que esa MAS se encuentra en buen estado, en consonancia con la adopción de un enfoque basado en el riesgo.

En el marco de la caracterización inicial y de la adicional, ya se habrá llevado a cabo una evaluación de presiones e impactos, para identificar las masas en riesgo de no alcanzar sus objetivos medioambientales. En este caso, las presiones se relacionarán con el estado cuantitativo. El proceso de caracterización implicará la reunión de la información especificada en el anexo II (2) tal como se precisa para apoyar la evaluación del estado, entre otros sobre la situación de las captaciones y la recarga artificial, los datos de captación/descarga, las características hidrogeológicas, las tasas de recarga, etc.

---

[30] Un ecosistema terrestre dependiente de las aguas subterráneas (ETDAS) sufrirá un daño significativo si no logra alguno de sus objetivos de conservación. Por ejemplo, cuando existen impactos antropogénicos sobre las condiciones de las aguas subterráneas, por ej. el flujo, nivel o calidad, que desembocan en que un ETDAS no logra “condición favorable”. Los objetivos de conservación pueden relacionarse con el logro de los requisitos de conformidad con la legislación comunitaria, -Directiva 92/43/CEE o cualquier otra iniciativa pertinente de los Estados miembros-.

La DMA indica que el nivel piezométrico debe ser el principal parámetro para evaluar el buen estado cualitativo, No obstante, mientras que el control de los niveles de agua es esencial para determinar los impactos e identificar tendencias prolongadas, es insuficiente por sí solo y generalmente se necesitarán otros parámetros e información adicional. En el anexo 1 se incide más sobre el uso de los niveles piezométricos. En la guía sobre seguimiento de las aguas subterráneas[31] se apuntan otros parámetros pertinentes. Esta combinación de información, conocida como **enfoque del peso de la evidencia** ("*weight of evidence approach*") debe garantizar la fiabilidad de la evaluación del estado.

5.3 Procedimiento para la evaluación del estado cuantitativo de las aguas subterráneas

Para determinar el estado cuantitativo global de una masa de agua subterránea deben aplicarse una serie de tests que consideren los impactos de las alteraciones a largo plazo inducidas por el hombre del nivel de las aguas subterráneas o de su flujo. Cada test evaluará si una masa de agua subterránea cumple los objetivos medioambientales pertinentes. No todos los objetivos medioambientales se aplicarán a todas las masas de agua subterránea. Por ello, sólo serán necesarios los tests pertinentes para su aplicación en caso necesario.

Algunos de los elementos del estado cuantitativo se superponen con los de la evaluación del estado químico, en particular la evaluación relativa a la intrusión salina. En este caso, las evaluaciones del estado químico y cuantitativo para ese elemento pueden combinarse y llevarse a cabo un único test. En otras circunstancias será necesario compartir la información relativa a la evaluación del estado químico y del cuantitativo.

5.3.1 Test: Balance hídrico (escala de masa de agua subterránea)

Para que una masa de agua subterránea esté en buen estado con respecto a este test, la extracción anual media de la masa de agua subterránea a largo plazo[32] no debe exceder la recarga media a largo plazo, minorada por la cuantía de los caudales ecológicos a largo plazo. Este test considera los efectos acumulados por toda la masa y es un test referido a toda la masa.

Cuando existe información fiable sobre los niveles piezométricos en el conjunto de la masa de agua subterránea, dicha información pueden utilizarse para identificar la presencia de un descenso sostenido a largo plazo de los niveles provocado por la extracción de agua subterránea. La presencia de este descenso indicará que no se cumplen las condiciones de buen estado y que la masa está en mal estado. No obstante, es posible que los niveles piezométricos por sí solos no proporcionen una clasificación fiable y por ello una alternativa es la realización de una evaluación de balance hídrico.

Para el test de balance hídrico se debe evaluar la extracción media anual con respecto a un "recurso disponible de agua subterránea" en la masa de agua subterránea. El recurso disponible de agua subterránea significa la tasa media anual a largo plazo de la recarga global de la masa menos la tasa anual a largo plazo de flujo necesario para lograr la calidad ecológica para las aguas superficiales asociadas especificadas en el anexo 4, evitar cualquier disminución significativa del estado ecológico y evitar cualquier daño significativo a los ecosistemas terrestres dependientes de las aguas subterráneas.

El recurso de agua subterránea disponible es un valor aproximado, basado en la recarga y las necesidades de caudales para mantener las condiciones ecológicas de las masas de agua superficial y de los ecosistemas terrestres que dependen de la masa de agua subterránea. Conviene reseñar que, al tratarse de un test que se aplica a toda la masa de agua subterránea, tal vez no siempre sea posible definir claramente las necesidades locales de caudal de ríos y humedales. Además, el recurso de agua subterránea disponible para la masa de agua subterránea puede no estar enteramente disponible para su extracción debido a que las condiciones hidrogeológicas -por ej., transmisividad y almacenamiento- dificultan su explotación desde el punto de vista económico y práctico. También puede variar la distribución del "recurso de agua disponible" en la masa de agua subterránea, en relación con receptores sensibles, hecho que habrá que tener en cuenta para la evaluación del estado. En muchos casos el límite de mal estado no se encontrará simplemente allí donde la

[31] Documento guía nº 15 Seguimiento de las aguas subterráneas (2007)

[32] La consideración de las mediciones "a largo plazo" –captación, recarga, nivel del agua- pretende minimizar la influencia de los factores climáticos naturales a corto plazo y los impactos de la captación. Las mediciones a largo plazo permiten que los efectos a corto plazo puedan diferenciarse de las pautas y tendencias a largo plazo. Para los fines de la DMA, la duración necesaria de los registros dependerá de las condiciones hidrogeológicas y medioambientales asociadas a la masa de agua subterránea. Se recomienda que como mínimo sean no menos de 6 años (un ciclo de gestión de cuenca hidrográfica).

extracción supere el recurso disponible, sino que puede situarse muy por debajo. En algunas situaciones puede ser hasta de un 20% menor.

La recarga anual media debe calcularse para toda la masa de agua subterránea, incluyendo todas las entradas al acuífero -por ej. entradas laterales procedentes de estratos impermeables contiguos-. Las directrices elaboradas por la FAO (Organización de las Naciones Unidas para la Agricultura y la Alimentación) contienen información adicional sobre el cálculo de las recargas (Naciones Unidas, 1998).

La tasa de extracción media anual debería incluir todas las salidas de agua de la masa de agua subterránea, incluyendo todas las porciones confinadas del acuífero que estén conectadas. Puede considerarse que forma parte de las salidas la evaporación que se produce en masas de agua extensas, por ej. en graveras y en sistemas terrestres de drenaje. La decisión sobre descontar el agua captada que se ha devuelto localmente al acuífero o a un río -por ejemplo, retornos de riego o procedentes de la evacuación de agua de una cantera/mina- debe basarse en una evaluación de tipo hidrogeológico, teniendo en cuenta los impactos que afectan a la masa.

Deben determinarse tanto las necesidades de caudal ecológico de las aguas superficiales como las de los ecosistemas terrestres dependientes de las aguas subterráneas, así como el impacto de la captación del agua subterránea sobre flujos de baja cuantía. Dependiendo del grado en que las presiones derivadas de la captación afecten a la masa de agua subterránea podrán utilizarse unos métodos u otros. En algunos casos se pueden utilizar los conocimientos técnicos locales, herramientas simples, o modelos más sofisticados.

Cuando exista un flujo lateral o vertical entre masas de agua subterránea adyacentes y otros acuíferos, esa componente deberá tenerse en cuenta cuando se lleve a cabo el test de balance hídrico. En algunos casos los flujos pueden ser entradas –recarga- y en otros casos, salidas. También pueden agruparse las masas de agua subterránea para simplificar la evaluación del balance hídrico.

La figura 11 es un esquema de este test. Las estimaciones utilizadas para el cálculo de los distintos elementos deberían basarse en las mejores estimaciones disponibles. En algunos ambientes hidrogeológicos será difícil obtener cifras precisas -por ejemplo en acuíferos cársticos- y por ello habrá una cierta incertidumbre asociada a la evaluación. Es importante que la incertidumbre se refleje y se considere en la evaluación de la confianza asociada a los informes sobre el estado. En muchos casos, esta incertidumbre y confianza en la evaluación no podrán cuantificarse, porque pueden estar relacionadas con la incertidumbre en la comprensión del sistema físico, el modelo conceptual y otros aspectos considerados.

Cuando una masa de agua subterránea cubre zonas geográficamente extensas o comprende distintos acuíferos, puede ser apropiado subdividirla en partes más pequeñas que sean representativas para llevar a cabo este test. Cada parte debe ser adecuadamente delimitada para los objetivos de este test. Cuando las masas de agua subterránea se subdividen, el test debe aplicarse por separado a cada una de las partes. El estado global de la masa de agua subterránea para este test será entonces el menos favorable de los resultados de los distintos componentes individuales, siempre que los resultados en cuestión sean significativos.

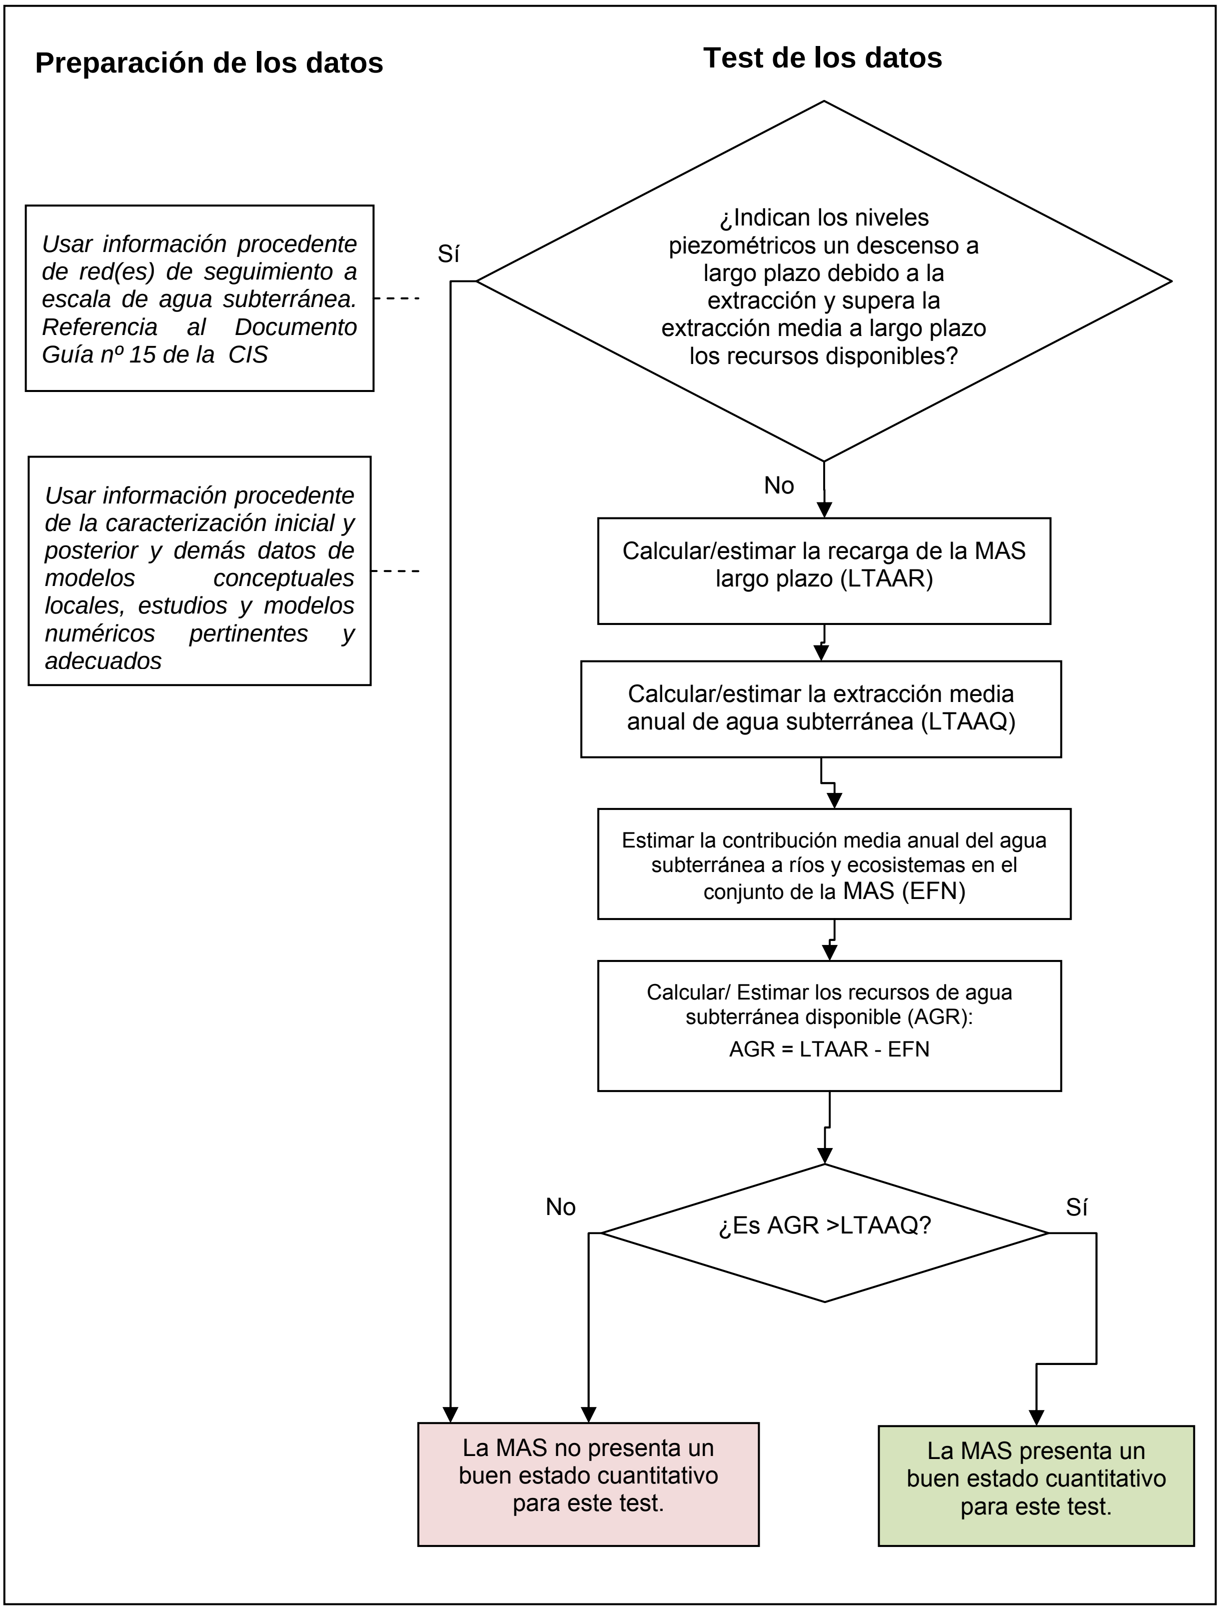

Figura 11. Esquema del procedimiento y necesidades de datos para el test de balance hídrico

LTAAQ – extracción media anual a largo plazo de agua subterránea

LTAAR – recarga media anual a largo plazo

EFN – caudales ecológicos a largo plazo

AGR – recursos de agua subterránea disponibles

5.3.2 Test: Flujo de agua superficial

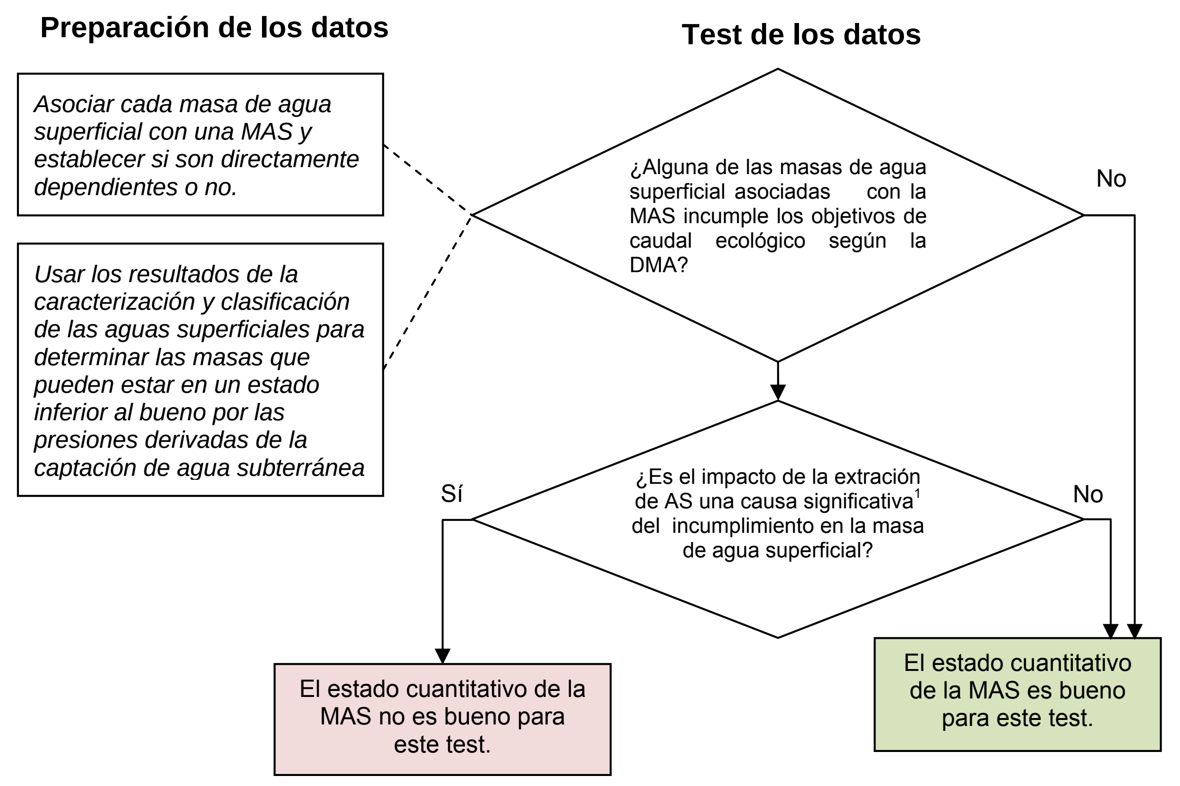
Para que una masa de agua subterránea se encuentre en buen estado para este test, no debe producirse ningún deterioro significativo de las características químicas o ecológicas de las aguas superficiales que afecten al logro de los objetivos reseñados en el artículo 4 de la DMA. Este test incluye tanto ríos como otras masas de agua superficial, como lagos, a las que se aplican los objetivos para las aguas superficiales de la DMA.

A diferencia del anterior, este test (véase la figura 12) toma en consideración si a escala local las presiones de la extracción de agua subterránea tienen un efecto significativo sobre las masas de agua superficial *consideradas de manera individual*, una vez que se han tenido en cuenta las distintas presiones sobre la(s) masa(s) de agua superficial. Dependiendo de la delimitación de las masas de agua, una MAS puede contener numerosas masas de agua superficial diferentes, cada una con sus propios objetivos.

Este test exige que se determinen las necesidades de flujo o de nivel de agua de las masas de agua superficial asociadas con MAS necesarias para contribuir a la consecución y el mantenimiento de un buen estado químico y ecológico. Los efectos de la extracción de agua subterránea pueden considerarse como una reducción del caudal en los ríos, y como una reducción del nivel en las restantes masas de agua superficial.

Si no se cumple este requisito de flujo/nivel como consecuencia de los efectos significativos derivados de la extracción de agua subterránea, la MAS se encontrará en mal estado, a no ser que la masa de agua superficial mantenga un estado ecológico bueno o alto. En todas las demás circunstancias, la MAS.

Frecuentemente no es posible medir con precisión la reducción de flujo/nivel que producen las presiones sobre las aguas subterráneas, puesto que, en muchas ocasiones, entre el momento en que se ejerce la presión de la extracción y la repercusión sobre la masa de agua superficial transcurre un tiempo, debido a la variabilidad y la respuesta de los sistemas hidrogeológicos. La imposibilidad de cumplir los requisitos necesarios de flujo/nivel en cualquier masa de agua superficial puede deberse también a la extracción de agua subterránea o de agua superficial. Por ello, será necesario estimar en qué medida el incumplimiento en las aguas superficiales es atribuible a las aguas subterráneas. Se ha sugerido un posible umbral para medir su importancia cuando más del 50% de la extracción permisible dentro de toda la zona de captación aguas arriba puede atribuirse a las aguas subterráneas. No obstante, el umbral que se utilice dependerá de cada Estado miembro y deberá tener en cuenta la incertidumbre en el proceso de evaluación y la importancia socio-económica de la extracción de agua subterránea con respecto a la de agua superficial.



[1]Test de importancia: Por ejemplo, si más del 50% -u otro umbral adecuado que tenga en cuenta la incertidumbre del procedimiento de evaluación y la importancia socioeconómica de la extracción de agua subterránea con respecto a la de agua superficial- del volumen admisible de abstracción de agua superficial puede atribuirse al agua subterránea, entonces se considerará importante.

Figura 12. Esquema del procedimiento propuesto para la evaluación del estado cuantitativo del elemento agua superficial

5.3.3 Test: Ecosistemas terrestres dependientes de las aguas subterráneas (ETDAS)

Para que una MAS se encuentre en buen estado no debe producirse ningún daño significativo para un ecosistema terrestre dependiente de dicha masa de agua subterránea. Los tests para evaluar el estado químico y el estado cuantitativo de ecosistemas terrestres dependientes de aguas subterráneas están estrechamente relacionados entre sí.

Para realizar este test es necesario determinar la situación medioambiental necesaria para apoyar y mantener las condiciones en un ecosistema terrestre dependiente de las aguas subterráneas, a saber, el flujo o el nivel necesario para el mantenimiento de comunidades vegetales dependientes.

Si no se cumplen las condiciones y se determina que el nivel de la masa de agua subterránea y el cambio del flujo debido a las captaciones son significativos, el estado de la masa de agua subterránea será deficiente. En todos los demás casos, la masa de agua subterránea estará en buen estado, pero potencialmente en riesgo. En la figura 13 se describe el procedimiento para este test.

En el marco de la caracterización inicial y de caracterizaciones adicionales deberá haberse realizado un ejercicio de investigación para determinar todos los ecosistemas terrestres dependientes de aguas subterráneas deteriorados, o en riesgo de estarlo, como resultado de las presiones que soporta el agua subterránea. Esta evaluación deberá haberse realizado sobre la base de criterios tales como las comunidades de indicadores ecológicos, la probable conexión con la masa de agua subterránea, la proximidad a presiones antropogénicas, acreditadas por conocimientos de ámbito local e informes sobre las condiciones del lugar. En la evaluación del estado solamente se considerarán los lugares respecto de los cuales se haya determinado que actualmente están “en riesgo”, partiendo del supuesto de que los ecosistemas terrestres dependientes de aguas subterráneas que “no están en riesgo” no provocarán el deterioro del estado de una masa de agua subterránea.

En muchos casos no será posible cuantificar con un alto grado de fiabilidad las aportaciones necesarias en este tipo de ecosistemas. Y ello se debe a que podría no existir información específica sobre el lugar en cuestión o información suficientemente detallada sobre todos los lugares. En tales circunstancias, la masa de agua subterránea estará en buen estado para este test, y se utilizarán los resultados del examen inicial de riesgos y de cualquier otro test disponible para decidir si los lugares en cuestión deben considerarse "en riesgo", en cuyo caso tendrán prioridad en investigaciones ulteriores.

5.3.4 Test: Intrusión salina u otras intrusiones

Para que una MAS esté en buen estado para este test no deberá existir intrusión salina prolongada ni intrusiones de otro tipo de agua de mala calidad que sea el resultado de un nivel sostenido o una presión hidrostática del agua inducidos antropogénicamente, de una reducción del flujo o de una alteración de la dirección del flujo como consecuencia de la captación. **Nota:** también podría producirse una intrusión salina prolongada incluso sin alteración de la dirección del flujo. Debido a las diferencias de densidad entre el agua salina y el agua dulce, una reducción de los niveles del agua o de la presión hidrostática provocará por sí sola la intrusión salina. Un descenso del gradiente hidráulico hacia la fuente de agua salina así como el correspondiente descenso en el flujo del agua subterránea favorecerán la intrusión salina antes de que el descenso de los niveles del agua sea suficiente para provocar un cambio en la dirección del flujo.

En este test, la intrusión se interpreta como una intrusión de agua de mala calidad en la masa de agua subterránea procedente de otra masa de agua (anexo V 2.3.2) más que el desplazamiento de un penacho de agua de mala calidad dentro de la masa. La intrusión podría provenir de una masa de agua situada más arriba, más abajo o adyacente a la masa cuyo estado se está evaluando.

Este test se combina con el test del estado químico para medir la intrusión salina, y se describe con mayor detalle en el capítulo 4.4.3 y la figura 7.

Cuando se realice la evaluación, se tendrán debidamente en cuenta los impactos históricos prolongados de la explotación, particularmente en acuíferos confinados y acuíferos con un bajo índice de recarga.[33] Los índices históricos de bombeo podrían haber provocado un descenso significativo de los niveles del agua subterránea o de los niveles piezométricos -p.ej. de centenares de metros- debido a una explotación excesiva, aun cuando desde entonces se haya reducido hasta niveles sostenibles, hasta alcanzar un equilibro actual con los índices de recarga. En tales casos, aun cuando el balance hídrico indique que no se sobrepasan los recursos disponibles, podría estar produciéndose una intrusión continuada y la calidad del agua subterránea podría seguir deteriorándose. Cuando se produzca una intrusión en la masa de agua, deberá aplicarse el test de intrusión salina.

Cuando la alteración de origen humano de los niveles piezométricos produzca cambios geoquímicos dentro de la propia masa de agua subterránea, y estos cambios ocasionen un deterioro de la calidad del agua dentro de la masa; y cuando estos cambios sean significativos y potencialmente puedan causar que se supere un valor umbral o una norma de calidad o cualquier otro objetivo pertinente de la DMA, deberán ser tomados en consideración en los tests del estado químico, (véase el capítulo 4.4.3). Un ejemplo de este proceso podría ser la oxidación del agua subterránea u otro cambio geoquímico en un acuífero anteriormente confinado a causa de una extracción excesiva que provoque la movilización o liberación de contaminantes. La gestión de la extracción de agua subterránea para el mantenimiento de las condiciones necesarias que minimicen el potencial incumplimiento del estado debido a los cambios geoquímicos inducidos por la actividad humana formará parte de un programa de medidas para dicha masa de agua subterránea. La definición de las medidas se sale del ámbito de este documento, pero cabría prever que dichas medidas incluyan el mantenimiento de acuíferos confinados en condiciones de confinamiento mediante el establecimiento de criterios sobre el nivel mínimo del agua, para evitar un futuro deterioro de su estado.

[33] En este contexto, el bajo índice de recarga se utiliza para hacer referencia a zonas semiáridas. La definición de lo que constituye una zona semiárida es cuando la relación entre la precipitación media anual y la evapotranspiración potencial es <0,5 (UNESCO, 1979).

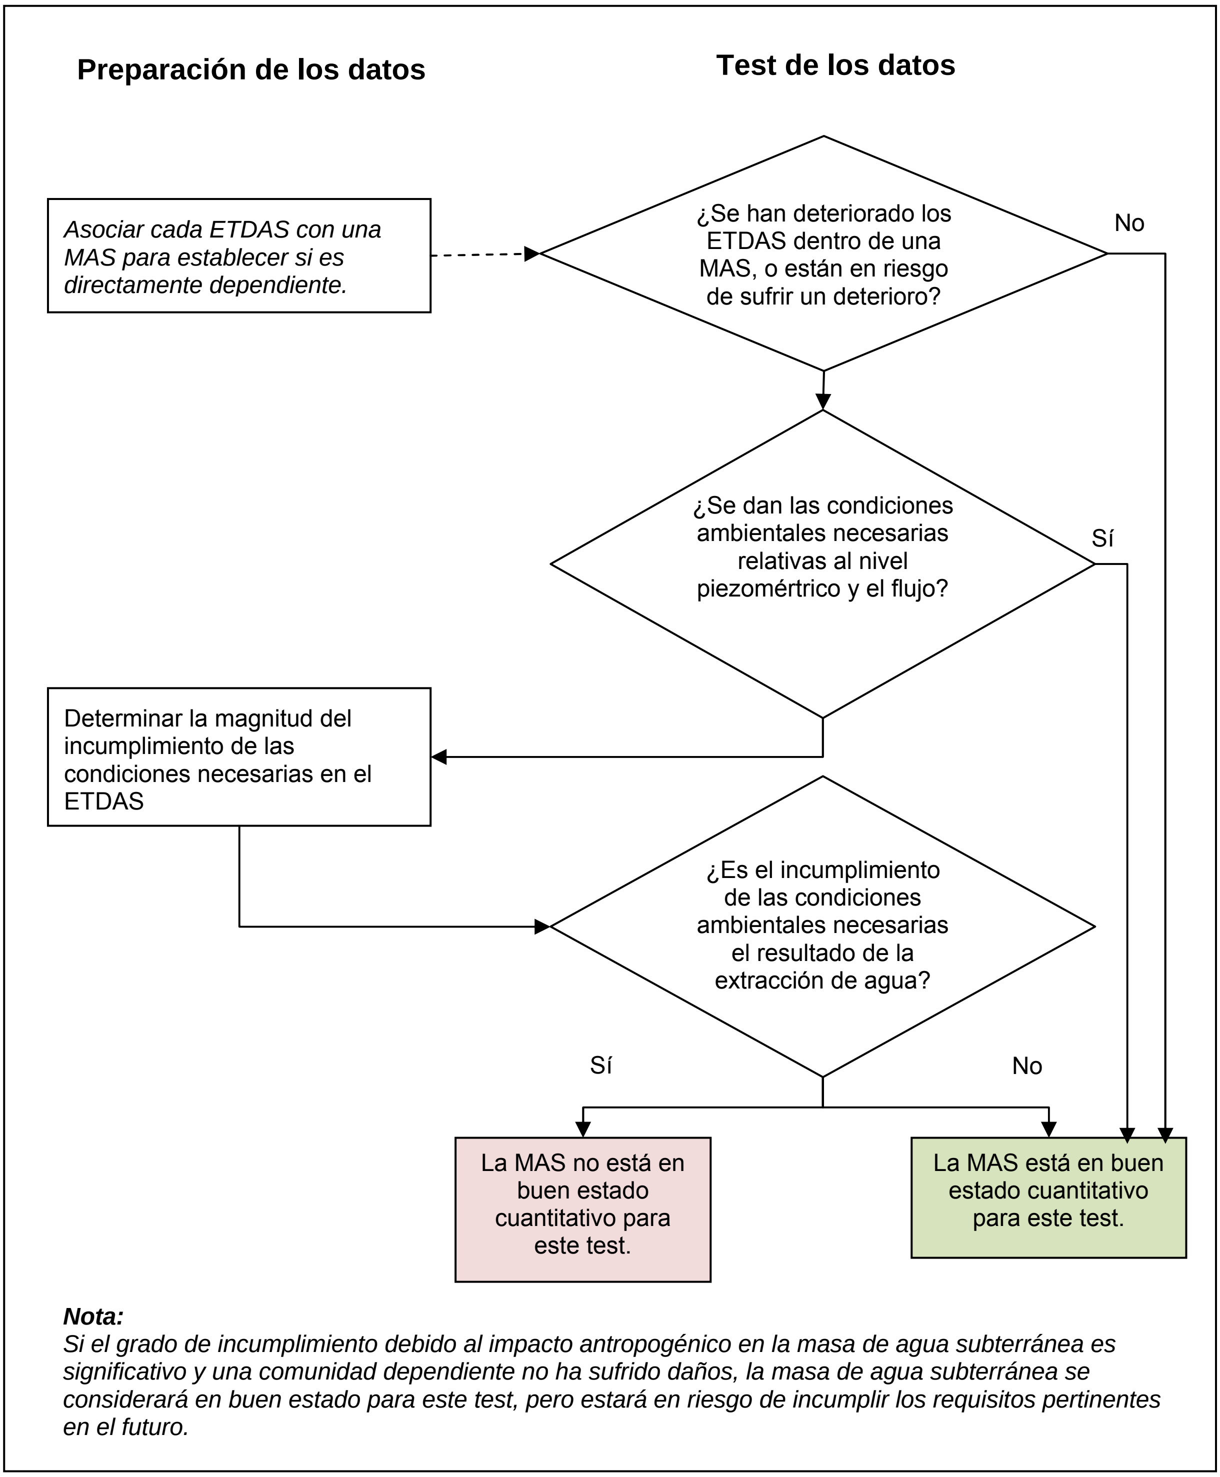


Figura 13. Esquema del procedimiento propuesto para el elemento ETDAS en la evaluación del estado cuantitativo

6 EVALUACIÓN DE TENDENCIAS Y DE LA INVERSIÓN DE LAS TENDENCIAS

6.1 Definición de tendencias significativas y sostenidas al aumento de la contaminación e inversión de las tendencias

La DMA y la DAS establecen que los Estados miembros deberán determinar si existen tendencias al aumento significativo y sostenido de las concentraciones de contaminantes, grupos de contaminantes o indicadores de contaminación encontrados en las masas o grupos de masas de agua subterránea respecto de las cuales se haya determinado que están en riesgo (anexo V 2.4.4 de la DMA y artículo 5 de la DAS). Los Estados miembros deberán asimismo invertir dichas tendencias: *"los Estados miembros habrán de aplicar las medidas necesarias para invertir toda tendencia significativa y sostenida al aumento de la concentración de cualquier contaminante debida a las repercusiones de la actividad humana con el fin de reducir progresivamente la contaminación de las aguas subterráneas."* (artículo 4.1.b)iii) de la DMA). Las medidas deben ir dirigidas a reducir progresivamente la contaminación y a impedir nuevos deterioros de las aguas subterráneas (artículo 5.2 de la DAS).

Una tendencia significativa y sostenida al aumento es *"cualquier aumento significativo desde el punto de vista estadístico y medioambiental de la concentración de un contaminante, grupo de contaminantes o indicador de contaminación en aguas subterráneas para el que se haya determinado la necesidad de una inversión de la tendencia, de conformidad con el artículo 5"* (artículo 2.3 de la DAS).

Una *tendencia significativa desde el punto de vista estadístico* es aquella que haya sido determinada utilizando una técnica reconocida de evaluación de tendencias.

Una tendencia *significativa desde el punto de vista medioambiental* es aquélla estadísticamente significativa y que, de no invertirse, derivaría en el incumplimiento de uno o más de los objetivos medioambientales estipulados en la DMA.

6.2 Elementos de la evaluación de tendencias y de la inversión de las tendencias

La evaluación de tendencias sólo deberá realizarse en las masas de agua subterránea que estén en riesgo de incumplir los objetivos estipulados en el artículo 4 de la DMA en relación con cada uno de los contaminantes que contribuyan a que la MAS haya sido caracterizada como tal (anexo IV de la DAS). Esto no sólo incluye a las masas de agua identificadas en 2004 en cuanto al cumplimiento de los objetivos del artículo 5 de la DMA, sino también a todas las masas de agua subterránea respecto de las cuales se haya determinado que están en riesgo como resultado de una actualización de la evaluación de riesgos y/o de nuevos resultados obtenidos mediante el control de vigilancia.

También podría ser necesario iniciar una evaluación de las tendencias en las masas de agua subterránea que no estén en riesgo actualmente a fin de distinguir las tendencias prolongadas como consecuencia de cambios de las condiciones naturales y de la actividad humana (anexo V 2.4.2 de la DMA).

Los Estados miembros definirán el punto de partida de las inversiones de tendencia de manera que se puedan invertir las tendencias en el tiempo para evitar un (futuro) incumplimiento de los objetivos medioambientales pertinentes (artículo 5.3 y anexo IV, B de la DAS). Este punto de partida se definirá como porcentaje de la norma de calidad de las aguas subterráneas o del valor umbral pertinente, y se notificará en el PHC.

Los Estados miembros identificarán en los planes hidrológicos de cuenca las MAS que presenten tendencias a un aumento significativo y sostenido y, cuando proceda, aquéllas donde se hayan invertido las tendencias. El PHC explicará asimismo de manera resumida la forma en que se hayan utilizado los resultados obtenidos en los distintos puntos de control para identificar dichas tendencias (artículo 5.4 de la DAS).

Los Estados miembros podrán también realizar evaluaciones de tendencia adicionales a fin de verificar que los penachos procedentes de sitios contaminados no representan una amenaza para el logro de los objetivos del artículo 4 de la DMA; en particular, que no se expandan ni deterioren el estado químico de la masa o grupos de masas de agua subterránea, y que no supongan un riesgo para la salud humana y el medio ambiente (artículo 5.5 de la DAS).

En el marco de la evaluación de tendencias significativas y sostenidas al aumento y de la evaluación de la inversión de las tendencias deberán tomarse en consideración los siguientes elementos (véase también la figura 14):

- cuál es el método estadístico correcto para evaluar las tendencias en cada punto de control (como el análisis de regresión);
- cómo tratar los valores obtenidos mediante el seguimiento que se sitúan por debajo del límite de cuantificación;
- cuál es la duración adecuada de las series temporales;
- cómo considerar los niveles básicos de sustancias que se producen de manera natural y antropogénica;
- cuál es el grado de fiabilidad aceptable de la evaluación de las tendencias:
- cómo establecer un punto de partida de la inversión de tendencias;
- cómo demostrar estadísticamente que se ha invertido la tendencia declarando el grado de fiabilidad de la identificación.

De conformidad con el mandato recibido por el grupo de redacción de este documento, los criterios sobre la evaluación de tendencias y la evaluación de la inversión de las tendencias deben considerar como fuente básica el Informe Técnico nº 1 de la CIS”[34]. Asimismo deben tenerse en cuenta el desarrollo de nuevas metodologías y las experiencias adquiridas en los Estados miembros.

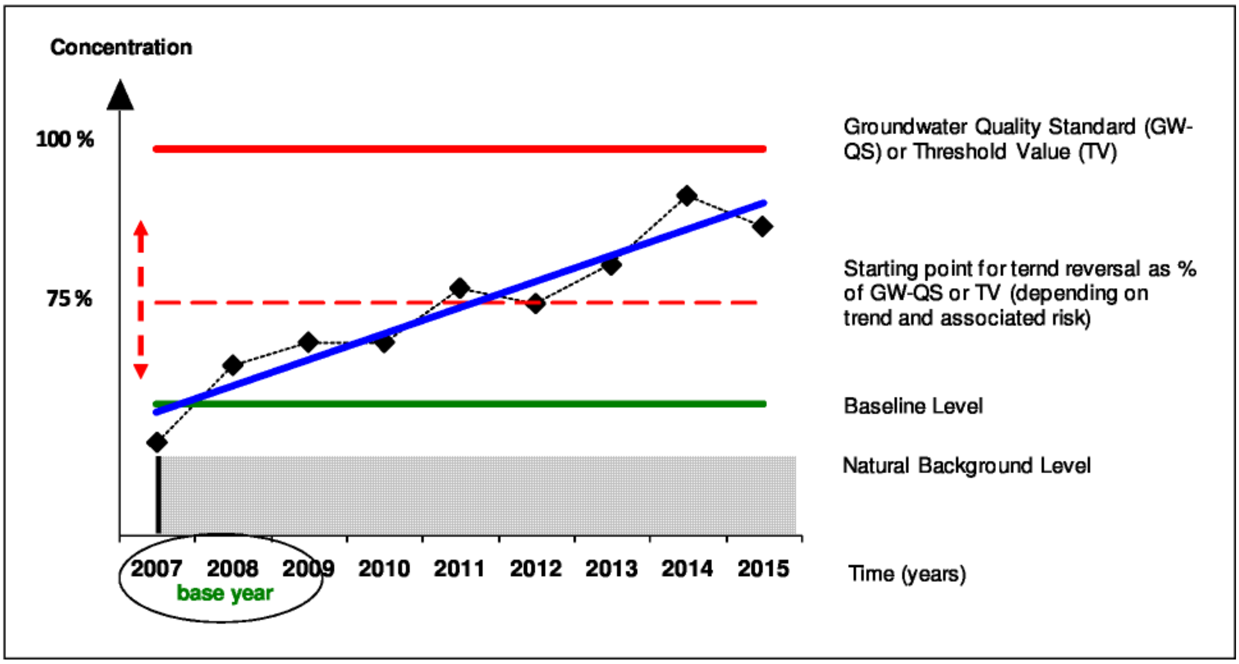

Figura 14. Elementos de la evaluación de tendencias y de inversión de las tendencias

6.2.1 Parámetros considerados

El anexo V 2.4.4 de la DMA y el artículo 5.1 de la DAS establecen que se determinará toda tendencia significativa y sostenida al aumento de las concentraciones de los contaminantes, grupos de contaminantes o indicadores de contaminación detectada en masas de agua subterránea o grupos de masas de agua subterránea en riesgo. A diferencia de la evaluación del estado químico, ninguna de las directivas establece de manera explícita qué parámetros deben someterse a esta evaluación.

El punto de partida de la inversión de las tendencias se establecerá en relación con las normas de calidad de las aguas subterráneas recogidas en el anexo I de la DAS y/o los valores umbral establecidos en el artículo 3 para parámetros que supongan un riesgo para la MAS. Se considera, por consiguiente, que debe realizarse una evaluación de las tendencias y de la inversión de éstas para los parámetros que representen un riesgo para la masa de agua subterránea.

La evaluación de tendencias podría realizarse también para cualquier otro parámetro –natural- que pueda ocurrir en cualquier punto de la masa de agua subterránea como consecuencia de la actividad humana, si los Estados miembros consideran que existe potencial para que en un futuro aparezcan tendencias significativas para el medio ambiente.

[34] Technical Report No. 1: Statistical aspects of the identification of groundwater pollution trends and aggregation of monitoring results – WG 2.8 Statistics (2001).

Esta información podrá utilizarse en la caracterización y evaluación de riesgos, y constituye una alerta temprana ante posibles problemas futuros para las masas de agua subterránea que actualmente estén en riesgo, así como para aquéllas que no lo estén.

La evaluación de tendencias para comprobar que no se expanden los penachos contaminantes es muy específica de cada caso y debe centrarse en los contaminantes o indicadores de contaminación correspondientes a los respectivos tests del estado de las aguas subterráneas.

6.2.2 Diseño de la red de seguimiento

De conformidad con el anexo IV A, 2.a) de la DAS, las características de la red de seguimiento –determinación de frecuencias de medida y selección de puntos de control- deberá ser suficiente para:

- garantizar que las tendencias al aumento puedan distinguirse de las variaciones naturales con un nivel adecuado de fiabilidad y precisión;
- determinar con tiempo suficiente las tendencias al aumento para que puedan adoptarse medidas;
- tener en cuenta las características temporales, físicas y químicas, de la masa de agua subterránea, incluidas las condiciones de flujo y los índices de recarga del agua subterránea, así como el tiempo que ésta tarda en atravesar el suelo o el subsuelo.

El anexo IV A, 2.b) de la DAS establece asimismo que *"se utilizarán métodos de control y análisis acordes con los principios internacionales de control de la calidad, entre ellos, si procede, las normas CEN o los métodos nacionales normalizados, para garantizar que se proporcionen datos de calidad científica equivalente que puedan compararse".*

6.2.3 Datos de la red de seguimiento

La evaluación de tendencias y de la inversión de las tendencias se basará en los datos obtenidos en los controles de vigilancia y operativo en los distintos puntos de control. Esta determinación de tendencias se llevará a cabo por primera vez en 2009, si es posible, y teniendo en cuenta los datos recopilados con anterioridad al ciclo en curso del PHC, a fin de permitir una evaluación fiable de las tendencias e informar sobre las mismas en el primer PHC (anexo IV A,2.a,ii y anexo IV A,3).

Cuando dispongan de datos de seguimiento adicionales que sean representativos, los Estados miembros tendrán libertad para incluirlos en la evaluación cuando puedan contribuir a mejorar la fiabilidad de la misma. No obstante, los datos deberán ser directamente comparables con los datos de seguimiento previstos en la DMA -p.ej. con respecto a los métodos de análisis, el muestreo y el control de calidad-.

6.2.4 Utilización de los niveles básicos

Para la determinación de tendencias en las concentraciones de sustancias que se produzcan naturalmente y como resultado de las actividades humanas se considerarán también los niveles básicos (anexo IV A,3 de la DAS).

"Nivel básico" es el valor medio medido por lo menos durante los años de referencia 2007 y 2008 sobre la base de los programas de control aplicados De conformidad con el artículo 8 de la Directiva 2000/60/CE o, en el caso de sustancias identificadas después de los citados años de referencia, durante el primer período para el que se disponga de un período representativo de datos de control" (artículo 2.6 de la DAS).

El nivel básico proporciona un punto de referencia respecto al cual puedan medirse futuros cambios -tendencias- en las concentraciones de contaminantes. Los Estados miembros podrán utilizar todos los demás datos representativos[35] de que puedan disponer que sean anteriores a la aplicación de los programas de seguimiento previstos en el artículo 8 de la DMA. **Atención**: el nivel básico no debe confundirse con el nivel de referencia (natural).

De conformidad con el anexo V 2.4.4 de la DMA, el año de base corresponde al año en que se midieron los niveles básicos. **Atención**: no debe confundirse el año de base de la evaluación de tendencias con el punto de partida de la inversión de tendencias.

6.2.5 Duración de las series temporales utilizadas

La duración de las series temporales que deben utilizarse en la evaluación de tendencias dependerá de cómo reacciona la masa de agua subterránea a los cambios en las prácticas que se desarrollan en la superficie del suelo -modelo conceptual-, de la capacidad del método de test de tendencias para

[35] Véase la guía pertinente sobre muestreo y seguimiento QA/QC en la que se encontrará una descripción completa de cómo garantizar que los datos se hayan generado utilizando métodos reproducibles y que son representativos de la MAS.

detectar las tendencias y de la calidad de los datos (véase tratamiento de valores menores que el límite de cuantificación (LC), capítulo 3.4). Los datos de calidad deficiente y los altos LC en el pasado, así como las series temporales demasiado largas, podrían tener una influencia significativa y duradera en los resultados de la evaluación de tendencias, aun cuando los datos recientes puedan ser de buena calidad.

Para evitar posibles sesgos en la evaluación global -p.ej. a escala de masa de agua subterránea o a escala regional- es preferible utilizar series temporales de datos de la red de seguimiento de una duración constante. La extensión mínima de las series temporales que deben utilizarse, en términos de número de mediciones normalizadas y del número mínimo de años considerados, dependerá de la frecuencia del seguimiento, del método estadístico, del punto de partida de la inversión de tendencias y de la potencia del método. La extensión máxima de las series temporales que deben utilizarse dependerá del modelo conceptual de la MAS, de la evolución temporal de las concentraciones y de la variabilidad de los datos. Una serie temporal demasiado larga podría dar resultados de tendencias sesgados por cambios que se hayan producido en los primeros años de la serie temporal. En consecuencia, podría ser de utilidad probar con una serie temporal larga para comprobar si se producen cambios significativos en la tendencia. Si es éste el caso, habrá que investigar utilizando solamente datos recientes, siempre que su duración sea suficiente para evaluar las tendencias. Sin embargo, se recomienda siempre cautela para garantizar que la duración de la serie temporal considerada sigue siendo coherente con el modelo conceptual de la MAS -p.ej. tasas de transferencia, tiempos de residencia, etc-. Como regla general, nunca deben descartarse datos a menos que se demuestre que son incorrectos como consecuencia de algún error cometido en el muestreo o en las determinaciones analíticas.

6.2.6 Metodología de evaluación de tendencias

La evaluación se basará en un método estadístico conocido y apropiado, como el análisis de regresión (anexo IV A,2.c)). Habida cuenta de que “significativo” se refiere a significación estadística -además de medioambiental-, el método elegido debe poder probar la significación estadística de la tendencia en cuestión.

Cuando se definan los puntos de partida de la inversión de las tendencias, el tiempo transcurrido desde el punto de partida hasta el momento en que se superan las normas de calidad de las aguas subterráneas o los valores umbral deberá ser suficiente para que la metodología de evaluación de tendencias utilizada pueda detectar una tendencia significativa, es decir, que el tiempo transcurrido sea suficiente para detectar una tendencia significativa desde el punto de vista medioambiental y para adoptar medidas para invertir dicha tendencia. La capacidad de un método para detectar un aumento determinado en las concentraciones de contaminantes con una probabilidad determinada se denomina “potencia” del método[36].

A fin de distinguir con un grado adecuado de fiabilidad y precisión entre variación natural y tendencias, la metodología para evaluar la tendencia también debe incluir, cuando proceda, un test de estacionalidad, es decir, cuando en las concentraciones se produzcan variaciones significativas dentro de un mismo año.

6.2.7 Confianza en la evaluación

El grado de fiabilidad asociado a cualquier tendencia identificada o inversión de tendencia deberá demostrarse y registrarse (anexo V 2.4.4 de la DMA y anexo IV B,3. de la DAS).

Para que una tendencia sea estadísticamente significativa se recomienda como norma que la fiabilidad de la evaluación sea de un 95%.

6.2.8 Punto de partida de la inversión de tendencias

La DAS establece en su artículo 5.3 que los Estados miembros definirán puntos de partida para la implantación de medidas destinadas a invertir las tendencias, y el anexo IV, parte B de la DAS especifica los criterios para el establecimiento de dichos puntos de partida. El punto de partida debe tener en cuenta el riesgo o los riesgos medioambientales asociados a la masa de agua subterránea, los objetivos medioambientales y las normas de calidad de las aguas subterráneas y/o los valores umbral que se hayan establecido para la masa de agua. El punto de partida será un porcentaje de dichas normas de calidad o valores umbral.

[36] Informe Técnico nº 1: Aspectos estadísticos de la identificación de las tendencias contaminantes de aguas subterráneas y agregación de los resultados del seguimiento – GT 2.8 Statistics (2001).

Como norma general, el punto de partida será el momento en el cual la concentración del contaminante alcance el 75% de los valores paramétricos de las normas de calidad las aguas subterráneas y de los valores umbral pertinentes, a menos que:

a) sea necesario un punto de partida anterior para permitir que las medidas de inversión impidan del modo más rentable, o al menos mitiguen en la medida de lo posible, cualquier cambio adverso significativo en la calidad del agua subterránea;

b) se justifique un punto de partida distinto si el límite de detección -o el límite de cuantificación- no permite establecer la presencia de una tendencia cifrada en el 75% de los valores paramétricos; o

c) la tasa de aumento y la reversibilidad de la tendencia sean tales que, de tomarse un punto de partida posterior para aplicar medidas de inversión de la tendencia, éste seguiría permitiendo que dichas medidas impidan del modo más rentable, o al menos mitiguen en la medida de lo posible, cualquier cambio adverso significativo desde el punto de vista medioambiental en la calidad del agua subterránea. Este punto de partida posterior no podrá suponer retraso alguno en el cumplimiento de los plazos para el logro de los objetivos medioambientales.

Un punto de partida diferente podría estar justificado también cuando las concentraciones de referencia naturales y los valores umbral estén muy cerca unas de otros o sean los mismos (caso 2 en el apartado 4.3.3).

El punto de partida para aplicar medidas encaminadas a invertir las tendencias depende principalmente de las características de la MAS -según definición en el modelo conceptual- y de su capacidad de responder a dichas medidas. El punto de partida elegido debe permitir a los Estados miembros invertir estas tendencias de la manera más rentable antes de que las concentraciones de contaminantes causen cambios adversos significativos en la calidad del agua subterránea. En MAS que reaccionen muy lentamente a los cambios podría ser necesario un punto de partida anterior; para las masas de agua subterránea que responden con rapidez podría justificarse un punto de partida posterior.

Una vez establecido un punto de partida para una tendencia, éste no se modificará durante el ciclo de seis años del plan hidrológico de cuenca (anexo V, B, 2 de la DAS).

6.2.9 Metodología de evaluación de la inversión de las tendencias

Tal como establece la DAS (anexo IV B, 3), deberá demostrarse la inversión de tendencias.

En el Informe Técnico nº 1[37] se describe una metodología de evaluación de la inversión de tendencias, que esté basada en un análisis de regresión, en el que se analiza cada serie temporal para determinar si se ha producido un cambio en la tendencia. Esto ocurre cuando una tendencia sostenida y significativa al aumento va seguida de una tendencia significativa al descenso.

6.2.10 Calendario de la evaluación de tendencias y de la inversión de las tendencias

La determinación de tendencias se llevará a cabo por primera vez en 2009, si es posible, y en lo sucesivo, una vez cada seis años como mínimo (anexo IV A, 2. ii) de la DAS), teniendo en cuenta los datos existentes obtenidos en el control de vigilancia y el control operativo, así como los datos de seguimiento recopilados antes del comienzo del programa de seguimiento. Esto permitirá informar sobre las tendencias en el primer PHC (anexo IV A, 2. a), ii) y anexo IV A, 3).

Habida cuenta de que el proyecto de PHC se someterá a la participación pública un año antes de su entrada en vigor, se recomienda que, si es posible, los Estados miembros evalúen las tendencias y la inversión de tendencias antes de presentar el proyecto de PHC.

6.3 Tests para evaluación de tendencias y de la inversión de las tendencias

Para cumplir los requisitos previstos en la DMA y la DAS, la evaluación de tendencias deberá:

- determinar si una masa de agua subterránea en riesgo está sometida a una tendencia significativa y sostenida al aumento que de conformidad con el artículo 5.1 y 5.2 deba invertirse; estas tendencias entran dentro de dos categorías generales (véase la tabla 3):
  - *“que presenten un riesgo para los usos legítimos, reales o potenciales, del medio acuático”*

[37] Informe Técnico nº 1: Aspectos estadísticos de la identificación de las tendencias contaminantes en aguas subterráneas y agregación de los resultados de seguimiento – GT 2.8 Statistics (2001)

– *"que representen un riesgo para la calidad de los ecosistemas acuáticos" o "para los ecosistemas terrestres"*

- en el marco de la evaluación del estado químico (evaluación de la intrusión salina y objetivos para zonas protegidas para la captación de agua potable) (véase la tabla);
- evaluar, cuando corresponda, el impacto de penachos de contaminación procedentes de fuentes contaminantes y lugares contaminados que puedan comprometer el cumplimiento de los objetivos especificados en la DMA y la DAS (artículo 5.5 de la DAS) (véase la tabla 4).

La evaluación de la inversión de las tendencias es necesaria si una MAS está sometida a una tendencia significativa y sostenida al aumento que, de conformidad con el artículo 5.1 y 5.2 deba invertirse.

Tabla 3. Evaluación de tendencias (artículo 5.1 y 5.2 de la DAS). Resumen de elementos y tests correspondientes

Nueva evaluación de tendencias	**Test**	**Evaluación de tendencias**	**Evaluación de inversión de tendencia**	**Determ. a nivel de la MAS**	**Puntos de control pertinntes**
Evaluación de penachos (artículo 5.5 de la DAS)					
Se considerará una evaluación de tendencias para comprobar que los penachos resultantes de lugares contaminados no se expanden, no deterioran el estado químico de la masa o grupo de masas de agua subterránea y no suponen un riesgo para la salud humana ni para el medio ambiente (DAS, art. 5.5).	No hay expansión de penachos que supongan deterioro del estado químico ni riesgo para la salud humana ni el medio ambiente.	x			x
Evaluación del estado					
En la masa de agua subterránea no hay entradas ni conato de entrada de agua de mar ni de agua de una composición química sustancialmente diferente de otras masas de agua subterránea o aguas superficiales que pueda causar contaminación (DMA, anexo V 2.3.2).	No hay intrusión salina ni de otro tipo.	x			x
No hay deterioro de la calidad de las aguas para el consumo humano (DAS, artículo 4.2.c), iii) y anexo III 4)	Cumple los requisitos del artículo 7.3 de la DMA Zonas protegidas de captación de agua potable	x			x

6.3.1 Determinación de tendencias significativas desde el punto de vista medioambiental y escala de la evaluación (artículo 5.1 de la DAS)

La DAS establece en su artículo 5.1 que los Estados miembros determinarán si la *masa de agua subterránea* está afectada por una tendencia significativa y sostenida al aumento desde el punto de vista medioambiental inducida antropogénicamente.

Habida cuenta de que la evaluación de tendencias se basa en los datos procedentes del seguimiento individual o de los puntos de control operativo, será necesario un procedimiento para combinar los resultados de las distintas evaluaciones de tendencias y de inversión de tendencias en los puntos de control a fin de medir la tendencia a nivel de la masa de agua subterránea (artículo 5.4.a) de la DAS).

Para determinar si una tendencia es significativa desde el punto de vista medioambiental pueden aplicarse los mismos principios que para evaluar el estado químico. Esto significa que la evaluación de tendencias deberá aplicarse a la misma escala que se utilice para medir la magnitud de la tendencia, es decir, podría ser necesario realizar la evaluación de tendencias en los puntos de control individuales, en los grupos de puntos de control o agregando los resultados obtenidos en toda la MAS. Por ejemplo, cuando se examine la importancia medioambiental de un riesgo medioambiental extenso procedente de los contaminantes -p.ej. como consecuencia de fuentes de contaminación difusa-, deben agregarse los datos de la tendencia en la MAS porque todos los puntos de control podrían considerarse importantes. Cuando el riesgo afecte a un ecosistema específico -acuático o terrestre- que dependa del agua subterránea, lo importante podrían ser las tendencias en los puntos de control individuales o en los grupos de puntos de control por su relevancia en que la MAS no alcance los objetivos medioambientales.

6.3.2 Test: “Riesgo para los usos existentes, reales o potenciales del medio acuático” (DAS, artículo 5.1 y 5.2)

Este test permite determinar las tendencias de relevancia medioambiental causadas por la extensión del impacto o por el riesgo procedente de contaminantes -por ej. de fuentes de contaminación difusas que afecten a toda la MAS-. Para poder realizar la evaluación deberán agregarse los datos sobre las tendencias procedentes de toda la MAS y, en consecuencia, todos los puntos de control podrían considerarse importantes. Si la evaluación general de tendencias a escala de MAS detecta una tendencia sostenida al aumento, una evaluación específica en los puntos de control podría ayudar a centrar, de una manera más eficaz, las medidas encaminadas a invertir dichas tendencias.

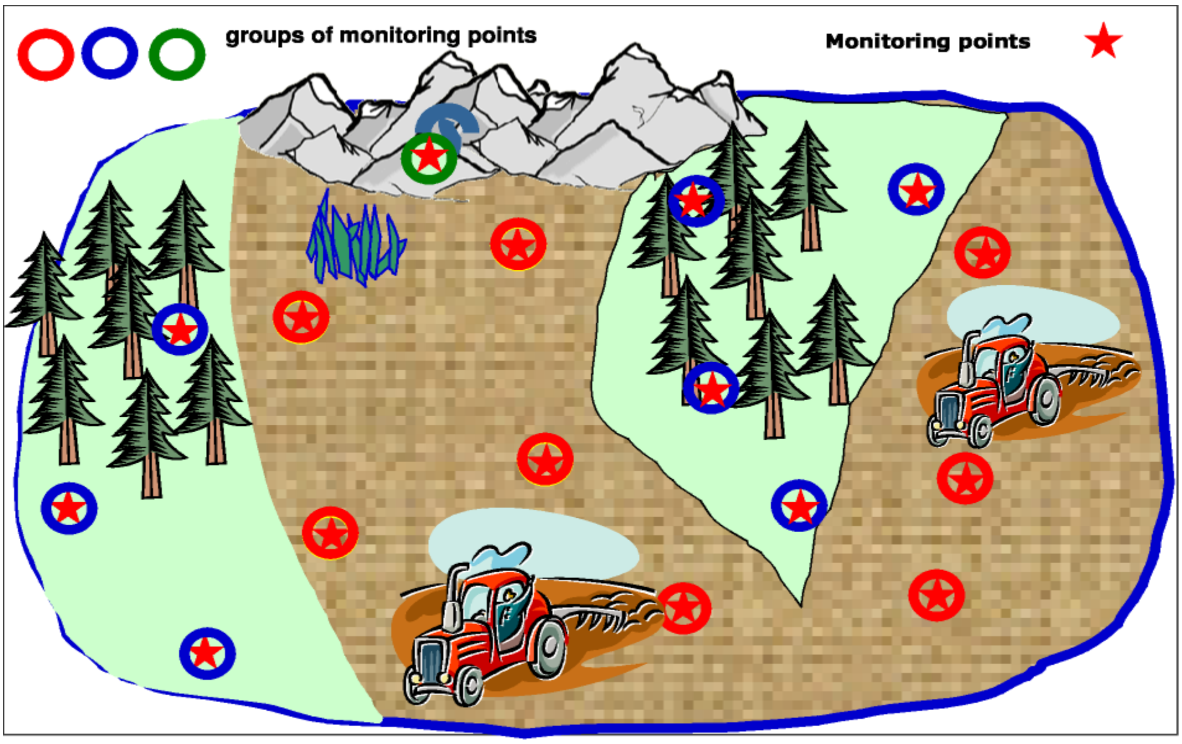

Figura 15. Selección de todos los puntos de control que se consideran pertinentes para el test de riesgo para usos legítimos. Agrupación opcional de puntos de control según modelo conceptual.

La evaluación de impactos de ámbito más local -por ej. fuentes de contaminación difusas regionales o fuentes de contaminación puntuales- exige que se agrupen los puntos de control en la masa de agua subterránea. Según el modelo conceptual -presiones pertinentes, vulnerabilidad del acuífero, etc.-, solamente deben utilizarse los "grupos" de puntos de control pertinentes.

6.3.3 Test: "Riesgo para ecosistemas acuáticos" y "Riesgo para ecosistemas terrestres" (DAS, artículo 5.1 y 5.2)

El test de riesgo para ecosistemas acuáticos y terrestres es comparable a la evaluación mencionada anteriormente, relativa a los impactos de ámbito más local. Es similar a la evaluación del estado que sólo utiliza los puntos de control pertinentes en la masa de agua subterránea -por ej. puntos de control en zonas donde los contaminantes podrían pasar a la masa de aguas superficiales o a un ecosistema terrestre dependiente-. En el caso de los ecosistemas acuáticos y terrestres, un único punto de control pertinente podría ser suficiente para indicar que en la masa de agua subterránea existe una tendencia significativa siempre que dicho punto de control pertinente indique una tendencia.

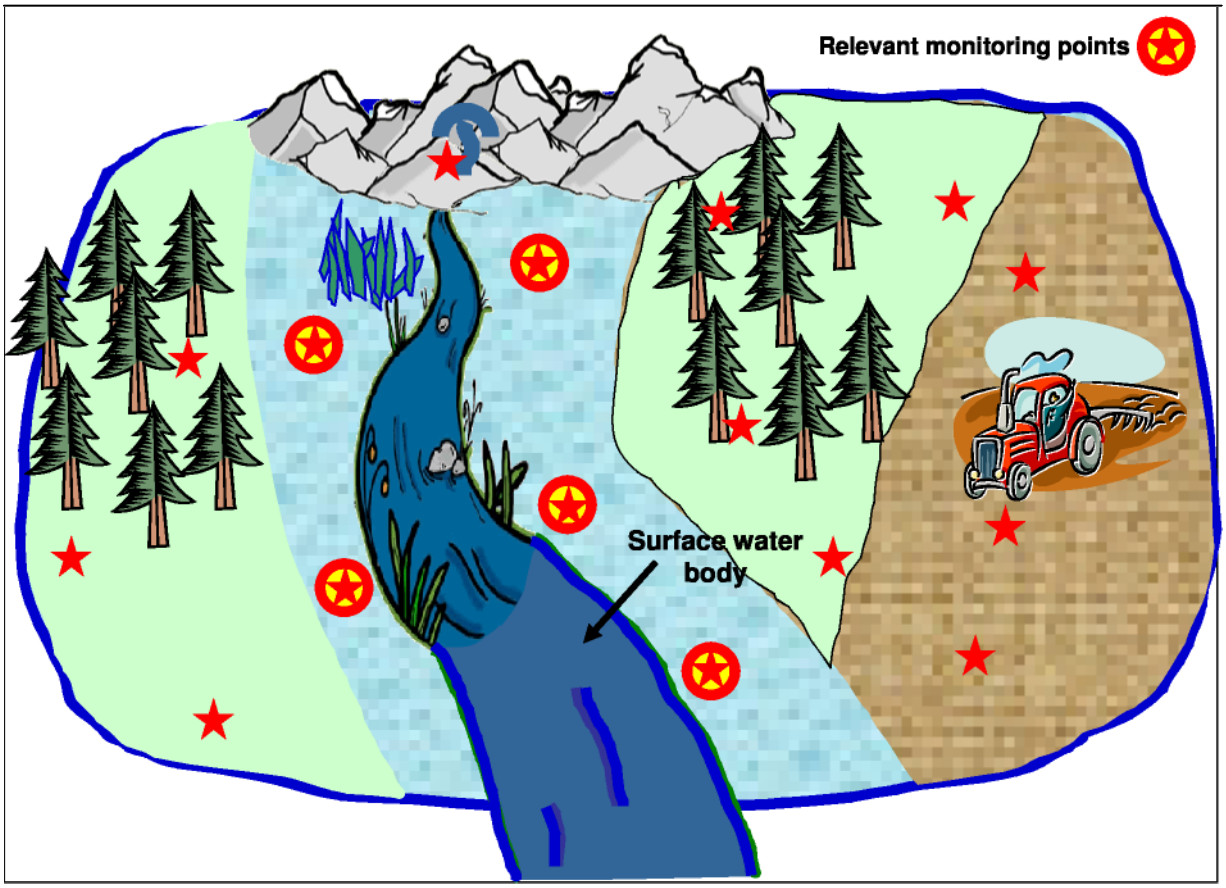

Figura 16. Selección de puntos de control considerados pertinentes para el test sobre riesgo para ecosistemas acuáticos y terrestres.

6.3.4 Evaluación de tendencias como apoyo de la evaluación del estado

La evaluación de tendencias forma parte integral del análisis del estado para detectar intrusiones salinas o de otro tipo (véase capítulo 4.4.3) y del test para determinar que el agua destinada al consumo humano no ha sufrido deterioro y cumple los requisitos especificados en el artículo 7.3 de la DMA (véase capítulo 4.4.6) (tabla 4). La evaluación de tendencias en estos casos se aplica en puntos de control que sean apropiados para los procedimientos pertinentes de evaluación del estado.

6.3.5 Evaluación de tendencias como apoyo de la caracterización de penachos de contaminación

Podría ser necesaria una evaluación de tendencias para garantizar que los penachos procedentes de lugares contaminados no se expanden (artículo 5.5 de la DAS) (tabla 4). El término "expandir" se utiliza aquí para indicar penachos en cuyo interior aumenta la masa general de contaminantes, es decir, el término indica que existe una fuente activa. La evaluación debe centrarse en los penachos pertinentes que puedan suponer un riesgo para la salud humana y el medio ambiente o deteriorar el estado químico de las masas de agua subterránea. Cuando proceda y sea necesario, se realizará una evaluación de las tendencias en los puntos de control que puedan verse afectados. Esta evaluación podría incluir puntos de control que no formen parte de la red de control de vigilancia y control operativo. La evaluación se centrará en los parámetros pertinentes dentro del penacho.

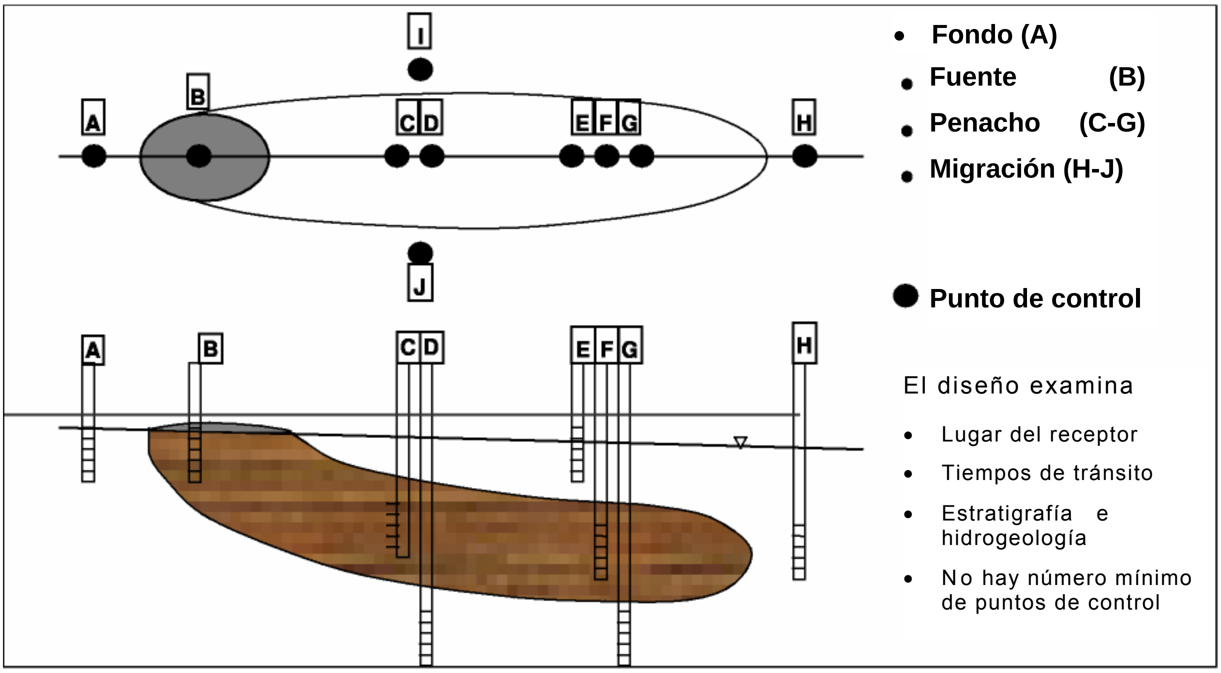

Figura 17. Red de seguimiento para comprobar que no se expanden los penachos

8 ANEXO 1: PRINCIPIOS DE APLICACIÓN DE FACTORES DE DILUCIÓN Y ATENUACIÓN

Los valores umbral tienen como finalidad última proteger receptores, como los ecosistemas de aguas superficiales, los ecosistemas terrestres dependientes de aguas subterráneas y los usos para el consumo humano. La mayor protección se logrará definiendo los valores umbral al nivel de la norma de calidad medioambiental del receptor o una norma de uso pertinente, y será necesario su cumplimiento en cada punto comprendido entre la zona de recarga y la zona de descarga de los sistemas de aguas subterráneas. No obstante, podría no ser siempre necesario fijar estos valores de una manera tan estricta porque pueden ocurrir procesos de dilución y de atenuación entre la zona de recarga y el receptor. Tanto si el receptor es una corriente de aguas superficiales, un manantial o un pozo de bombeo, el agua receptora es siempre una mezcla de aguas con diferentes tiempos de permanencia y diferente contribución de contaminantes. Los valores umbral pueden fijarse de manera que reconozcan estas distintas contribuciones desde aguas someras y más profundas, eligiendo un valor que, a largo plazo, impida suficientemente que el agua del manantial sobrepase la norma de calidad ambiental (NCA) para aguas superficiales o los ecosistemas terrestres.

Al tiempo que se tienen en cuenta la dilución y la atenuación cuando se calculan los valores umbral, es importante considerar la posición de los puntos de control en el régimen de flujo y los tiempos de tránsito hacia el receptor, tanto en dirección horizontal como vertical. Respecto de esta última, es importante recordar que la edad de las aguas subterráneas suele aumentar con la profundidad, y las aguas subterráneas jóvenes y someras se mezclan con las aguas subterráneas más antiguas al incorporarse a la corriente fluvial o al alcanzar los pozos de extracción. Dadas las diferencias que existen entre las distintas tipologías de acuíferos en los Estados miembros, podemos distinguir diferentes tipos de seguimiento, entre los que se incluyen la utilización de pozos de bombeo, sondeos específicos de seguimiento, manantiales y sondeos de observación de niveles múltiples. Estos tipos de seguimiento podrían tener una posición diferente dentro del sistema de flujo de las aguas subterráneas así como distribuciones de tiempo de permanencia distintas. La aplicación de factores de dilución y atenuación es especialmente sensible para el seguimiento en profundidades someras y en tiempos de permanencia cortos desde la zona de recarga. A fin de alcanzar un nivel adecuado de protección, los factores de dilución y atenuación deben ser adaptados a la mezcla de aguas en el receptor que se produce de forma natural con tiempos de permanencia cortos y largos.

8.1 Dilución

La dilución incluye, por lo general (véase figura 18 A):

- la extensión de las zonas donde los contaminantes entran en el sistema con respecto a toda la cuenca hidrográfica;
- la distribución de tiempos de permanencia de las aguas subterráneas que alimentan la corriente fluvial, que viene determinada por el campo de flujo tridimensional;
- el volumen de aguas subterráneas que alimentan la corriente fluvial con respecto a otras fuentes de agua, entre las que se incluyen la escorrentía superficial y el abastecimiento de aguas superficiales procedente de aguas arriba que están fuera de la masa de agua subterránea.

En la figura 18 A, cerca del 10% de la zona de recarga es contaminada por una fuente difusa, por ejemplo pesticidas en tierras de cultivo. En las tierras de cultivo próximas al curso fluvial las líneas de flujo tienen recorridos cortos hasta la corriente fluvial y contribuyen a la contaminación del río. A la corriente fluvial se incorporan también aguas no contaminadas procedentes de otras zonas, entre las que se incluyen tierras agrícolas con líneas de flujo y tiempos de tránsito demasiado largos como para que contribuyan de manera significativa. Se puede calcular el factor de dilución general considerando la distribución de tiempos de permanencia de las tierras agrícolas y la distribución de los tiempos de permanencia de otras zonas no contaminadas. Se recomienda tomar en consideración las aportaciones a largo plazo de una duración media cuando deban definirse los factores de dilución, sin olvidar las consecuencias de la rotación de cultivos y los futuros cambios en el uso del suelo.

8.2 Atenuación

Procesos reactivos como sorbción y transformación pueden reducir aún más la amenaza de contaminación de los receptores, y podrían utilizarse en el cálculo de valores umbral. La figura 18 B ilustra el efecto de la atenuación, lo que significa que los contaminantes son transformados o ralentizados con respecto al propio transporte de las aguas subterráneas. En la metodología descrita pueden utilizarse factores de atenuación adicionales. Tal como establece la DAS (anexo II.2), estos factores incluyen la “tendencia de dispersión, la persistencia y el potencial de bioacumulación” de los contaminantes.

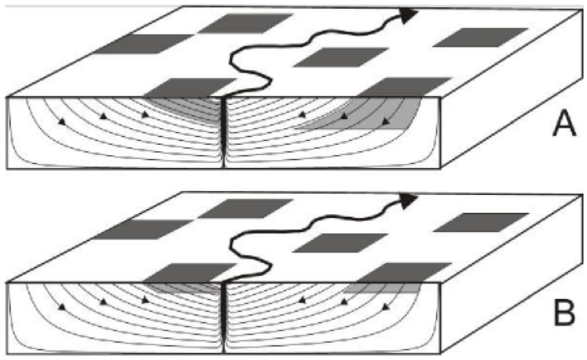

Figura 18: Ilustración de factores que determinan cómo la dilución y la atenuación pueden afectar el cálculo de valores umbral. A: sólo dilución, B: dilución y atenuación. El modelo conceptual se basará preferentemente en una comprensión tridimensional del sistema de aguas subterráneas y tomará en consideración la mezcla de aguas no contaminadas y contaminadas que descargan en el receptor.

Para el seguimiento a profundidades someras se pueden aplicar los factores de dilución y atenuación cerca de la zona de recarga, y deben ser adaptados a las profundidades del seguimiento a fin de que garanticen una protección suficiente. Para el ejemplo de la figura 18 A y un seguimiento en profundidades someras de las zonas de recarga, un factor de dilución de 0,1 parece proteger suficientemente la calidad de las aguas superficiales porque un 10% aproximadamente de la superficie del suelo que cubre la masa de agua subterránea contribuye a la contaminación de la corriente. El valor umbral pertinente se definió como: VU = NCA*FA/FD. Esto significa que el valor umbral de las aguas subterráneas = norma de calidad ambiental de las aguas superficiales (1/0,1) en esta situación específica. Si incluimos también la atenuación, y estimamos para el ejemplo ilustrativo un factor de atenuación de 3, el valor umbral podría elevarse a NCA*3/0,1 y aún ser suficiente para proteger este receptor de aguas superficiales.

Los factores de atenuación y dilución podrán aplicarse asimismo para establecer los criterios de uso, salvo que los puntos de control donde debe medirse el cumplimiento con respecto a los valores umbral estén situados en lugares con tiempos de tránsito largos desde el punto de captación. Aquí, los factores de atenuación y dilución pueden utilizarse para atajar los efectos de la mezcla natural del agua que tiene lugar cuando se bombea desde un acuífero, y las líneas de flujo someras y profundas contribuyen a la calidad del agua que se mide en el pozo de captación o en sus inmediaciones. El proceso de mezcla es conceptualmente muy similar a la mezcla que se produce en una corriente fluvial cuando un recorrido corto y otro largo convergen en la zona de transición de aguas subterráneas y aguas superficiales. La decisión sobre si es apropiado o no utilizar factores de dilución y atenuación para establecer criterios de uso deberán tomarla los propios Estados miembros.

9 ANEXO 2: UTILIZACIÓN DEL SEGUIMIENTO DEL NIVEL PIEZOMÉTRICO DE LAS AGUAS SUBTERRÁNEAS PARA EVALUAR SU ESTADO

La definición de estado cuantitativo que hace la DMA está enmarcada en términos de la relación que existe entre una serie de factores a nivel de las aguas subterráneas. Sólo la utilización del nivel piezométrico de las aguas subterráneas no garantiza una clasificación fiable. Los flujos de aguas subterráneas son igualmente importantes, aunque éstos no pueden medirse directamente, sino sólo estimarse sobre la base de mediciones hidrológicas y meteorológicas. Consideramos que los niveles de las aguas subterráneas por sí solos no deben determinar el estado cuantitativo. Este anexo presenta una sugerencia de cómo podrían, en la práctica, utilizarse dichos niveles. Sobre los parámetros adicionales necesarios para evaluar el estado cuantitativo se trata en la guía de seguimiento sobre la DMA (Unión Europea, 2007).

Elemento Balance hídrico: Si los niveles piezométricos descienden de una manera sostenida y prolongada, este descenso confirmará que, durante el período del registro, el volumen de extracción es mayor que el de recarga, lo que indica un estado deficiente en relación a este factor. No obstante, unos niveles sostenidos no indican necesariamente un buen estado, puesto que el agua necesaria para mantener constante este nivel podría provenir de aguas superficiales, lo que podría causar un daño ecológico.

Elemento Aguas superficiales: Cuando existe una conexión plena -al 100%- entre aguas superficiales y aguas subterráneas, los ríos tienden a estabilizar el nivel piezométrico de manera que las variaciones son mínimas. En tales circunstancias, el nivel piezométrico no es un indicador útil de la interacción entre aguas superficiales y aguas subterráneas. Si no existe ninguna conexión entre las aguas superficiales y las aguas subterráneas, el nivel en el acuífero puede estar por encima o por debajo del nivel del río y, una vez más, nada indica acerca de la repercusión de las aguas subterráneas en el río.

Elemento Ecosistemas dependientes de aguas subterráneas: El nivel piezométrico de las aguas subterráneas en ecosistemas terrestres o sus inmediaciones es fundamental para mejorar el modelo conceptual de cómo funcionan estos ecosistemas. Es un mecanismo esencial para confirmar la conexión con aguas subterráneas, mientras que el seguimiento del nivel no aporta ni una sola señal que apunte o confirme dicha conexión. Se trata, más bien, de una combinación de mediciones del nivel absoluto, del registro de las variaciones en el acuífero, los estratos de los humedales y la zona de aguas libres. Casi con toda probabilidad incluirá algún tipo de modelo que se haya elaborado para confirmar la fiabilidad del modelo conceptual. Este modelo incluirá las aguas superficiales, las aguas subterráneas o ambas.

Elemento Intrusión: La determinación de intrusión se basará en la calidad, más que en la medición de los niveles.

En acuíferos de baja permeabilidad y acuíferos kársticos, las estaciones de la red de seguimiento podrían no reflejar fielmente la superficie piezométrica y, en algunas zonas, el concepto de superficie piezométrica carecerá por completo de importancia. En tales circunstancias, podría ser mejor utilizar otros indicadores del estado cuantitativo -y cualitativo-, como el caudal de ríos y manantiales.

Proponemos que el mejor uso que puede darse a los datos sobre niveles piezométricos es para confirmar el funcionamiento de la masa de agua subterránea y, luego, utilizar los conocimientos de cómo funciona la masa de agua subterránea para determinar si su estado es bueno o no. Las variaciones del nivel a largo plazo serán las de mayor utilidad. Si los datos que se obtienen en un punto de control son inconsistentes, ello podría servir para delimitar una zona que necesitará mayores esfuerzos para comprender el funcionamiento del sistema de circulación de las aguas subterráneas.

10 ANEXO 3. CASOS PRÁCTICOS

10.1 Caso práctico 1: Aplicación de la DMA y la DAS en Alemania

Información específica
Título/nombre: Aplicación de la Directiva Marco del Agua y de la Directiva de Aguas Subterráneas en Alemania.
Tipo:
Enlace web:
Objetivo: Aplicación del planteamiento alemán para el establecimiento de valores umbral relativos a las aguas subterráneas.
Contribución a…
Aspectos básicos: valores umbral
Contribuciones específicas
Antecedentes La guía sobre el estado de las aguas subterráneas y la evaluación de tendencias propone una metodología para fijar valores para las masas de agua subterránea y evaluar su estado, así como para el cumplimiento, en la práctica, de los requisitos pertinentes previstos en la DMA y la DAS. Los debates en el transcurso de la elaboración del documento revelaron que las circunstancias y marcos nacionales en los Estados miembros aconsejan cierta flexibilidad en la implantación y aplicación de las disposiciones. El objetivo es obtener resultados comparables, al tiempo que se permite cierta flexibilidad en cuanto al modo de alcanzarlos. **Antecedentes científicos** Las aguas subterráneas son un elemento de capital importancia para el equilibrio medioambiental. Forman parte del ciclo hidrológico y desempeñan importantes funciones ecológicas. Los recursos hídricos subterráneos próximos a la superficie abastecen de agua a las plantas y constituyen biotopos húmedos de gran valor. Las aguas subterráneas descargan en manantiales y alimentan arroyos y ríos, por lo que la calidad y la cantidad de las aguas subterráneas influyen también en las aguas superficiales. Más del 70% del agua potable de Alemania procede de aguas subterráneas, lo que las convierte en el principal recurso de agua potable. Además, las aguas subterráneas son un hábitat por derecho propio y albergan una gran diversidad biológica. En consecuencia, para un desarrollo sostenible y para garantizar el abastecimiento de agua en el futuro es de suma importancia que se adopten medidas cautelares orientadas al uso que protejan todas las aguas subterráneas. **Las aguas subterráneas como bien protegido por derecho propio** Tomando como base la importancia particular que las aguas subterráneas tienen para el medio ambiente y para los humanos, el enfoque adoptado en Alemania consiste en considerar las aguas subterráneas en su conjunto como un bien que hay que proteger. La experiencia ha demostrado que para proteger las aguas subterráneas de una manera integral y preventiva no basta con proteger sencillamente sus usos. Las aguas subterráneas son un componente integral del ciclo hidrológico y del medio ambiente en su conjunto. Esta opinión está en consonancia con la legislación vigente y ha sido incorporada en distintas leyes y ordenanzas aprobadas a nivel federal y a nivel de los *Länder*. **Determinación de valores umbral para las aguas subterráneas** El artículo 3.2 de la DAS contempla la posibilidad de establecer valores umbral a nivel nacional, en las cuencas hidrográficas o en la parte de una cuenca hidrográfica internacional situada en territorio de un Estado miembro, o a escala de masa o grupo de masas de agua subterránea. En Alemania se establecerán los valores umbral a nivel nacional. Se garantiza así un procedimiento uniforme y comparable en todos los estados federales (*Länder*), que reduce la carga administrativa y permite economizar costes. Asimismo, los valores umbral constituyen la base de nuevas normas legales -p.ej. sobre gestión de residuos o conservación del suelo-.

Metodología alemana para obtener los valores umbral para aguas subterráneas

La metodología alemana para obtener los valores umbral para aguas subterráneas sigue el concepto de los denominados umbrales marginales, y tiene en cuenta los requisitos en materia de protección de la salud así como aquéllos para la protección de ecosistemas acuáticos y terrestres. Los valores umbral obtenidos son aplicables, en principio, a todas las masas de agua subterránea. Se elimina así la compleja y lenta tarea de obtener valores umbral individuales para cada masa de agua subterránea.

Dicha metodología se basa en los conocimientos científicos y considera las condiciones geológicas e hidrogeológicas del territorio alemán en su conjunto. El cálculo se basa, principalmente, en los aspectos toxicológicos para la salud humana y para el medio ambiente, y fundamentalmente utiliza normas ya establecidas en directivas de la UE y en valores adoptados por organismos de la UE. En el caso de la toxicología para la salud humana, se toman en consideración los valores límite de la Directiva de Aguas Potables, salvo en lo relativo a la distribución a la población. Cuando no existan, los valores se obtendrán sobre la base de esta Directiva, en cuyo caso los criterios decisivos incluyen especialmente el olor, el sabor y el color. Para la ecotoxicología se utilizan varias fuentes de datos comparables para calcular los valores umbral en el siguiente orden:

En primer lugar se toman siempre como punto de partida las normas de calidad vinculantes en materia de ecotoxicología medioambiental para las comunidades bióticas acuáticas de aguas superficiales que incluyen, en particular, las normas de calidad medioambiental para determinar el estado químico de las aguas superficiales, Directiva 76/464/CEE relativa a la contaminación causada por el vertido de determinadas sustancias peligrosas, y las normas sobre sustancias prioritarias. Éstas no se adoptan cuando los niveles de referencia o el contenido de materia en suspensión de las aguas superficiales son importantes para calcular la norma de calidad ambiental. A tenor de los conocimientos actuales, parece estar justificado recurrir a los resultados obtenidos en las evaluaciones de ecosistemas de aguas superficiales. Los organismos que viven en aguas subterráneas reaccionan con mayor sensibilidad porque no tienen ninguna posibilidad de escapar, y los contaminantes suelen disponer de más tiempo para influir en su entorno debido a la baja velocidad a la que circulan las aguas subterráneas.

Cuando la legislación vigente no establece normas de calidad ambiental, se utilizan valores PNEC (concentración prevista sin efecto). Estos valores se han calculado sobre la base de los conocimientos más recientes y de conformidad con los principios uniformes y transparentes más estrictos aplicables a toda la UE (Documentos guía); son sometidos a examen por parte de un gran número de expertos y son conformes a las disposiciones de la legislación europea en materia de sustancias químicas y reconocidos en el “informe de evaluación de riesgos".

Si tampoco existen valores establecidos a nivel europeo, se tomarán los valores de concentración máxima admisible (MPC) o de adición máxima admisible (MPA) de un informe de Países Bajos como base para establecer los valores umbral, utilizando para ello el mismo método de extrapolación estadística que el utilizado para calcular los valores PNEC.

Los valores umbral se establecen siempre de acuerdo con los valores más bajos obtenidos mediante el cálculo toxicológico para la salud humana y el medio ambiente. Habida cuenta de que este valor puede situarse por debajo de las concentraciones naturales en aguas subterráneas, por ejemplo en el caso de metales pesados, se evaluará el valor umbral sobre la base del nivel de referencia (VU = NR). En tales casos, el valor es aplicable únicamente a esa masa de agua subterránea específica. Asimismo debe introducirse un límite mínimo de 0,01 µg/L para las sustancias orgánicas no naturales para las que se obtienen valores muy bajos mediante el tipo de cálculo ecotoxicológico, a menos que no existan resultados concretos de pruebas que justifiquen un valor inferior. Habida cuenta de que en todos los casos se utiliza el valor más estricto como valor umbral, esta metodología protege todos los receptores contemplados en la DMA y la DAS.

Resultados obtenidos. Conclusiones y recomendaciones

10.2 Caso práctico 2. Establecimiento de valores umbral en los Países Bajos

Información específica
Título/nombre: Establecimiento de valores umbral en los Países Bajos
Tipo:
Enlace web: http://www. kaderrichtlijnwater.nl
Objetivo: Establecimiento de los valores umbral y metodología en Países Bajos
Contribución a…
Aspectos básicos: valores umbral, niveles de referencia
Contribuciones específicas Descripción de la metodología general para calcular los valores umbral que se describen en este documento. Desde dicha perspectiva, en los Países Bajos se hace una distinción entre los enfoques a corto y a largo plazo.

2. ENFOQUE A LARGO PLAZO

2.1 Objetivo y condiciones de contorno: valores umbral como base de la calidad de las aguas subterráneas

Debido a su peculiar situación geohidrológica, en la que no existen límites hidrogeológicos, las masas de agua subterránea en los Países Bajos son relativamente extensas. No obstante, y a pesar de su larga tradición en gestión del agua, los Países Bajos aún no han decidido cómo resolver la protección de los receptores ni qué papel desempeñan los valores umbral en esta protección. Los principales aspectos de la función que desempeñan los valores umbral en la protección de los receptores son:

- el alcance de la interacción real de aguas subterráneas con un receptor específico: el impacto de la calidad de aguas subterráneas en los receptores es a menudo limitado respecto a otros impactos;
- la extensión de la zona asociada a receptores respecto de la extensión de la masa de agua subterránea;
- el grado de eficacia de medidas encaminadas a mejorar la protección de los receptores: cambiar el impacto de aguas subterráneas en los receptores es una tarea onerosa y podría requerir mucho tiempo debido a los largos tiempos de tránsito de las aguas subterráneas.

La extensión de los receptores suele ser pequeña si se compara con la de una masa de agua subterránea. Asimismo, las escalas temporales de las masas de agua subterránea desde el punto de infiltración hasta la llegada al receptor se sitúan en torno a decenios, siglos o incluso una duración mayor, y en el transcurso de este transporte tienen lugar los procesos de atenuación y dilución. En consecuencia, los valores umbral en los Países Bajos deben guardar relación con la calidad base de las aguas que prevalece en una masa de agua subterránea. Esta calidad base garantiza la protección de los receptores pertinentes, es decir, ecosistemas terrestres y acuáticos que dependen de aguas subterráneas y de las aguas subterráneas que se destinan al consumo humano. Los problemas potenciales con estas funciones locales deben resolverse, por consiguiente, con valores umbral para toda la masa de agua subterránea. Sin embargo, la protección específica de funciones o valores específicos de aguas subterráneas debería realizarse mediante medidas específicas adicionales.

Las medidas adicionales encaminadas a restablecer los ecosistemas terrestres y acuáticos o a proteger la calidad del agua potable serán específicas y de ámbito local. El enfoque se basa en que se indiquen los espacios protegidos de la red “Natura 2000” y se determinen por separado las zonas protegidas de aguas subterráneas como zonas distintas –especiales- con objetivos “locales” en materia de calidad de las aguas y donde, además de las medidas generales, se apliquen medidas locales adecuadas que permitan cumplir estos objetivos.

Este enfoque se base asimismo en los siguientes razonamientos pragmáticos:

- los esfuerzos y costes administrativos para calcular valores umbral para cada receptor pertinente serán considerables;
- el tiempo para calcular valores umbral de la manera ampliada que propone la guía es limitado. A final de 2007, los Países Bajos calcularon valores umbral como propone este documento con vistas a su implantación legal a finales de 2008.
- la guía no tiene en cuenta las diferencias existentes entre los receptores pertinentes identificados que existen en una masa de agua subterránea.

Los valores umbral indicarán, por consiguiente, la calidad base de las aguas subterráneas regionales, en lugar de la norma de calidad ambiental (NCA) del receptor local más crítico.

Como consecuencia de las razones expuestas más arriba, el enfoque utilizado en los Países Bajos será ligeramente diferente de los de las figuras 3 y 4 de la guía. El enfoque comienza con la selección de uno o más receptores pertinentes, y se calculan los valores criterio (VC) para cada uno de estos receptores. Tras comparar los VC con el nivel de referencia, el resultado de la primera parte de la figura 4 trata sobre el cálculo de un valor umbral (VU) pertinente para cada masa de agua subterránea. Este VU se introducirá en el segundo rectángulo de la figura 3 de la guía. En la segunda parte de esta figura se llevará a cabo la "investigación adecuada" para los receptores pertinentes seleccionados.

3. ENFOQUE A CORTO PLAZO

3.1 Selección de sustancias

El procedimiento para seleccionar y establecer los valores umbral es oneroso y lento, por lo que el enfoque a corto plazo se centra en las sustancias que sean motivo de preocupación, es decir:

- sustancias cuya caracterización apunta a que no se cumplirán los objetivos medioambientales;
- los conocimientos más recientes sobre los niveles de determinadas sustancias en relación con los riesgos para la salud humana y el medio ambiente.

La necesidad de calcular valores umbral para otras sustancias se establecerá después de una nueva caracterización de las masas de agua superficial y de agua subterránea prevista entre 2008 y 2012. Se dará prioridad a las sustancias mencionadas en el anexo II, parte B de la DAS.

3.2 Establecimiento de los valores umbral

En los Países Bajos se establecen las normas medioambientales de una manera integrada para garantizar la coherencia entre las normas sobre los diferentes aspectos medioambientales. En este sentido se ha decidido fijar valores umbral siguiendo la actual versión de la guía sobre el cálculo de los límites de riesgo ambiental en el marco del proyecto "Normas internacionales y nacionales sobre calidad ambiental para sustancias en los Países Bajos" (INS: van Vlaardingen y Verbruggen, 2006). Este Documento guía fue elaborado de conformidad con la DMA y adaptado en cumplimiento de los Documentos técnicos de orientación[38] allí donde la DMA no era aplicable. Se propondrá como valor umbral el más bajo de los dos límites de riesgo ambiental (ERL). La concentración máxima admisible (MPC) se utilizará como valor umbral para las sustancias de origen natural que se producen en el medio ambiente, como los metales y las sales.

Con el enfoque de fijar normas para las sustancias de origen natural, es habitual calcular la MPC sumando la adición máxima admisible (MPA) al nivel de referencia (NR). La MPA puede ser una interpretación más detallada de la pequeña adición mencionada en la presente guía. En el caso de los metales, la MPC se calcula como la suma del NR y la MPA. Esta MPA para metales es un valor constante basado en el riesgo. Para los fosfatos, la MPA dependerá de los objetivos ecológicos y se determinará, por tanto, en función del receptor más importante en la masa de agua subterránea. Hasta ahora no se ha hecho ninguna diferenciación para el NR, pero los NR para las masas de agua subterránea identificadas pueden ser muy diferentes de aquéllos de las masas de agua subterránea de las inmediaciones. Se calcularán NR para cada masa de agua subterránea individual, lo que puede derivar en valores umbral para sustancias de origen natural diferentes para cada masa de agua subterránea.

Paso 1: cálculo de los límites de riesgo ambiental (ERL): calcular los $ERL_{eco,\ natural}$ de la adición máxima admisible (MPA) y el nivel de referencia (NR) para obtener las concentraciones máximas admisibles (MPC):

Sustancias de origen natural

- Cloro: $ERL_{eco,\ natural}$ = MPC-Cl
- Metales: $ERL_{eco,\ natural}$ = MPC-metales = MPA-metales + $BI_{masa\ de\ agua\ subterránea}$, suponiendo un valor constante de MPA para las distintas masas de agua subterránea
- Fosfatos: $ERL_{eco,\ natural}$ = MPC-P = $MPA\text{-}P_{masa\ de\ agua\ subterránea}$ + $BI_{masa\ de\ agua\ subterránea}$, suponiendo una función de la MPA y el NR de la masa de agua subterránea;

[38] Manual sobre el marco metodológico para el cálculo de normas de calidad medioambiental para sustancias prioritarias de conformidad con el artículo 16 de la Directiva Marco del Agua (2000/60/CE).

Agua potable

- ERL$_{\text{salud humana}}$ = norma de calidad del agua potable
- Si ERL$_{\text{salud humana}}$ < NR$_{\text{masa de agua subterránea}}$, ERL$_{\text{salud humana}}$ = NR$_{\text{masa de agua subterránea}}$

Paso 2: cálculo de los ERL más bajos (salud humana o eco, sustancias de origen natural)

- seleccionando los receptores pertinentes
- tomando el ERL más bajo de los receptores pertinentes seleccionados (eco o agua potable)

Paso 3: cálculo del valor umbral:

- comparando el valor ERL con el nivel de referencia
- si ERL < NR el valor umbral será = NR
- si ERL > NR el valor umbral será = CV

3.3. Nivel de referencia

En los Países Bajos está en funcionamiento desde 1979 una red de medición de la calidad de las aguas subterráneas. La distribución de los pozos de observación por todo el país es bastante homogénea y tiene en cuenta los usos predominantes del suelo y la combinación de tipos de suelo para discernir la calidad de las aguas subterráneas y las tendencias a escala regional. Cada pozo de observación está equipado con tres filtros a profundidades de 10, 15 y 25 m respectivamente. Para calcular el nivel de referencia se han seleccionado filtros de longitudes comprendidas entre 1 y 5 m y situados en una columna de agua de 10 m en la zona saturada a una profundidad de 1 m como mínimo del suelo. La parte superior del filtro se sitúa a menos a 2 m por debajo del nivel piezométrico. Para la ubicación de los sondeos se han evitado los puntos de contaminación conocidos, aunque a estos niveles ya no existen aguas subterráneas en estado natural en los Países Bajos. Para obtener los niveles de referencia, para cada sondeo de observación y filtro se examinan las series temporales de las observaciones. En la masa de agua subterránea Central Graben (Hondonada Central) no hay ningún sondeo de observación de la red de medición. El nivel de referencia de esta masa de agua subterránea se establece con los datos de los pozos de captación de agua subterránea. Se supone que la mediana de cada serie temporal es la que mejor representa la distribución. A partir de los valores de la mediana se calcula un percentil 50 y un percentil 90, y para establecer el nivel de referencia se utilizan dos planteamientos:

- uso del percentil 50 sin ningún procedimiento de selección previa;
- uso del percentil 90 con selección previa basada en el impacto antropogénico.

Cuando las concentraciones son bajas -metales pesados, pesticidas-, el tratamiento de los valores por debajo del “Límite de Detección” (LD) que sugiere la guía puede tener una fuerte repercusión en los niveles de referencia y dar niveles de referencia artificiales. En consecuencia, es necesario considerar la posibilidad de apartarse del tratamiento de los valores LD propuesto en la guía y sustituir todos los valores LD que se produzcan en una serie temporal por los LD más bajos, excluyendo los LD menores de cero o por debajo de valores negativos.

En el primer enfoque no se realiza una selección previa de las muestras. Para evitar contabilizar dos veces el impacto antropogénico se toma el nivel de referencia en el percentil 50. La ventaja de este procedimiento es que no se elimina ninguna muestra del conjunto de datos.

En el segundo enfoque, las muestras se seleccionan en función de las concentraciones de sulfatos, cloruros y nitratos para suprimir las muestras afectadas antropogénicamente. Para tener en cuenta la diferencia de las condiciones geohidrológicas y geohidroquímicas se hace una distinción entre el modo en que la presión antropogénica en el ecosistema afecta al agua salobre y al agua dulce en una masa de agua subterránea. Se aplican aquí diferentes algoritmos para establecer qué observaciones de aguas subterráneas salobres y de aguas subterráneas dulces se descartarán y cuáles no, tomando en consideración las condiciones geohidrológicas y geohidroquímicas. Tras la eliminación de las muestras afectadas antropogénicamente, se toma el nivel de referencia de la parte inferior del intervalo de fiabilidad del percentil 90.

Por último, el nivel de referencia se determina en el valor más alto de ambos enfoques.

Resultados obtenidos. Conclusiones y recomendaciones

10.3 Caso práctico 3. Cálculo de niveles de referencia y valores umbral en una masa de agua subterránea en Rumania

Información específica

Título/nombre: Establecimiento de valores umbral para una masa de agua subterránea contaminada por vertidos para alcanzar los objetivos medioambientales de DMA y DAS.

Tipo: Proyecto holandés-rumano en el marco del Programa holandés de preadhesión

– Servicio ambiental. El proyecto ha sido financiado por EVD (Agencia internacional de negocios y cooperación) y tiene dos asociados del Gobierno de Países Bajos: el Ministerio de la Vivienda, Planificación y Medio Ambiente y SenterNovem/Bodem+. Las organizaciones de la parte rumana son el Ministerio de Medio Ambiente y Desarrollo Sostenible y la Administración Nacional “Apele Române”. El Ministerio, “Apele Române” y la Dirección General de Aguas Banat son beneficiarios.

El proyecto lo lleva a cabo un consorcio de consultores (Grontmij Nederland bv, Witteveen+Bos, Ecorys y BDO Conti Audit) en estrecha cooperación con las partes mencionadas.

Enlace web:

Objetivo: Rumania recibió, en el marco de este proyecto asistencia técnica por parte de Países Bajos en la implantación de tres directivas europeas: la DMA, la nueva DAS y la Directiva sobre Vertidos. El proyecto tiene como principal objetivo formular medidas para restaurar aguas subterráneas contaminadas por vertidos en una zona piloto de la región de Banat (suroeste del país), donde se encuentran dos grandes vertederos, Parta y Jimbolia.

Un programa de seguimiento especial estudió la influencia de estos vertederos en las aguas subterráneas y se elaboró un modelo de transporte. Para evaluar exactamente los resultados y formular el programa de medidas más idóneo, se calcularon, en primer lugar, niveles de referencia (NR) y valores umbral (VU) para la masa de agua subterránea situada debajo de ambos vertederos, a saber ROBA03 y Timisoara. Para calcular los NR y VU se formularon y aplicaron directrices por primera vez, de cara a su uso ulterior por parte de otras Direcciones Generales del Agua del país.

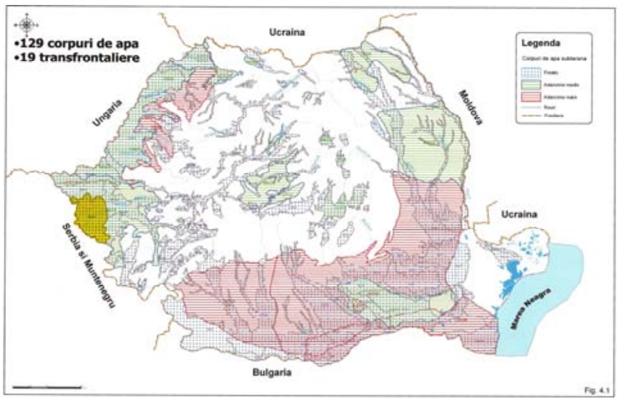
Contribución a…

Aspectos básicos: cálculo de los niveles de referencia y valores umbral.

Contribuciones específicas: Formular directrices y una metodología para calcular los NR y VU para Rumania, incluidas hojas de cálculo Excel para los diferentes pasos de los cálculos.

Caracterización

Un informe sobre el artículo 5 de la DMA caracterizaba la masa de agua subterránea ROBA03 Timisoara (con una extensión de 2.577 km² en territorio rumano) en situación de riesgo porque las concentraciones de nitratos y amoniaco sobrepasan los niveles establecidos para el agua potable



Rumania y sus masas de agua subterránea delineadas (en amarillo, la masa piloto)

Cuenca hidrográfica del río Banat y la masa de agua subterránea piloto (ROBA03)

ROBA03 está alojada en un acuífero poroso poco profundo formado por arena y grava con capas intermedias de arcilla y limo. El acuífero se explota hasta 15 m en llanuras de inundación y bancales, y hasta 30–35 m en los interfluvios. La conductividad hidráulica varía entre 10 y 50 m/día. En lugares reducidos existe una espesa capa superior de arcilla, especialmente cerca del vertedero de Jimbolia, pero las condiciones generales del flujo son las características de los acuíferos someros.

La masa de agua subterránea ROBA03 se recarga principalmente con las precipitaciones (recarga neta 15–30 mm/año) y con el agua de ríos de praderas durante las crecidas y las inundaciones. Cuando descienden los niveles, los ríos drenan la capa freática salvo en las inmediaciones del río Bega. El río Bega recarga permanentemente el acuífero porque su curso está muy encauzado en sus márgenes.

Resultados obtenidos. Conclusiones y recomendaciones

Tomando como base el Documento guía GTC "Estado químico y valores umbral de las aguas subterráneas, versión 2.0 (25.10.07)" y las recomendaciones del proyecto BRIDGE, para calcular los NR y VU para la masa de agua subterránea ROBA03 se introdujeron en una base de datos Excel todos los informes químicos desde 1976 hasta 2006 -207 pozos de observación, 3.300 muestras, 45.000 análisis- organizados en una hoja por año y una fila por muestra.

Para el cálculo de los NR y VU se dispuso de los siguientes indicadores:

- 1975 - 2008: pH, EC, Cl-, SO42-, NO3-, NO2-, Alcalinidad, Ca2+, Mg2+, Fe y NH4-.
- 1986 - 2008: también Na+, K+, Mn2+
- 1993 - 2008: también Zn2+
- 1996 - 2008: también PO4
- 2006 - 2008: también se analizaron Cu, Ni y Pb por primera vez en 2006.

Se filtró la base de datos calculando errores en el equilibrio entre iones en todas las muestras (sin excluir ningún dato) y los parámetros estadísticos, y utilizando también la correlación entre la suma de aniones y la conductividad medida. Se eliminaron todas las muestras identificadas como no fiables. A continuación se excluyeron los pozos con influencias antropogénicas en dos fases (Cl < 200 mg/l; NO3 < 10 mg/l). Se establecieron los valores umbral comparando los niveles de referencia del agua potable con las normas de calidad de las aguas superficiales.

Los resultados finales del cálculo de los NR y VU han sido los siguientes (aunque sólo para algunas de las sustancias utilizadas en los análisis y sustancias responsables del riesgo de no cumplir el requisito de buen estado, es decir nitratos y amonio):

Cuadro 10: Resultado de los VU para la masa de agua subterránea GWB03, 2008

		NR Percentil 90 Pozos con: NO3 < 10 mg/L, Cl < 200 mg/L	Normativa rumana sobre agua potable	Normativa rumana sobre aguas superficiales	**VU**
Número de pozos		*92*			
Cl	mg/L	103			
SO4	mg/L	197			
NH4	mg/L	2,11	0,50	1,0	**2,11**
K	mg/L	11,9			
NO3	mg/L	7,7			
NO2	mg/L	0,21			
EC	µS/cm	1409			
Ni	µg/L	0,005			
Fe	mg/L	3,43			
Mn	mg/L	0,60			
Zn	mg/L	0,067			

1) *Directrices de la UE sobre compuestos químicos en el agua potable (Sulivan et al., 2005)*

Principales conclusiones basadas en la metodología utilizada:

- La mayoría de los datos sobre la masa de agua subterránea GWB03 piloto no estaban disponibles en formato digital, por lo que hubo que realizar un gran esfuerzo para digitalizarlos. Es importante tener esto en cuenta porque es una tarea que requiere una gran capacidad y mucho tiempo. No obstante, es una tarea necesaria no sólo para esta finalidad, sino también de cara a futuras actividades relacionadas con la Directiva Marco del Agua y la Directiva de Aguas Subterráneas;
- La metodología utilizada incluye la elaboración y el tratamiento de datos utilizando MSExcel, por lo que se deberán tener conocimientos suficientes sobre esta aplicación;
- La metodología descrita en el Documento guía de la UE exige ciertos conocimientos básicos en materia de hidrogeoquímica. Sin estos conocimientos, el cálculo de los NR y VU, aunque será posible, será más laboriosa (y el estudio de los problemas pertinentes)

Recomendaciones

- Probablemente se obtendrán los mejores resultados siguiendo un enfoque paso a paso.

Perspectivas. Siguientes pasos y accesibilidad a los resultados

Todos los Directores Generales del Agua de Rumania están siguiendo los pasos prácticos utilizados para calcular los NR y VU, sobre la base de esta primera aplicación de las directrices de la UE, realizada por la Dirección General del Agua Banat y con la ayuda de expertos neerlandeses. El enfoque desarrollado en el marco de este proyecto y los resultados obtenidos serán publicados en la página web del Ministerio de Medio Ambiente y Desarrollo Sostenible: http://www.mmediu.ro. Los documentos elaborados para Rumania están basados en documentos guía de la UE, aunque han sido convertidos en instrumentos y medidas de apoyo más prácticos.

Se puede obtener información adicional sobre la implantación de los valores umbral y la estrategia rumana previa solicitud a la Sra. R. Balaet, ruxandra.balaet@mmediu.ro del Ministerio de Medio Ambiente y Desarrollo Sostenible. Asimismo, los interesados en obtener información sobre el proyecto podrán solicitarla a su director Sr. FJL Vliegenthart (frank.vliegenthart@grontmij.nl) o al Sr. P. Schipper (peter.schipper@grontmij.nl) de Grontmij Nederland B.V.

10.4 Caso práctico 4. Concentraciones naturales elevadas de sulfatos en acuíferos kársticos

Información específica

Título/nombre: Algunas consideraciones sobre la influencia de las aguas subterráneas y superficiales con sulfatos procedentes de yesos sobre los niveles de referencia. El informe, redactado por Ingenieurbüro en diciembre de 2006, está publicado en alemán, con un sumario en inglés. El título es: "Einige Bemerkungen zur bedingten Hintergrundbelastung von Grund- und Oberfläschenwässern mit Sulfaten in Gipskartsgebieten"

Tipo: Evaluación de la fiabilidad del parámetro sulfato en un medio kárstico. Las zonas de yesos están localizadas en Alemania.

Enlace web: www.eurogypsum.org. Asociación Europea de Fabricantes de Yeso y Productos de Yeso

Objetivo: Explicación de elevados contenidos de ión sulfato en acuíferos kársticos.

Contribución a…

Directiva Marco del Agua: niveles de referencia, valores umbral

Contribuciones específicas: Concentraciones elevadas de sulfatos en acuíferos kársticos

Descripción.

Características de las aguas subterráneas con elevados contenidos de sulfatos de origen geológico.

El contacto del agua con depósitos de yeso produce elevados contenidos de sulfatos. Valores superiores a 500 mg/L indican un contacto directo del agua con el sustrato de yesos en el terreno. Debido a que el contenido de sulfatos se debe al sulfato cálcico (yeso), pueden detectarse también valores elevados de dureza del agua.

La conductividad es un indicador adicional de utilidad para distinguir acuíferos en contacto con yesos. En este caso la influencia de otros parámetros en la conductividad deberá tomarse en cuenta, en particular los cloruros. No obstante, la conductividad es un buen indicador cuando los cloruros y otros parámetros no son relevantes. En zonas con depósitos de yesos, los autores distinguen entre cavidades con agua en el karst procedente de la infiltración de agua de lluvia y otras aguas en contacto con el sustrato de yeso.

Los valores característicos de conductividad, sulfato y dureza encontrados en una zona kárstica con yesos de 0,6 km2 en Baja Sajonia son:

	Conduct. (μS/cm)	Sulfato (mg/L)	Dureza total (mg/L)
Cavidad con manantial	1.728	1.324	67
Arroyo con manantial. Dic 2000	1.625	1.180	63
Surgencia próxima a los yesos	1.910	1.472	78

No obstante, en la misma zona hay aguas que no están en contacto con el sustrato con yesos, hecho corroborado por los siguientes valores medidos de sulfato y conductividad:

	Conductividad (μS/cm)	Sulfato (mg/L)	Dureza total (mg/L)
Flujo de drenaje en un valle con pastos	180	23	5
Arroyo con manantial fuera del contacto con los yesos	177	18	4

Ejemplos en acuíferos kársticos prácticamente saturados (Völker, 1999):

	Conductividad (µS/cm)	Sulfato (mg/L)	Dureza total (mg/L)
Manantial “Kniequelle”	2.580	1.200	85
Manantial “Neuer Garten”	2.310	1.140	84
Manant. kárstico “Uftrunger See”	2.480	1.215	89
Cavidad con agua subterránea “Heimkehle”	2.028	1.490	89

Influencia sobre las aguas superficiales

Las aportaciones de agua al arroyo procedentes del drenaje del karst afectan a los acuíferos vecinos a lo largo de amplias zonas. El agua tiene una alta calidad medioambiental y ecológica. El contenido en sulfato no ha sido medido hasta la realización de este estudio.

El arroyo drena una zona del Bundsandstein y muestra valores bajos de ión sulfato -19-62 mg/L durante el periodo 26/04/2002 A 20/03/2004- en un tramo de varios kilómetros en un valle.

A partir del punto donde el arroyo entra en contacto con la zona de karst con yesos la situación cambia de manera significativa, con los aportes de sulfatos, cuyas concentraciones pasan de 91 mg/L a 472 mg/L en el punto de control 44.

La influencia de esta zona de karst se acentúa especialmente durante el estiaje, en que el caudal de los manantiales se reduce considerablemente.

El sulfato disuelto es transportado a lo largo de varios kilómetros hacia una zona sin yesos y puede ser detectado claramente a 10 km de distancia de la zona de yesos.

Las concentraciones de sulfatos se deben exclusivamente a causas geológicas y no a contaminación. No existe influencia de actividad humana. Las variaciones en las concentraciones de sulfato se explican por la dilución producida por infiltración de aportaciones estacionales.

Influencia en acuíferos con circulación muy reducida

Los acuíferos en contacto con yesos y otras formaciones –en este caso con porosidad intergranular- muestran un estado de saturación completa de sulfato. No obstante, cuando se acumula el agua subterránea a consecuencia de la infiltración de agua de lluvia, puede detectarse una cierta dilución. Una fluctuación mayor no es relevante pues el yeso se disuelve rápidamente. Como prueba de este hecho se adjunta la siguiente tabla en la que figura la evolución de la dilución del yeso en el arroyo:

Tiempo (seg.)	Conductividad (µS/cm)
0:00	240
0:10	360
0:20	530
0:30	624
0:40	920
0:50	1.300
0:60	1.630
0:120	1.920

Resultados obtenidos. Conclusiones y recomendaciones. Las aguas subterráneas no contaminadas contienen habitualmente menos de 50 mg/L de sulfatos. Esta concentración se supera frecuentemente en zonas kársticas con yesos, donde los niveles normales están comprendidos entre 500 mg/L y 1.400 mg/L. Estas concentraciones son el resultado de la disolución de los yesos. En estas zonas el agua subterránea es poco ácida y no se produce daño ecológico. El pH es ligeramente alcalino (pH= 7.2)y el sulfato natural no produce un efecto tóxico en el medio ambiente. La disolución del sulfato en los yesos es un proceso inevitable.

Por ello, **recomendamos** que, si se demuestra que es sulfato es exclusivamente de origen natural, sin influencia de actividad humana, no se establezca un valor umbral. Si no es ese el caso, el establecimiento del valor umbral es obligatorio, siempre que exista un riesgo de no alcanzar el buen estado. En ese caso, la investigación relativa a cationes como el Cu^{++} debería ayudar a la comprensión del proceso. La presencia de cloruros que indiquen intrusión salina y el nivel del pH para detectar oxidación de sulfuros en piritas deben ser asimismo objeto de estudios adicionales. Se recomienda asimismo que en países con depósitos de yesos o formaciones yesíferas sólo se deberían establecer valores umbral en puntos concretos y cuando haya constancia de influencia antropogénica.

10.5 Caso práctico 5: Evaluación del estado cuantitativo de las aguas subterráneas en los Países Bajos

Información específica
Título/nombre: Evaluación del estado cuantitativo de dos masas de agua subterránea en los Países Bajos. Proyectos de restauración natural en Groot Salland (NL)
Tipo:
Enlace web: Boetelerveld: http://www. landschapoverijssel. nl/terreinen/boetelerveld. htm
Olde Maten y Veerslootlanden: http://provincie.overijssel. nl/beleid/natuur_en_platteland/landinrichting/item_89390/strategisch/projectinformatie
Objetivo: Aplicación de la evaluación del estado cuantitativo
Contribución a…
Aspectos básicos: evaluación del estado cuantitativo
Contribuciones específicas: Examen de 4 tests propuestos para evaluar el estado cuantitativo.

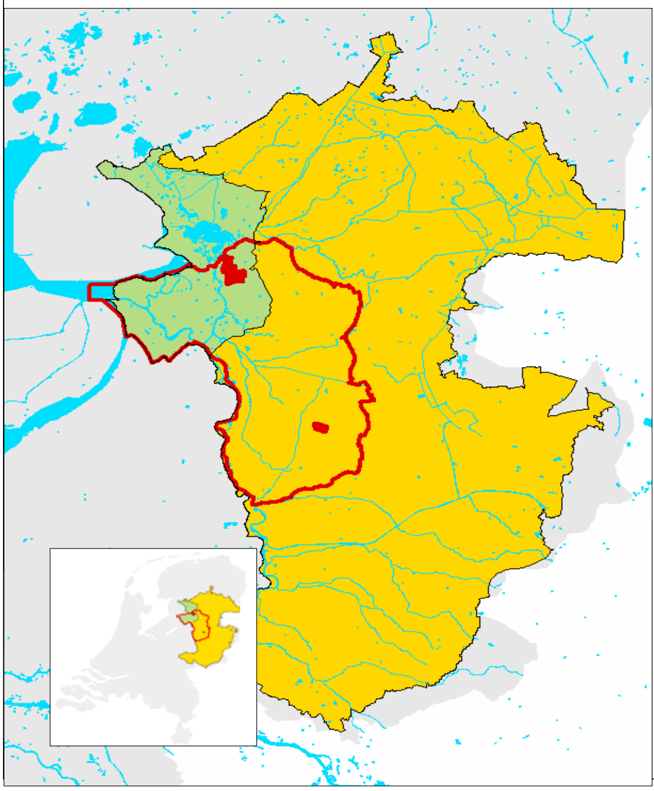
Caracterización

La cuenca hidrográfica "Waterschap Groot Salland" (82.000 ha) está situada en la parte holandesa del Rin Esta zona alberga dos grandes ecosistemas terrestres dependientes de aguas subterráneas reconocidos como lugares de Natura 2000 – Boetelerveld (173 ha) y "Olde Maten y Veerslootlanden (993 ha). Ambas zonas son los restos de zonas naturales mucho más extensas. La masa de agua subterránea situada bajo Boetelerveld (GWB B en la figura 1) es arenosa y está formada por capas de arena del Pleistoceno de unos 100 m de espesor. Las capas impermeables de arcilla y bolos dificultan el drenaje de las precipitaciones y el ecosistema natural era un humedal cubierto de brezales.

La masa de agua subterránea bajo Olde Maten y Veerslootlanden (GWB A en la figura 1) está formada por extensas capas de arcilla y turba del Holoceno. También aquí el drenaje es escaso; el ecosistema natural eran pantanos.

A partir de la década de 1950 una red de zanjas y canales de drenaje convirtió esta pobre zona rural en tierras de cultivo intensivo. Para la gestión del Agua se ajusta el nivel en las zanjas y se consigue optimizar los niveles del agua subterránea para la agricultura. Como resultado de este tipo de cultivo, los ecosistemas terrestres dependientes de las aguas subterráneas han desaparecido en su mayor parte. Queda un pequeño número de lugares fuertemente influenciados por el bajo nivel de las aguas subterráneas así como por las aguas del Rin, ricas en nutrientes, que en la temporada seca entran en la red de zanjas.

La política en Países Bajos de gestión del agua y la naturaleza aspira a poder conservar y restaurar las zonas con tipos de hábitat naturales típicos del país que aún existen. En este contexto se han tomado varias medidas para elevar el nivel de las aguas subterráneas en estas zonas y mejorar su calidad.



Leyenda

Capa freática limítrofe Groot Saland
Ecosistema terrestre dependiente de aguas subterráneas
Masas de agua subterránea Rin-Oeste
Masa de agua subterránea A (arcilla / turba sobre arena)
Masa de agua subterránea B (arena)

Resultados obtenidos. Conclusiones y recomendaciones

En este caso se evalúa el estado cuantitativo de las dos masas de agua subterránea que se describen más arriba. La evaluación comprende 4 pruebas: balance hídrico, intrusión salina, ecosistemas acuáticos y ecosistemas terrestres.

Test del balance hídrico:

Debido a un excedente de precipitaciones netas, de la prueba del balance hídrico se infiere que no hay afección al buen estado de las masas de agua subterránea [capítulo 5.3.1 de la Guía].

Intrusión salina:

En este ámbito, el riesgo de elevación del interfaz de agua salada, principalmente en la captación de aguas subterráneas muy profundas, está controlado por un sistema permanente de “alerta temprana”. En consecuencia, se previenen las intrusiones salinas, y la prueba sobre este problema no afecta el buen estado de las aguas [capítulo 5.3.4 de la Guía].

Aguas superficiales (ecosistemas acuáticos):

Los cursos de agua en la cuenca de Groot Salland son casi todos artificiales y tienen por objeto drenar y prevenir inundaciones; adoptaron su forma actual en las décadas de 1960 y 1970 principalmente. Todas estas masas de aguas superficiales han sido designadas, por consiguiente, como “muy modificadas”. Los objetivos ecológicos para estas aguas -niveles máximos y buen estado- vienen determinados en parte por la calidad de las aguas del Rin que entran durante la temporada seca. El logro del buen estado no depende en gran medida de la cantidad de aguas subterráneas que se filtran en estas aguas superficiales, por lo que la prueba sobre la cantidad de agua subterránea que entra en las aguas superficiales no afecta al buen estado de la masa de agua subterránea [capítulo 5.3.2 de la Guía].

Ecosistemas terrestres dependientes de aguas subterráneas:

Las primeras medidas para elevar la capa freática del acuífero Boetelerveld se tomaron ya en la década de 1970. Las zanjas se llenaron, lo que mejoró la conservación de las precipitaciones en la zona. En 2000 se construyó un canal con un nivel de agua elevado alrededor de la zona para drenar mejor las precipitaciones y elevar el nivel de las aguas subterráneas. Una medición de las captaciones de agua potable en otras partes de la masa de agua subterránea llevó a la conclusión de que los efectos de estas captaciones son de escasa importancia para la capa freática en los dos espacios de Natura 2000. También se han adoptado medidas para elevar el nivel de las aguas subterráneas en Olde Maten y Veerslootlanden. Desde 2000, año de la entrada en vigor de la DMA, las condiciones hidrológicas en ambas zonas no han sufrido ningún deterioro. Estas condiciones son suficientemente favorables para conservar las dos zonas en su estado actual. Se considera, por tanto, que el estado de ambas masas de agua subterránea es bueno [capítulo 5.3.3 de la Guía].

Si, por el contrario, desde 2000 se hubieran deteriorado las condiciones hidrológicas, el principio de “uno fuera, todos fuera” propiciaría una valoración global del estado de ambas masas de agua subterránea en 2009 como deficiente, a pesar de que los ecosistemas terrestres dependientes de aguas subterráneas son pequeños respecto de la masa global de estas aguas (véase figura 1).

Perspectivas. Siguientes pasos. Accesibilidad a los resultados

Como ha quedado dicho, la gestión del agua y la naturaleza en los Países Bajos aspira a restaurar y ampliar aún en los espacios de Natura 2000 los tipos de hábitat deseados. Para ello es necesario seguir mejorando las condiciones hidrológicas respecto de la situación en 2000. El objetivo es restablecer las condiciones hidrológicas necesarias a más tardar en 2015. Las medidas incluyen la mejora de la calidad de las aguas superficiales entrantes, elevar los niveles de estas aguas, cavar zanjas alrededor de la zona, además de otras medidas en los espacios de Natura 2000. No obstante, hasta qué punto son factibles estas mejoras es aún objeto de investigación y debate. Aún no ha concluido el proceso de evaluación de costes y beneficios, y la falta de aceptación social (especialmente en lo relativo a la pérdida de producción agrícola) podría impedir la entrada en vigor de determinadas medidas. Por otra parte, algunas medidas podrían no ser tan eficaces como se prevé. Por último, algunas alteraciones de las condiciones hidrológicas desde la década de 1950 son irreversibles, por ejemplo, la construcción en la parte occidental de Flevopolders ha incrementado considerablemente el flujo subterráneo hacia el oeste, a costa del agua de infiltración local. Se prevé que en el transcurso de 2009 se aprueben los objetivos y las medidas necesarias. Los objetivos fijados en el plan hidrológico de cuenca de 2009 corresponderán a la situación en 2000. El intento de alcanzar los objetivos para 2015, así como las medidas correspondientes, se mencionan en dicho plan hidrológico para 2009, al objeto de exponer claramente las aspiraciones de las actuales políticas.

10.6 Caso práctico 6. Propuesta del Grupo de Trabajo CIS 2.8 sobre la evaluación de tendencias y la inversión de tendencias

Información específica
Título/nombre: Propuesta del GT CIS 2.8 sobre metodología para evaluar las tendencias y la inversión de tendencias a escala de la masa de agua subterránea
Tipo: Conclusiones del GT CIS 2.8 "Aspectos estadísticos de la determinación de tendencias contaminantes de aguas subterráneas y agregación de los resultados del seguimiento"
Enlace web: www.DMAgw.net
Objetivo: El objetivo del GT CIS 2.8 era, entre otros, establecer un método adecuado y pragmático para evaluar las tendencias y la inversión de tendencias en toda la masa de agua, incluida la determinación de requisitos mínimos de evaluación. Los métodos debían ser adecuados para su aplicación en toda la UE sobre la base de las disposiciones de la DMA y teniendo en cuenta las fuentes de contaminación difusas y puntuales.
Contribución a…
Aspectos básicos: evaluación de tendencias y de la inversión de las tendencias
Contribuciones específicas Procedimientos para evaluar tendencias y la inversión de tendencias a nivel de la masa de agua subterránea. Tratamiento de valores por debajo del LC. Requisitos mínimos desde una perspectiva
Caracterización El GT CIS 2.8 creó en 2000 y 2001 un consorcio de 16 países de la UE -11 participantes, 5 observadores- y desarrolló una metodología para agregar datos y evaluar tendencias e inversión de tendencias. Las condiciones del método eran: un método único, estadísticamente correcto y pragmático, para todas las masas de agua subterránea, aplicable a parámetros de todo tipo. Los participantes aportaron los conjuntos de datos en 21 masas de agua y 69 parámetros así como un inventario de los métodos aplicados. El resultado del proyecto incluye un método para evaluar la red de seguimiento, las metodologías para la agregación de datos, una evaluación de tendencias y otra de inversión de las tendencias, el tratamiento de valores menores que LC, los requisitos estadísticos mínimos, documentación exhaustiva y una herramienta de *software* para prueba y verificación. Todo ello está disponible en la página web del proyecto.
Resultados obtenidos. Conclusiones y recomendaciones El procedimiento completo de evaluación de tendencias y de la inversión de tendencias comprende los siguientes pasos: 1. Tratamiento de valores menores que el LC. Regularización temporal de los datos de calidad de las aguas subterráneas en los puntos de control. 3. Agregación de los datos para la masa de agua subterránea. 4. Test de tendencias y de inversión de tendencias. **Evaluación de tendencias** *Test de tendencias propuesto:* Se propone el test de regresión lineal generalizada ANOVA basado en el suavizador LOESS para medir tendencias monotónicas estadísticamente significativas a escala de masa de agua subterránea. Respecto a la extensibilidad y potencia, los métodos lineales -basados en un modelo lineal- superan los métodos no paramétricos basados en la prueba Mann-Kendall y, en consecuencia, se optó por los métodos lineales. La metodología propuesta considera los siguientes requisitos específicos: aplicabilidad a todo tipo de parámetros, extensibilidad a factores potenciales de ajuste y potencia suficiente para detectar tendencias. La robustez se consideró menos importante que la capacidad y la extensibilidad -la validación de datos es responsabilidad de los Estados miembros-. *Potencia del test:* Uno de los hallazgos durante la fase de evaluación de datos fue que una tendencia significativa al aumento debe detectarse con una potencia del 90% para la mayoría de las sustancias si el aumento en la concentración de contaminantes es al menos del 30% o incluso mayor, dependiendo del tipo de contaminante. Con el punto de partida por defecto para la inversión de tendencias del 75% de la norma de calidad o valor umbral, un aumento del 33% de la concentración de contaminantes significaría que no se alcanza el buen estado de la masa.

Se señaló la importancia de los datos procedentes del control operativo para evaluar las tendencias porque, de lo contrario, los datos serían insuficientes para detectar a tiempo la tendencia.

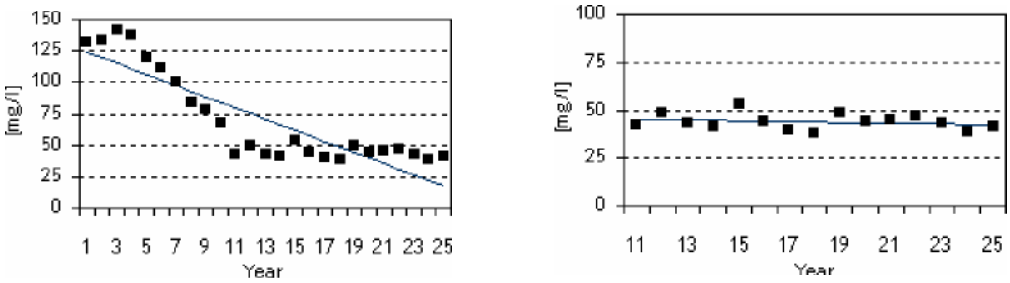
Duración mínima de la serie temporal: Para establecer la duración mínima de la serie temporal para detectar las tendencias se tuvieron en cuenta el calendario de aplicación de la DMA así como su requisito mínimo relativo a la frecuencia de seguimiento (anual). Como el seguimiento comenzó en 2007, y en 2015 está prevista una revisión y actualización de los PHC, cabe suponer que en 2015 se dispondrá de los datos recogidos entre 2007 y 2014. Esto equivale a una serie temporal de 8 años con 8 valores como mínimo.

Puesto que la evaluación de tendencias estadística con menos de 8 mediciones anuales podría ser cuestionable, se recomienda realizar análisis de tendencias con un mínimo de 8 mediciones. En el caso de mediciones semestrales, el número total de muestras no será inferior a 10, y a 15 cuando sean trimestrales. En cada caso, el periodo entre las mediciones debe ser como mínimo de 5 años, porque los cambios a corto plazo pueden distorsionar la detección de tendencias prolongadas.

Duración máxima de las series temporales: Si se evalúan series temporales largas, existe el riesgo de obtener resultados de tendencias claramente afectadas por cambios en los primeros años de las series temporales, por lo que se propone restringir estas series a los últimos 15 años.

Una alternativa sería aplicar un método flexible para comprobar si se ha producido algún cambio significativo de tendencia (lineal) -p.ej. mediante un método de inversión de tendencias de dos secciones-. Si se ha producido un cambio significativo, la sección reciente podría someterse a una evaluación de tendencias. **Observación**: Deben considerarse el modelo conceptual y el tiempo de residencia del agua subterránea.

Figura 19: Influencia de la duración de la serie temporal en la detección de una tendencia



Estacionalidad: A fin de evitar sesgos por los efectos estacionales, las muestras se tomarán en una época determinada del año. En particular, para las mediciones anuales, se procurará que las mediciones se tomen siempre en el mismo trimestre o en una época determinada del año. Los efectos de la estacionalidad pueden deberse también a frecuencias de seguimiento distintas entre los diferentes lugares. La estacionalidad causa una alta variación aleatoria que reduce la capacidad del análisis de tendencias. El método propuesto permite también medir la estacionalidad.

Falta de datos: En las series temporales pueden faltar observaciones, pero se evitará que falten dos o más valores consecutivos, porque ello causaría un sesgo debido a la extrapolación.

Evaluación de la inversión de tendencias

Test de inversión de tendencias propuesto: Para medir la inversión de tendencias se propone el modelo de dos secciones, fácil de interpretar, flexible y muy sensible para detectar cualquier inversión. Se trata de un método lineal basado en un modelo de regresión lineal ampliado, en el que encaja una tendencia lineal con un cambio en el intervalo.

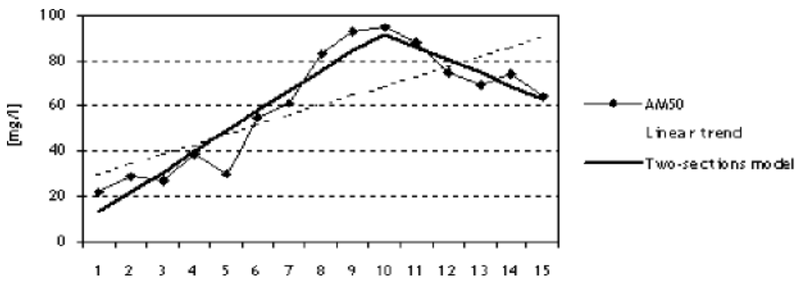


Figura 20: Modelo de dos secciones para medir la inversión de tendencias

Duración mínima de las series temporales: Para la segunda revisión y actualización de los PHC en 2021 -con datos de 2007-2020-, se recomienda realizar al menos 14 mediciones, con regularidad anual, a fin de garantizar un cierto nivel de capacidad de detección de una inversión de tendencias. Si los datos son semestrales o trimestrales, se examinarán 10 años como mínimo. Las mediciones semestrales comprenderán, al menos, 18 valores, y cuando sean trimestrales, serán necesarios 30 valores como mínimo.

Duración máxima de la serie temporal: 30 años.

Preparación de datos

Tratamiento de valores menores que el límite de cuantificación (LC): El tratamiento de datos deberá ser consistente, ya que los LC pueden cambiar en el tiempo. Para el tratamiento de medidas inferiores al LC se aplicará el "enfoque minimax" (minimizar el riesgo máximo). Para evitar sesgos -tendencias inducidas-, el análisis de tendencias se realizará con un LC_{max} constante. Se eliminarán todas las mediciones –mayores o menores que el LC- en las que el LC sobrepase el LC_{max} , y los LC que no sobrepasen el LC_{max} serán sustituidos por el LC_{max} . En el sitio web puede encontrarse una definición y ejemplos de LC_{max}.

Sustitución de valores menores que el LC: Se recomienda calcular las tendencias sobre la base de AM50 -50 significa que los valores <LC son sustituidos por un LC del 50%- siempre que AM0/AM100 ~ 0.6. En tales circunstancias, el sesgo máximo no sobrepasa del 25%. Si se dispone de una norma de calidad o un valor umbral, el LC no deberá superar el 60% de la norma de calidad o el valor umbral. En general, si AM0/AM100 < 0.6, toda evaluación de tendencias deberá basarse a nivel del lugar de muestreo siempre que existan suficientes datos disponibles.

Regularización: Para cada punto de control y cada período de agregación, la media aritmética de los datos de concentraciones se calcula examinando los valores menores que el LC. Los períodos de agregación (regularización) posibles son trimestrales, semestrales o anuales y, para evitar sesgos, dichos períodos deberán ser los mismos en cada punto de control de la masa de agua subterránea que se someta a una evaluación de tendencias.

Agregación espacial: Se propone que el método de evaluación de tendencias esté basado en la media aritmética a escala de masa de agua subterránea, es decir, la media aritmética de las medias aritméticas de todos los puntos de control.

Accesibilidad a los resultados. El proyecto finalizó en diciembre de 2001. Los informes, datos y la aplicación informática están disponibles en la página web del proyecto: www.DMAgw.net El informe definitivo se ha publicado como:*"Technical Report No. 1: Statistical aspects of the identification of groundwater pollution trends and aggregation of monitoring results. WG 2.8 Statistics (2001)"* [Informe Técnico nº 1: Aspectos estadísticos de la determinación de tendencias contaminantes en aguas subterráneas y agregación de los resultados de seguimiento – GT 2.9 Statistics (2001)]

10.7 Caso práctico 7. Tendencias en relación con presiones y vulnerabilidad

Información específica

Título/nombre: Tendencias en relación con presiones, seguimiento y propiedades de los sistemas de aguas subterráneas

Tipo: Resultados del proyecto de FP6 Aquaterra, TREND2 "Tendencias"

Enlace web: http://www.attempto-projects.de/aquaterra/21.0.html

Objetivo:

Probar que es preferible adaptar la detección a las presiones que soporta el sistema de aguas subterráneas al seguimiento y sus propiedades hidrológicas y químicas. Ilustra asimismo cómo determinando la edad de las aguas mejora la detección de tendencias.

Contribución a…

Directiva Marco del Agua: tendencias, seguimiento, tiempos de tránsito, establecimiento de la

Contribuciones específicas: usos del suelo, presiones, tiempos de respuesta, determ. de la edad

Caracterización

Aquaterra investigó con el proyecto TREND2 métodos operativos para evaluar, cuantificar y extrapolar tendencias en aguas subterráneas. Se probaron técnicas de análisis de tendencias en una gran variedad de casos europeos, como depósitos de llanura en los Países Bajos y Alemania, acuíferos de yeso en Bélgica y un acuífero fracturado con una gruesa capa no saturada en Francia.

Se definió tendencia como "*el cambio en la calidad de aguas subterráneas en un período de tiempo específico y una región determinada, relacionado con el uso del suelo o la gestión de la calidad del agua".* El análisis de tendencias para la DAS tiene por objeto distinguir estos cambios antropogénicos de las variaciones naturales con un nivel adecuado de fiabilidad y precisión (DAS, anexo IV, 2. a), i)). Es evidente que las variaciones temporales debidas a factores climatológicos y meteorológicos pueden complicar la detección de tendencias, al igual que el factor de la variabilidad espacial, especialmente cuando, como se exige, se agregan las tendencias a escala de la masa de agua subterránea. Las variaciones espaciales pertinentes incluyen: 1. los recorridos y tiempos de tránsito, 2. las presiones y entradas contaminantes, y 3. la reactividad química de las masas de agua subterránea. Estas variaciones se traducen en un comportamiento de tendencias muy variable, más allá de la propia masa de agua subterránea, porque podría haber pozos en el recorrido conectados a una zona con entradas significativas de contaminantes, pero también otros conectados a entradas de contaminantes de menor entidad.

Las técnicas de análisis de tendencias intentan reducir la variabilidad no relacionada con los propios cambios antropogénicos, por lo que la detección de tendencias es más eficaz cuando se reduce la mencionada variabilidad espacial y temporal, teniendo en cuenta las características físicas y químicas de la masa de agua subterránea, incluidas las condiciones de flujo, los índices de recarga y el tiempo de tránsito en la zona no saturada (DAS, anexo IV, 2 a), iii)). Para el análisis de tendencias existen varias técnicas estadísticas, de simulación y combinaciones de ambas. En el marco del proyecto TREND2 se ensayaron algunas técnicas prometedoras, incluidos algunos planteamientos para determinar la edad y la función de las transferencias (Visser et al. 2008).

Resultados obtenidos. Conclusiones y recomendaciones

El enfoque comparativo TREND2 reveló que no existe un único enfoque aplicable a todas las condiciones hidrogeológicas y todos los lugares de seguimiento. No obstante, la reducción de la variabilidad incluyendo información sobre presiones, hidrología e hidroquímica contribuyó a mejorar la detección de tendencias pertinentes en cada lugar hidrogeológico estudiado. Algunas conclusiones específicas son:

- se recomienda la agrupación de pozos para mejorar la eficacia de la detección;
- es preferible agruparlos en función de las presiones -a menudo relacionadas con el uso del suelo-, vulnerabilidad -distribución de tiempos de tránsito, profundidad de la zona no saturada- y características químicas -tipo de rocas, contenido de materia orgánica- (Figura 1);

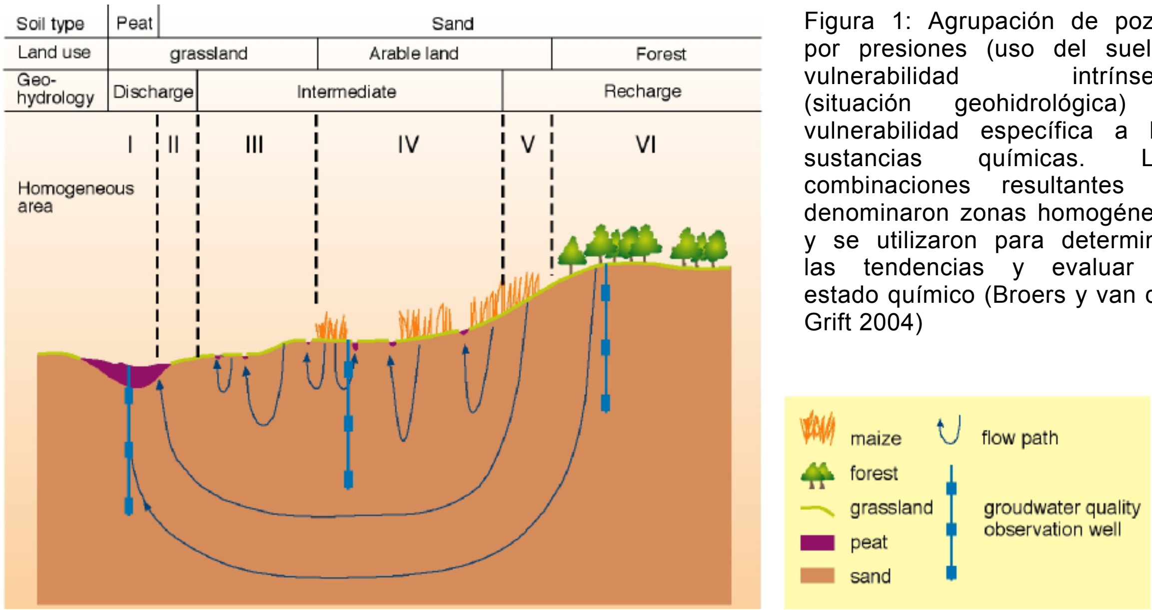

Figura 1: Agrupación de pozos por presiones (uso del suelo), vulnerabilidad intrínseca (situación geohidrológica) y vulnerabilidad específica a las sustancias químicas. Las combinaciones resultantes se denominaron zonas homogéneas y se utilizaron para determinar las tendencias y evaluar el estado químico (Broers y van der Grift 2004)

- la agrupación de pozos para el análisis de tendencias debe considerar también la profundidad porque las aguas subterráneas envejecen en la profundidad, y los cambios pueden ser completamente diferentes a gran profundidad y a poca profundidad (figura 2);

- es fundamental distinguir entre pozos de captación y manantiales, por un lado, y sondeos de observación sin bombeo, por otro.

– Los pozos de bombeo y los manantiales contienen normalmente una mezcla de aguas de diferentes capas, y la calidad del agua resultante es la consecuencia de la mezcla de aguas con tiempos de tránsito muy diferentes. Un factor que complica las mediciones es el hecho de que los aportes a la mezcla de aguas jóvenes y aguas más antiguas pueden cambiar con el tiempo.

– La calidad del agua que suele medirse en sondeos de observación corresponde normalmente a una edad específica del agua, y una vez determinada la edad del agua se puede relacionar la serie temporal a un período de infiltración específico.

– Si se producen diferentes tipos de seguimiento en una masa de agua subterránea, el mejor modo de detectar tendencias es agrupando estos tipos por separado.

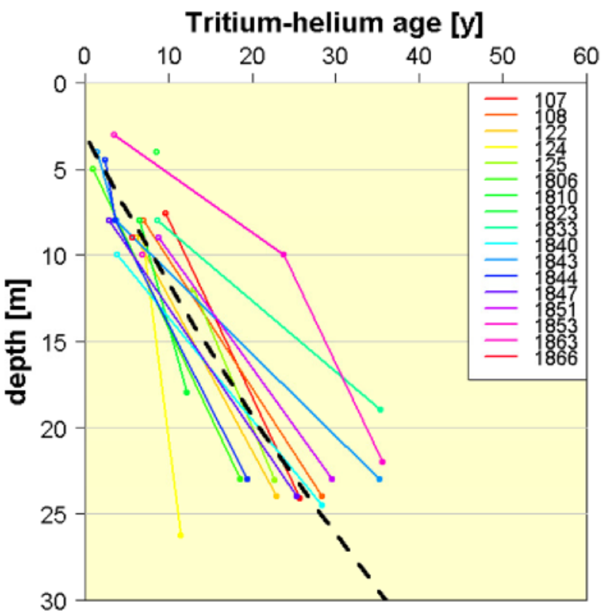

Figura 2: Aumento de la edad del agua subterránea con la profundidad, determinado por una ecuación analítica (línea de trazos) y determinación de la edad por tritio-helio en 14 pozos de observación de niveles múltiples (color distinto para cada pozo)

- El espesor de la zona no saturada es una de las variables de control en la elección de técnicas de análisis de tendencias. Las zonas no saturadas de gran espesor provocan largos tiempos de respuesta que dificultan la rápida detección de tendencias por cambios antropogénicos.

- Las técnicas para determinar la edad resultaron ser muy adecuadas en zonas con depósitos no consolidados y capas freáticas poco profundas (figura 3), pero se descubrió que su uso era limitado en acuíferos con porosidad dual y zonas no saturadas muy espesas.

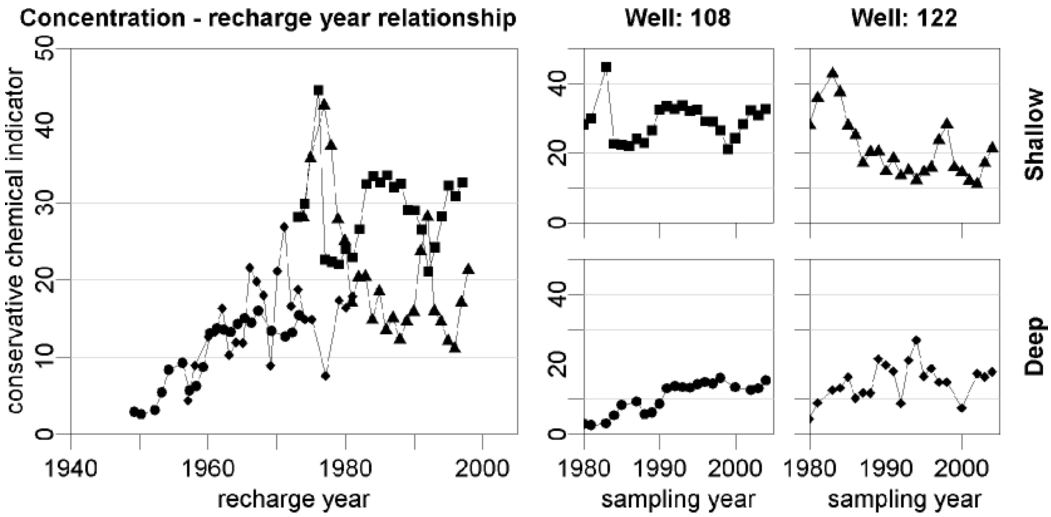

Figura 3: Conversión de la serie temporal medida en sondeos de observación individuales de capas múltiples a poca profundidad (10 m por debajo del nivel de las aguas superficiales) y a mayor profundidad (25 m por debajo del nivel de las aguas superficiales) en un gráfico de serie temporal agregada utilizando el año de recarga como eje X tras haber determinado su edad utilizando tritio-helio (Visser et al. 2007). La serie temporal agregada muestra una tendencia sostenida al aumento con mayores concentraciones a medida que crece el tiempo de recarga.

10.8 Caso Práctico 8. Agregación de tendencias en masas de agua subterránea

Información específica

Título/nombre: Agregación de tendencias en la masa de agua subterránea

Tipo: resultados del proyecto de Aquaterra TREND2 “Tendencias en aguas subterráneas”

Enlace web: http://www.attempto-projects.de/aquaterra/21.0.html

Objetivo:

Procedimiento de agregación de las tendencias en estaciones de seguimiento individuales en la masa de agua subterránea, incluida una evaluación del nivel de fiabilidad y el número de estaciones necesarias. Identificación de la inversión de tendencias a escala de la masa de agua subterránea.

Contribución a…

Directiva Marco del Agua: tendencias, inversión de las tendencias, agregación, nivel de fiabilidad

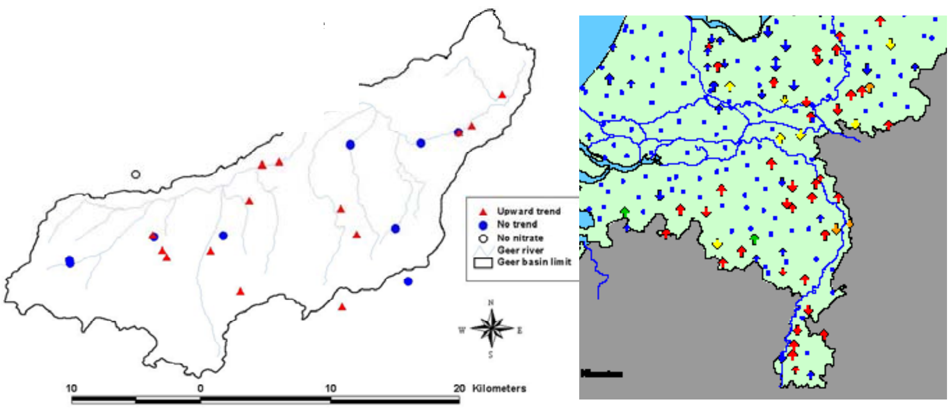
Contribuciones específicas: procedimiento de agregación, tiempos de respuestas a los impactos, determinación de la edad

Caracterización

El proyecto de Aquaterra TREND 2 consistió en el desarrollo de métodos operativos para evaluar, cuantificar y extrapolar las tendencias en sistemas de aguas subterráneas. Las técnicas de análisis fueron ensayadas en una amplia gama de casos europeos, que incluía depósitos de llanura no consolidados en los Países Bajos y Alemania, acuíferos yesíferos en Bélgica y un acuífero fracturado con una potente zona no saturada en Francia.

Se definió tendencia como “*el cambio en la calidad de aguas subterráneas en un período de tiempo específico y una región determinada, relacionado con el uso del suelo y la gestión del agua”.* El análisis de tendencias para la DAS tiene por objeto distinguir entre los cambios antropogénicos y las variaciones naturales con un nivel adecuado de fiabilidad y precisión (DAS, anexo IV, artículo 2.a),i)). Es evidente que las variaciones temporales causadas por factores climatológicos y meteorológicos pueden complicar la detección de tendencias, al igual que el factor de la variabilidad espacial, especialmente cuando, como se exige, se agregan las tendencias a escala de la masa de agua subterránea. Las variaciones espaciales pertinentes incluyen: 1. los recorridos y los tiempos de tránsito, 2. las presiones y entradas contaminantes, y 3. la reactividad química de las masas de agua subterránea. Estas variaciones derivan en un comportamiento muy variable de las tendencias a escala de la masa de agua subterránea, porque podría haber pozos en el recorrido conectados a una zona con fuertes entradas de contaminantes.

Figura 1: Variabilidad espacial de las tendencias en la cuenca del Geer, Bélgica (izquierda) y el sureste de los Países Bajos (derecha)



A pesar de que la agrupación de sondeos en función de las presiones y profundidades de seguimiento ya contribuye a determinar las tendencias (véase estudio de caso 1), a menudo se observa una gran variabilidad espacial en las direcciones que siguen las tendencias y las pendientes de la tendencia en la totalidad de una masa de agua subterránea (figura 1). La aplicación de la DAS requiere "un procedimiento en el que las evaluaciones de las tendencias individuales en las estaciones de control contribuyan a determinar una tendencia significativa y sostenida en la masa de agua subterránea. A continuación se ilustran dos modos posibles de agregar las tendencias individuales a escala de la masa de agua utilizando datos de la red de seguimiento neerlandesa en Brabante Norte. La red de seguimiento comprende sondeos normalizados con rejillas fijas a profundidades específicas. Los sondeos consisten en piezómetros agrupados de 2" de diámetro y rejillas de 2 metros de longitud a una profundidad de entre 8 y 25 metros (Broers, 2002). El subsuelo de Brabante Norte está formado por depósitos de arena y grava fluviales no consolidados procedentes del río Mosa, cubiertos de una capa de entre 2 y 5 m de espesor de depósitos fluvio-periglaciares y eólicos del Pleistoceno medio-superior de arena fina y arcilla. La provincia Brabante Norte es una zona relativamente llana con altitudes que oscilan entre 0 m sobre el nivel medio del mar (MSL) en el norte y oeste y 30 m en el sureste. Las capas freáticas son por lo general poco profundas; se sitúan entre 1 y 5 metros por debajo del suelo.

Perspectivas. Siguientes pasos. Accesibilidad a los resultados

Como primer paso en la agregación de tendencias se recomienda agrupar los sondeos de seguimiento en función de las presiones, la vulnerabilidad y las propiedades hidrológicas, tales como la distribución probable de los tiempos de tránsito en la masa de agua subterránea (véase el otro caso práctico). Existen dos modos de agregar entre los que elegir:

1. estadístico, por ejemplo, definiendo la pendiente media de la tendencia y el correspondiente intervalo de fiabilidad; y
2. determinístico, por ejemplo, utilizando la determinación de la edad para agregar series temporales en el eje X normalizado que indique el tiempo de recarga.

Ambos enfoques se ilustran a continuación utilizando los resultados del proyecto Aquaterra.

Ejemplo 1: Agregación utilizando las pendientes medias de las tendencias

En primer lugar se determinan todas las pendientes de las tendencias de los puntos de control individuales a través de una regresión lineal o una línea sólida Kendall-Theil (Helsel y Hirsch 1992). A continuación se determinan las tendencias agregadas tomando la mediana de todas las pendientes de las tendencias y se examina si la mediana de todas estas pendientes es significativamente diferente de cero (Broers y van der Grift 2004). Se establece una tendencia agregada significativa al aumento para el grupo de pozos cuando el nivel de fiabilidad del 95% de la mediana se sitúa completamente por encima de la línea de pendiente cero (figura 2). Se determinará una tendencia a la baja cuando el intervalo completo de fiabilidad se sitúa por debajo de la línea de pendiente cero. Aquí, los intervalos de fiabilidad en torno a la pendiente media se determinaron de manera no paramétrica, de acuerdo con Helsel y Hirsch (1992, p.70), utilizando un cuadro de la distribución binomial. Conviene observar que las tendencias podrían haber cambiado de dirección a diferentes profundidades del acuífero, debido a las diferentes edades de las aguas subterráneas y a las correspondientes entradas de contaminantes durante el período de infiltración.

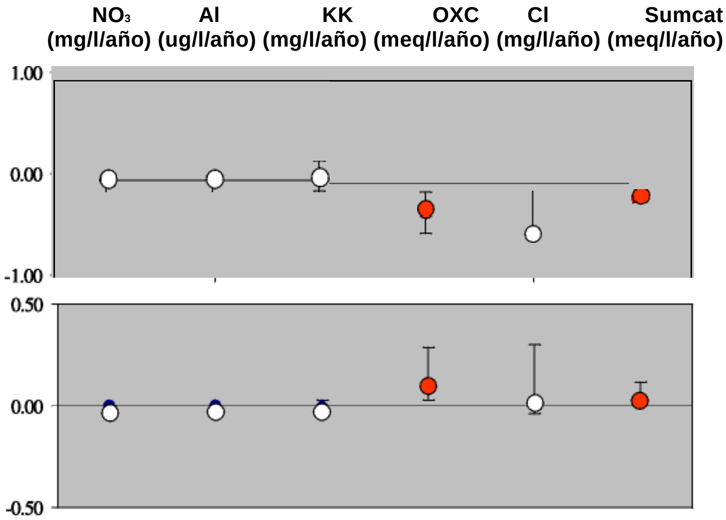


Figura 2: Pendientes de las tendencias medias agregadas de zonas de recarga agrícolas en la provincia de Brabante Norte para 6 indicadores químicos de rejillas a poca profundidad (gráfico superior) y rejillas a mayor profundidad (gráfico inferior). Fuente: Visser et al. 2005.

OXC = capacidad de oxidación. Sumcat = suma de cationes. Se detectaron tendencias significativas al aumento (símbolos rellenos) de OXC a niveles someros, y de Sumcat a mayor profundidad, y tendencias a la baja de Sumcat a niveles someros y de OXC a mayor profundidad.

Una de las conclusiones de agregar tendencias por un procedimiento estadístico es que suele ser necesario un gran número de pozos de observación -entre 20 y 40- para demostrar estadísticamente las tendencias debido a la gran variabilidad temporal y espacial observada, que es inherente a los datos sobre la calidad de las aguas subterráneas.

Ejemplo 2: Agregación basada en el tiempo de recarga utilizando la determinación de la edad

Una nueva técnica de agregación prometedora es utilizar la edad para determinar el período de recarga de las aguas subterráneas y relacionar los datos de concentración medidos con el tiempo de recarga obtenido. Esta técnica ha demostrado funcionar bien en sistemas de seguimiento basados en pozos de observación de niveles múltiples en zonas con acuíferos porosos. En el ejemplo se utilizaron las edades averiguadas con tritio-helio para determinar el tiempo de tránsito hasta las rejillas de control. En lugar del momento del muestreo, se utilizaron estos tiempos de tránsito para relacionar la serie temporal de las concentraciones medidas con el tiempo de recarga. A continuación, se agregaron los resultados de las 28 series temporales en el tipo de zona “uso del suelo: agricultura intensiva en zonas de recarga” en un gráfico y se analizaron utilizando el cálculo LOWESS de regresión lineal suavizada (Cleveland 1979) y ordinaria (figura 3). El método permitió determinar con éxito la inversión de tendencias de las concentraciones de nitratos en este tipo de zonas. La tendencia observada se puede comparar perfectamente con la historia de las entradas de contaminantes agrícolas, deducidas de una serie de datos históricos sobre producción y utilización de fertilizantes y estiércol con varios tipos de cultivos. La inversión de tendencias más fácil de demostrar fue la correspondiente a sustancias conservativas en solución y a indicadores tales como la “capacidad de oxidación” (Visser et al. 2007). Las tendencias al descenso en aguas subterráneas más recientes también pudieron demostrarse en lo relativo a solutos tales como los nitratos, que se transforman en nitrógeno cuando encuentran la desnitrificación por materia orgánica reactiva o sulfuros a cierta profundidad del subsuelo.

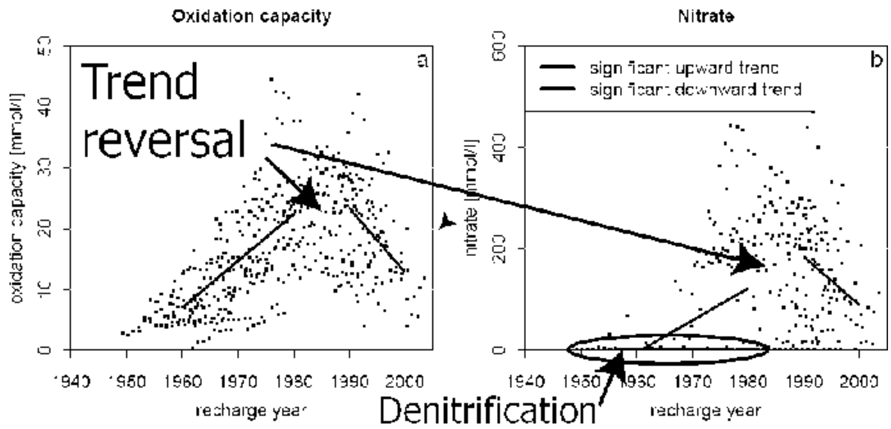

Figura 3:

Agregación utilizando la edad para determinar el año de recarga correspondiente a las concentraciones medidas. La inversión de tendencias quedó significativamente demostrada (P<0.005) en la capacidad de oxidación y nitratos.

FOREWORD

The Water Directors of the European Union (EU), Acceding Countries, Candidate Countries and EFTA Countries have jointly developed a common strategy for supporting the implementation of the Directive 2000/60/EC, "establishing a framework for Community action in the field of water policy" (the Water Framework Directive). The main aim of this strategy is to allow a coherent and harmonious implementation of the Directive. Focus is on methodological questions related to a common understanding of the technical and scientific implications of the Water Framework Directive. In particular, one of the objectives of the strategy is the development of non-legally binding and practical Guidance Documents on various technical issues of the Directive. These Guidance Documents are targeted to those experts who are directly or indirectly implementing the Water Framework Directive in river basins. The structure, presentation and terminology are therefore adapted to the needs of these experts and formal, legalistic language is avoided wherever possible.

In the context of the above-mentioned strategy, a range of guidance documents have been developed and endorsed by the Water Directors during the period 2002-2008 (18 documents in total). They provide Member States with guidance on e.g. the identification of water bodies (CIS Guidance No. 2), the analysis of pressures and impacts (CIS Guidance No. 3), monitoring (CIS Guidance No. 7) etc. in the broad context of the development of integrated river basin management plans as required by the WFD.

As a follow-up, and in the context of the development of the new Priority Substances Directive (2008/105/EC) developed under Article 16 of the Water Framework Directive, Member States have expressed the need to clarify chemical monitoring issues concerning priority substances and other chemical substances covered by the WFD. This has resulted in the decision to develop a new guidance document which would complement the existing series (in particular the Monitoring CIS Guidance No. 7 and the Groundwater Monitoring CIS Guidance No. 15). For this purpose, an informal drafting group has been established under the umbrella of the CIS Chemical Monitoring Activity (CMA). This drafting group has been coordinated by Germany and the EC Joint Research Centtre, and involved a range of experts from other Member States and from stakeholder organisations

The present Guidance Document is the outcome of this drafting group. It contains the synthesis of the output of discussions that have taken place since December 2006. It builds on the input and feedback from a wide range of experts and stakeholders that have been involved throughout the procedure of Guidance development through meetings, workshops, conferences and electronic media, without binding them in any way to this content. It also contains inputs from the AMPS (Analysis and Monitoring of Priority Substances) Report, as well as from the EAQC-WISE (European Analytical Quality Control in support of WISE) funded under the 6th Framework Programme.

"*We, the water directors of the European Union, Norway, Switzerland and the countries applying for accession to the European Union, have examined and endorsed this Guidance during our informal meeting under the French Presidency in Paris (24-25 November 2008). We would like to thank the participants of the Chemical Monitoring Activity and, in particular, the leaders of the inputs drafting group for preparing this high quality document. We strongly believe that this and other Guidance Documents developed under the Common Implementation Strategy will play a key role in the process of implementing the Water Framework Directive and its daughter Priority Substances Directive.*

This Guidance Document is a living document that will need continuous input and improvements as application and experience build up in all countries of the European Union and beyond. We agree, however, that this document will be made publicly available in its current form in order to present it to a wider public as a basis for carrying forward ongoing implementation work.

We also commit ourselves to assess and decide upon the necessity for reviewing this document in the light of scientific and technical progress and experiences gained in implementing the Water Framework Directive and Priority Substances Directive".

TABLE OF CONTENTS

1. PURPOSE OF THIS GUIDANCE DOCUMENT

A strategy for dealing with pollution of water from chemicals is set out in Article 16 of the Water Framework Directive 2000/60/EC (WFD). As a first step of this strategy, a list of priority substances was adopted (Decision 2455/2001/EC) identifying 33 substances of priority concern at Community level. The proposal of a Directive of the European Parliament and of the Council on environmental quality standards in the field of water policy (developed under Article 16 of Directive 2000/60/EC) has the objective to ensure a high level of protection against risks to or via the aquatic environment arising from these 33 priority substances by setting European environmental quality standards. In addition, the WFD requires Member States to identify specific pollutants in the River Basins and to include them in the monitoring programmes. Monitoring of both WFD priority substances and other pollutants for the purpose of determination of the chemical and ecological status shall be performed according to Article 8 and Annex V of the WFD.

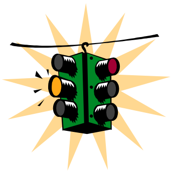
Member States have expressed the need for more guidance on implementation details of the monitoring for chemical substances. In-line with previous documents under the WFD Common Implementation Strategy (WFD CIS) this guidance document has, therefore, been developed as mandated through the Chemical Monitoring Activity (Mandate of Chemical Monitoring Activity 2005-2006). While not being legally-binding, it presents the common view of EU Member States on how to monitor chemical substances in the aquatic environment. This document should present best practices, complement existing CIS guidance and give links to relevant guidance and international standards or procedures already in practice. Guidance on groundwater monitoring is given in a separate document elaborated by CIS Working Group C[1].

This guidance includes the monitoring of the WFD priority substances, other specific pollutants and all other chemical parameters relevant in the assessment of the ecological or chemical status of a water body or in the assessment of programmes of measures. The guidance focuses on monitoring including sampling and laboratory analyses, it covers also in-situ field monitoring of physico-chemical quality elements, but not the monitoring of hydromorphological elements.

This document represents the current state of technical development in a field that is undergoing continuous changes through ongoing scientific research. This denotes that the guidance is open to continuous improvements according to the boundary conditions set in the WFD with possible updates along the 6 years river basin management cycle of the Directive. Since there is an overlap between WFD and the Marine Strategy Framework Directive (Directive 2008/56/EC) as regards chemical pollutants in territorial waters a link between monitoring activities for both Directives has to be established. However, this guidance refers to monitoring of inland, transitional and coastal water bodies under the WFD, and includes some areas of territorial waters also covered by the MSFD. It does not cover some specific aspects of marine monitoring.
Member States will have the opportunity to adjust their monitoring programmes starting in 2007 according to technical progress and the outcome of discussions on the proposal of a

[1] CIS Guidance document No. 15 'Groundwater Monitoring', European Commission, 2006

Directive on environmental quality standards in the field of water policy, amending Directive 2000/60/EC.



Look out!
Issues of compliance, statistical treatment and reporting of monitoring data are not within the mandate of this guidance document

2. BACKGROUND

The Water Framework Directive, including its amendments and existing guidance, provides the background for this guidance document. Links with these documents are indicated and sections of these documents of specific importance are provided for easier reading.

In the Water Framework Directive provisions regarding monitoring of chemical substances in surface waters are laid down in Article 8 and the Annex V.

Look in:
Water Framework Directive 2000/60/EC Article 8 and Annex V

1. Member States shall ensure the establishment of programmes for the monitoring of water status in order to establish a coherent and comprehensive overview of water status within each river basin district.

The Directive sets the Environmental Quality Standards and the basic provisions for compliance checking.

Look in:
European Parliament legislative resolution of 17 June 2008 on the Council common position with a view to the adoption of a directive of the European Parliament and of the Council on environmental quality standards in the field of water policy and amending Directives 82/176/EEC, 83/513/EEC, 84/156/EEC, 84/491/EEC, 86/280/EEC and 2000/60/EC (11486/3/2007 – C6-0055/2008 – 2006/0129(COD))

General guidance on monitoring water quality elements can be found in the guidance document No. 7 MONITORING UNDER THE WATER FRAMEWORK DIRECTIVE produced by Working Group 2.7 - Monitoring. The document deals with both chemical and biological parameters, but specific requirements on guidance for chemical monitoring under the WFD like, e.g., sampling, analytical methods and quality assurance have not been covered completely.

Look in:
Guidance document No. 7 - MONITORING UNDER THE WATER FRAMEWORK DIRECTIVE

The monitoring requirements depend to a large extent on the pressures and impacts that have been identified for the specific water body. Monitoring requirements can, therefore, change with ongoing assessments and changes in anthropogenic pressures and impacts.

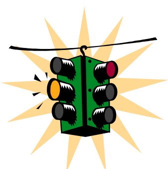
Look in:
Guidance document No. 3 - ANALYSIS OF PRESSURES AND IMPACTS

The Final Draft of the "Commission Directive laying down, pursuant to Directive 2000/60/EC of the European Parliament and of the Council, technical specifications for chemical analysis and monitoring of water status" specifies minimum performance criteria for analytical methods used by laboratories mandated by competent authorities of the Member States for chemical monitoring of water status as well as rules for demonstrating the quality of analytical results.

Look in:
Final Draft of the "Commission Directive laying down, pursuant to Directive 2000/60/EC of the European Parliament and of the Council, technical specifications for chemical analysis and monitoring of water status"

The content of this document has been based on the activities of the Expert Group on Analysis and Monitoring of Priority Substances (AMPS), the Chemical Monitoring Activity (CMA) and discussions throughout the ongoing WFD implementation process.

Look in:
EU REPORT CONTRIBUTIONS OF THE EXPERT GROUP ON ANALYSIS AND MONITORING OF PRIORITY SUBSTANCES AMPS to the Water Framework Directive Expert Advisory Forum on Priority Substances and Pollution Control (EUR 21587 EN)



Look out!
The guidance for chemical monitoring will have to be adapted to regional and local circumstances keeping in mind that the development in water status should be monitored by Member States on a systematic and comparable basis throughout the Community.

3. TERMS AND DEFINITIONS

Selected terms and definitions of specific importance for the chemical monitoring according to WFD are listed here. In addition, some terms of utmost importance are given here using the exact wording from WFD, daughter directives and the CIS guidance documents to assist clarity. All other terms, which have already been agreed upon and defined elsewhere in WFD and associated documents, are not listed here, but are used without amendment.

Look in:
Water Framework Directive 2000/60/EC Article 2

1. Surface water means inland waters, except groundwater; transitional waters and coastal waters, except in respect of chemical status for which it shall also include territorial waters.

3. Inland water means all standing or flowing water on the surface of the land, and all groundwater on the landward side of the baseline from which the breadth of territorial waters is measured.

7. Coastal water means surface water on the landward side of a line, every point of which is at a distance of one nautical mile on the seaward side from the nearest point of the baseline from which the breadth of territorial waters is measured, extending where appropriate up to the outer limit of transitional waters.

24. Good surface water chemical status means the chemical status required to meet the environmental objectives for surface waters established in Article 4(1)(a), that is the chemical status achieved by a body of surface water in which concentrations of pollutants do not exceed the environmental quality standards established in Annex IX and under Article 16(7), and under other relevant Community legislation setting environmental quality standards at Community level.

Look in:
Guidance document No. 7 - MONITORING UNDER THE WATER FRAMEWORK DIRECTIVE

"Significant quantities"
2.7.3 Selection of quality elements
...Those priority list substances discharged into the river basin or sub-basins must be monitored. Other pollutants also need to be monitored if they are discharged in significant quantities in the river basin or sub-basin. No definition of 'significance' is given but quantities that could compromise the achievement of one of the Directive's objectives are clearly significant, and as examples, one might assume that a discharge that impacted a Protected Area, or caused exceedance of any national standard set under Annex V 1.2.6 of the Directive or caused a biological or ecotoxicological effect in a water body would be expected to be significant.

Specific Terms and Definitions for the Guidance of Chemical Monitoring

Whole water:
"Whole water" is synonym for the original water sample and shall mean the water sample when solid matter and the liquid phase have not been separated.

Liquid (dissolved) fraction:
"Liquid (dissolved) fraction" shall mean an operationally defined fraction of whole water from which suspended particulate matter has been removed by an appropriate methodology.

Suspended particulate matter:
"Suspended particulate matter (SPM)" shall mean the particulate matter fraction of the whole water sample after separation with an appropriate methodology.

Total concentration of the analyte:
"Total concentration of the analyte" shall mean the total concentration of the analyte in the whole water sample, reflecting both dissolved and particle bound concentrations of the analyte.

Dissolved concentration of the analyte:
"Dissolved concentration of the analyte" shall mean the concentration of the analyte in the liquid (dissolved) fraction of a whole water sample.

Particle bound concentration of the analyte:
"Particle bound concentration of the analyte" shall mean the concentration of the analyte bound to SPM.

Discharged:
A substance is considered being discharged into a river basin when it is being introduced via point or diffuse sources or accidental releases.

4. MONITORING DESIGN RELATED TO SURVEILLANCE, OPERATIONAL AND INVESTIGATIVE MONITORING

4.1. General – Monitoring Design

The surface water monitoring network shall be established in accordance with the requirements of Article 8 of the Water Framework Directive (WFD). The monitoring network shall be designed so as to provide a coherent and comprehensive overview of ecological and chemical status within each river basin.

On the basis of the characterisation and impact assessment carried out in accordance with Article 5 and Annex II of the WFD, Member States shall establish for each river basin management plan period three types of monitoring programmes:

- surveillance monitoring programme,
- operational monitoring programme and,
- if necessary, an investigative monitoring programme.

Designing Surveillance/Operational Monitoring Programmes

All available information about chemical pressures and impacts should be used for setting up the monitoring strategy. Such information would include substance properties, pressure and impact assessments and additional information on sources, e.g., emission data, data on where and for what a substance is used, and existing monitoring data collected in the past.

In many cases, it will be relevant to use a stepwise screening approach to identify non-problem areas, problem areas, major sources etc. This approach may for instance start with providing an overview of expected hot spots and sources to receive a first impression of the scale of the problem. Thereafter, a more focused monitoring can be performed directed to relevant problem areas and sites. For many substances, screening of the levels in water as well as in biota with limited mobility and in sediment will be the best way to get the optimum information within a given amount of resources. When the problem areas are identified, analysis of a limited number of water samples can be performed.

The monitoring programmes will need to take account of variability in time and space (including depth) within a water body. Sufficient samples should be taken and analysed to adequately characterise such variability and to generate meaningful results with proper confidence.

The use of numerical models with a sufficient level of confidence and precision for designing the monitoring programmes can also be helpful.

The documentation of progressive reduction in concentrations of priority substances and other pollutants, and the principle of no deterioration are key elements of WFD and require appropriate trend monitoring. Member states should consider this when designing their monitoring programmes. Data obtained in surveillance and operational monitoring may be used for this purpose.

4.2. Sampling Strategy

Important principles of sampling strategy have been described in the CIS guidance document No.7 (e.g., 2.4., 2.7.2, 5.2.5). Depending on the objective of the monitoring, the physico-chemical properties of the substance to be monitored and the properties of the water body under study water, sediment and/or biota samples have to be taken.

The set-up of the monitoring strategy includes decisions on the sampling locations, sampling frequencies and methods. This selection is a compromise between a sufficient coverage of samples in time and space to generate meaningful results with proper confidence and limiting the monitoring costs.

As the establishment of environmental quality standards (EQS) has been limited for the majority of priority substances to water only, the principle matrix for assessing compliance[2] with respect to EQS is whole water, or for metals, the liquid fraction obtained by filtration of the whole water sample. EQSs referring to concentrations in biota have been established only for mercury, hexachlorobenzene, and hexachlorobutadiene at Community level. In order to allow Member States flexibility depending on their monitoring strategy, they may either monitor and apply the EQSs for biota, or introduce stricter EQS for water in order to provide the same level of protection as the EQS for biota. Furthermore, Member States may opt to establish and apply EQSs for sediment and/or biota for other substances listed in the proposed Directive. These EQSs shall offer at least the same level of protection as the EQS for water.

For other pollutants, the matrix for analysis should be in line with the matrix for which national EQS have been derived.

Water/SPM

WFD chemical status is generally assessed from analyses of water samples for substances with stated chemical water quality criteria. However, supporting parameters for the assessments of the ecological and chemical status may have to be analysed in water or other matrices.

The type of water sample to be taken at each site is part of the strategy for the monitoring programme. For most water bodies spot samples are likely to be appropriate. In specific situations, where pollutant concentrations are heavily influenced by flow conditions and temporal variation and if pollution load assessments are to be performed, other more representative types of samples may be beneficial. Flow-proportional or time-proportional samples may be better in such cases. In stratified water bodies such as lakes, some estuaries and coastal areas, waters samples may be taken in different depths to give a better representation of the water column compared to a single sampling depth. For example, multiparameter probes (e.g., CTD-probes) can be employed to detect stratifications.

[2] For the purpose of this guidance document the term compliance means that

a) reported annual average concentrations or reported concentrations of priority substances/other pollutants do not exceed the EQS laid down in Directive on Environmental environmental quality standards in the Field of water policy and amending Directive 2000/60/EC.

b) environmental objectives specified in the WFD such as no deterioration of the status of a water body, good chemical status of a water body, or trend reversal have been achieved.

In general, reliable data on emission sources reduce monitoring costs because they give a good basis for choosing proper sampling locations, and optimising the number of sampling sites and the appropriate sampling frequencies.

Look in:
Water Framework Directive 2000/60/EC Article 16(7)

The Commission shall submit proposals for quality standards applicable to the concentrations of the priority substances in surface water, sediments ***or*** *biota.*

Whole water data may be generated by analysis of the whole water sample, or by separate determinations on liquid and SPM fractions. If it can be justified – for example by considerations of expected contaminant partitioning – it may be argued that there is not a need to analyse a particular fraction. If a sampling strategy is selected involving only liquid or SPM fractions, then, Member States shall justify the choice with measurements, calculations, etc.

However, demonstrating compliance with EQS in water may be problematic in some cases. Examples include:

- available analytical methods are not sufficiently sensitive or accurate for quantification of substances at the required concentration level (see 6.1),
- water bodies with high and fluctuating SPM content and varying properties (sampling representative water sample is problematic).

Sediment and Biota[3]
To check compliance with biota EQS values, the most appropriate indicator species among fish, molluscs, crustaceans and other biota should be monitored (this will be dealt with in a separate guidance document, see footnote 3).

In addition to chemical and ecological status assessement, the prevention of further deterioration of the status of aquatic ecosystems is another important objective of the WFD. Monitoring of contaminants in sediment and biota may be used to assess the long-term impacts of anthropogenic activity and thus, to assess the achievement of the above mentioned objective. It includes the determination of the extent and rate of changes in levels of environmental contamination.

Hydrophobic and lipophilic substances that tend to accumulate in sediment and biota may be monitored in these matrices for resource effective trend monitoring in order to:

- assess compliance with the no deterioration objective (concentrations of substances are below detection limits, declining or stable and there is no obvious risk of increase) of the WFD,
- assess long-term changes in natural conditions and those resulting from widespread anthropogenic activity,

[3] Further guidance on monitoring of WFD relevant substances in biota and sediment is under development within the Chemical Monitoring Activity of the European Commission

- monitor the progressive reduction in the concentrations of priority substances (PS) and the phasing out of priority hazardous substances (PHS).

Furthermore, the use of sediment and biota in monitoring hazardous substances is important in other issues of WFD implementations, viz.:

- identify fate and behaviour of pollutants,
- describe the general contaminant status and supply reference values for regional and local monitoring programmes,
- accumulating matrices give an integrated and less varible measure of the contaminant burden over a longer time period, and consequently, an improved statistical power for time series analysis

The selection of the monitoring matrix has implications on the monitoring frequencies on both scientific and cost grounds.

If sediment or biota are used for temporal trend monitoring it is recommended, if practicable, that the quantitative objectives of the monitoring are determined before any monitoring programme is started. For instance, the quantified objective could be to detect an annual change of 5 % within a time period of 10 years with a power of 90 % at a significance level of 5 % with a one-sided test.

Sediment samples should be collected at an appropriate frequency that will have to be defined on a local basis, where appropriate, taking into account the sedimentation rate of the studied water body and hydrological conditions (e.g., flood events). Typical sampling frequency will vary from once every 1 to 3 years for large rivers or estuaries that are characterised by high sedimentation rates, to once every 6 years for lakes or coastal areas with very low sedimentation rates.

The locations for sediment trend monitoring should be representative of a water body or a cluster of water bodies. Where possible, sampling should be performed in non-erosion areas, which are representative of sediment formation. For dynamic systems it might be useful to collect suspended matter for monitoring purposes.

In case of using biota in trend monitoring it is common practice to collect samples at least once per year during the non-spawning season.

Representativeness is a key point, i.e. how well a sample reflects a given area or how much area the sample represents given a certain level of statistical significance. For example, it is essential to collect specimens for analysis well away from the mixing zones when the sampling point is downstream of a significant discharge.

To improve the power of the monitoring programme samples should be collected from areas characterised by relatively low natural variability.

4.3. Use of Models as a Tool in WFD Monitoring

Numerical models are important tools for planning monitoring strategies and designing monitoring programmes. They can help to understand the spatial and temporal variations in pollutant concentrations. For instance, measurements in sediments and biota combined with models can be used to estimate dissolved water concentrations for some contaminants, particularly hydrophobic organic compounds. Thus, appropriately validated and tested models can provide, within the impact and pressure assessments, additional evidence that EQS will not be violated in a specific water body under the most adverse conditions.

Given the current levels of uncertainty, concentrations of contaminants estimated by modelling cannot be used for the purpose of compliance checking for water bodies that are at risk of failing WFD provisions. The approach can, however, be used in surveillance monitoring for estimation of concentrations in water bodies that are shown to be not at risk when the uncertainty of the model is considered.

According to partitioning theory, relationship curves and/or mechanistic models can be used to estimate a corresponding, or equilibrium water concentration from measured levels of hydrophobic contaminants in biota/sediments. This way, areas can be cost-efficiently scanned using sediments and biota to compare contaminant levels in different areas and to identify possible sources of contaminants to the area.

Relationship curve models are based on correlations between chemical measurement data and some descriptor, whereas mechanistic models are based on processes giving rise to the observed data. Some examples are the relationship curve models such as OMEGA (EU Rebecca project) or BCFWIN (MEYLAN et al. 1999)[4] and mechanistic models, such as Bioaccumulation Fish Model (MACKAY 2001)[5] and SEDFLEX[6]. One example of relationship curve models is the use of bioaccumulation factors (BAF) in relation to the partitioning coefficient between octanol and water (K_{OW}). BAFs have been used for the past 25 years to describe the net increase of organic contaminant concentrations from water to biota, as BAF = $CHEMICAL_{Animal}/CHEMICAL_{Water}$. Because BAF is related linearly to K_{OW}[7], this relationship curve can be used to calculate the water concentration of a chemical when the level in biota and its partitioning coefficient are known. In the absence of environmental measurements of a chemical in biota and water to calculate BAFs, this relationship is also a useful tool for exposure and risk assessments of new chemicals. This issue is being explored by several programmes, such as: Registration, Evaluation and Authorisation of CHemicals (REACH)[8] in the EU (European Commission 2004), the Canadian Environmental Protection Act (CEPA)'s Domestic Substances List (DSL) (ENVIRONMENT CANADA 2003)[9], and the US EPA high production chemicals assessments (WALKER et al. 2004)[10].

10 Walker, J. D.; Knaebel, D.; Mayo, K.; Tunkel, J.; Gray, D. A. (2004) Use of QSARs to promote more cost-effective use of chemical monitoring resources. 1. Screening industrial chemicals and pesticides, direct food additives, indirect food additives and pharmaceuticals for biodegradation, bioconcentration and aquatic toxicity potential. Water Qual. Res. J. Can. 39, 35-39.

The mechanistic model SEDFLEX is composed of a dispersion part simulating the sources, transport and sinks of contaminants in a fjord, estuary or lake system, and a food web part that calculates uptake and accumulation in biota as well as quantification of different food sources, mainly from sediment or from water[6]. When emission data are added to the dispersion part, SEDFLEX can predict how changes in the environment would be reflected in water, biota or sediment concentrations, respectively, and what the response time would be.

The predictive power of models is only valid within the framework and limits defined by its assumptions. Models with a sufficient level of confidence can be helpful for designing the monitoring programmes. However, it is important to define the desired level of confidence and consider uncertainties associated with chemical measurements in biota/sediments as well as with other parameters used in the model. As a result, estimated water concentrations may vary considerably. By the use of model sensitivity analyses, combined with knowledge on uncertainty of measurement, the confidence of the modelled concentrations can be assessed. The level of confidence will be site and chemical specific. It is crucial that the model performance is carefully documented. Existing knowledge gaps must be quantified and taken into account as uncertainty factors when applying models.

In using sediments and biota as a first level screening for certain chemicals in the monitoring programme, water measurements may be downscaled. The initial screening will help to identify areas of concern and where to direct effort, such as a follow up with water samples and direct measurements. This process provides good grounds for using models, where appropriate.

4.4. Monitoring Frequency

Look in:
Water Framework Directive 2000/60/EC Annex V 1.3.4

For the surveillance monitoring period, the frequencies for monitoring parameters indicative of physico-chemical quality elements given below should be applied unless greater intervals would be justified on the basis of technical knowledge and expert judgement.

For operational monitoring, the frequency of monitoring required for any parameter shall be determined by Member States so as to provide sufficient data for a reliable assessment of the status of the relevant quality element. As a guideline, monitoring should take place at intervals not exceeding those shown in the table below unless greater intervals would be justified on the basis of technical knowledge and expert judgement.

Guidance document No. 7 - MONITORING UNDER THE WATER FRAMEWORK DIRECTIVE, 2.1

The monitoring frequencies given in WFD, Annex V 1.3.4 of once-a-month for priority substances and once-per-three-months for other pollutants will result in a certain confidence and precision. More frequent sampling may be necessary e.g., to detect long-term changes, to estimate pollution loads and to achieve acceptable levels of confidence and precision in assessing the status of water bodies. In general, it is advisable to take samples in equidistant time intervals over a year, e.g., every four weeks resulting in 13 samples to compensate for missing data due to unusual weather conditions (drought, floods, etc.) or laboratory problems. In case of pesticides and other seasonally variable substances, which show peak concentrations within short time periods, enhanced sampling frequency compared to that specified in the WFD may be necessary in these periods. For example, the best sampling time for detecting concentration peaks of pesticides due to inappropriate application is after heavy rainfall within or just after the application period. Moreover, failure to comply with good agricultural practice, e.g., inappropriate cleaning of equipment during or at the end of the season before winter can also cause pesticide peak concentrations. Other reasons for enhanced sampling frequency include seasonal pressure from tourism, seasonal industrial activities, which are common practice for example in pesticide production etc. The results of those measurements should be compared with the MAC-EQS. For the calculation of the annual average concentrations results have to be weighted according to the associated time interval (time weighted average). For example, 12 equidistant values per year with two additional values in November could be accounted for with reduced weights for the three November values. In other words, the three November values would be averaged and a "November mean" be used in the calculation of the annual average value. Using this approach, any individual values should still trigger an immediate investigation if high levels are detected.

Collecting composite samples (24h to one week) might be another option to detect peak concentrations of seasonally variable compounds.

To estimate the pollutant load, which is transferred across Member State boundaries and into the marine environment, an enhanced sampling frequency may be advisable. In case of spot sampling for substances, which show a wide range of concentrations, biweekly sampling, i.e. 26 samples a year may be justified. Flow-proportional or time-proportional sampling may be beneficial in such cases.

Reduced monitoring frequencies, and under certain circumstances, even no monitoring may be justified when monitoring reveals/has revealed that concentrations of substances are far below the EQS, declining or stable and there is no obvious risk of increase.

The monitoring frequencies quoted in the Directive may not be practical for transitional and coastal waters, Nordic lakes, which can be iced for several months, and for Mediterranean rivers which may contain no water for several months each year.

4.5. Surveillance Monitoring

4.5.1. Objectives

According to WFD Annex V1.3.1 the objectives of surveillance monitoring of surface waters are to provide information for:

- supplementing and validating the impact assessment procedure detailed in Annex II;
- the efficient and effective design of future monitoring programmes;
- the assessment of long-term changes in natural conditions; and
- the assessment of long-term changes resulting from widespread anthropogenic activity.

It should be stressed that surveillance monitoring is not intended for:

- mapping and analysing water quality problems;
- testing the effectiveness of the programme of measures;
- obtaining a detailed or complete overview of the quality of all types of water.

Such information is to be gathered within operational monitoring, investigative monitoring, and existing non-WFD related monitoring activities.

It is recommended to use monitoring data, which have to be reported according to other European Directives and international river and sea conventions for the purpose of surveillance monitoring (e.g., 76/464/EWG, Nitrates Directive 91/676/EEC, OSPAR JAMP), where appropriate.

4.5.2. Selection of Monitoring Points

The criteria for selecting the surveillance monitoring points are given in WFD Annex V 1.3.1. Water bodies probably at risk, probably not at risk and not at risk of failing the environmental objectives should be covered adequately.

	**Look in:** Water Framework Directive 2000/60/EC Annex V 1.3.1 Guidance document No. 7 - MONITORING UNDER THE WATER FRAMEWORK DIRECTIVE, 2.7.2

Sampling points should include major rivers as well as points at the downstream end of relevant sub-catchments.

Sampling points for general physico-chemical parameters supporting the biological quality elements need to be representative of the sampling site of the biological elements (although it is recognised that physical characteristics may necessitate some flexibility in this regard). For priority substances and other pollutants, other sampling points may be selected.

Where possible, it is recommended to establish surveillance monitoring sites with fixed monitoring stations and automatic samplers allowing the collection of mixed samples. If not available, spot samples should be collected. Where possible, water level and flow should be recorded as well as pH, conductivity, and temperature, e.g., by using suitable probes.

In case of transboundary waters, consultations about the proposed water body and surveillance monitoring sites should be held between the Member States involved.

Monitoring sites to be used for pollution load estimation (country boundaries and transition from inland waters to marine environment), should, where possible, include representative water quantity as well as quality monitoring.

Representative approaches related to diffuse and widespread sources are often relevant in surveillance monitoring. In such cases sufficient monitoring points must be sampled within a selection of water bodies in order to assess the magnitude and impact of the pressures. Results can be scaled up by using measurements of biota or sediment samples from a larger number of bodies.

4.5.3. Selection of Monitoring Parameters

Chemical monitoring comprises three categories of parameters:

- substances that have to be assessed in respect of compliance with European environmental quality standards (EQS), e.g., priority substances
- other polluting substances, e.g., river-basin-specific substances, for which no European EQS are available and which have, hence, to be assessed in respect of compliance with national or river-basin-specific EQS
- primary physico-chemical parameters, e.g., nutrients, oxygen, temperature, salinity, conductivity, pH, which support interpretation of biological data and those required for reliable interpretation of the results of chemical measurements (e.g., DOC, Ca, SPM content).

For the purpose of surveillance monitoring, priority substances discharged into river basins or sub-basins must be analysed. Other pollutants defined as any substance liable to cause pollution in particular those listed in Annex VIII also need to be monitored if they are discharged in significant quantities in the river basin or sub-basin. In addition, relevant physico-chemical parameters should be measured.

4.6. Operational Monitoring

4.6.1. Objectives

Operational monitoring shall be undertaken (Annex V.1.3.2) in order to:

- establish the status of those bodies identified as being at risk of failing to meet their environmental objectives, and
- assess any changes in the status of such bodies resulting from the programmes of measures.

Contrary to surveillance monitoring, operational monitoring is characterised by spatial and temporal flexible monitoring networks, problem-oriented parameter selection and sampling.

The operational monitoring programme may be modified during the planning period (6 years) if the monitoring results indicate there is a reason to do so. The monitoring frequency can be reduced, for example, when an effect is no longer deemed to be significant or the pressure in question has been eliminated. This applies when good, or better, chemical and ecological status has been achieved. As soon as the good status has actually been achieved and there is no risk of failing the environmental objectives, the operational monitoring can be stopped and surveillance monitoring will suffice. If operational monitoring aims at the assessment of changes in the status of water bodies resulting from programme of measures, it might be justifiable to reduce monitoring frequencies or suspend monitoring for a certain time period as long as no change in the status can be expected.

4.6.2. Selection of Monitoring Points

The criteria for selecting operational monitoring sites are given in WFD Annex V 1.3.2.

	**Look in:** Water Framework Directive 2000/60/EC Annex V 1.3.2 Guidance document No. 7 - MONITORING UNDER THE WATER FRAMEWORK DIRECTIVE, 2.8.2

If there are significant chemical pressures from point sources, sufficient locations must be selected to assess the magnitude and impact of these point sources according to Annex V of the WFD.

If there are significant chemical pressures from diffuse sources the water body selected for operational monitoring must be representative of the occurrence of the diffuse pressures, and of the relative risk of failure to achieve good surface water status. However, it should be taken into account that water bodies can only be grouped where the type and magnitude of pressure are similar.

Aggregation of water bodies is possible if the water bodies can be compared in respect of geography, hydrology, geomorphology, trophic level and extent of human pressures. In such cases, Member States shall provide evidence that the water body where monitoring is carried out is indeed representative of the group of water bodies.

Provided that there is a good documentation that local sources are absent, a few water samples from a number of representative bodies should be sufficient to identify non-problem areas affected only by diffuse input via long-range transport of pollutants.

4.6.3. Selection of Monitoring Parameters

In order to assess the magnitude of the chemical pressure to which bodies of surface water are subjected, Member States shall monitor for any priority substances and other pollutants discharged in significant amounts to the water body concerned. In addition, physico-chemical parameters relevant for reliable interpretation of the results of chemical measurements (e.g., DOC, Ca, SPM content) should be measured.

4.7. Investigative Monitoring

4.7.1. Objectives

Investigative monitoring may be required in specified cases (Annex V.1.3.3). These are given as:

- where the reason for any exceedance (of environmental objectives) is unknown,
- where surveillance monitoring indicates that the objectives set under Article 4 for a body of water are not likely to be achieved and operational monitoring has not already been established,
- in order to ascertain the causes of a water body or water bodies failing to achieve the environmental objectives,
- to ascertain the magnitude and impacts of accidental pollution.

Investigative monitoring may also include alarm or early warning monitoring, for example, for the protection of water bodies used for drinking water abstraction that may be subject to accidental pollution.

Investigative monitoring may also be triggered when a water body has been identified as being at risk of failing the objectives due to chemical pressures on the basis of the assessment of biological elements.

4.7.2. Selection of Monitoring Points/Matrix/Parameters

The starting point of investigative monitoring will often be that surveillance or operational monitoring have revealed that the EQS values are exceeded, but the causes of the failures are unknown or poorly understood. It is, however, very difficult to give general guidance on how to proceed in investigative monitoring since a case by case approach is the only way forward to take account of local conditions, the type of pressures, and the specific aim of the investigation. This will in general require expert knowledge and judgment. The necessary monitoring points, the matrix and parameters to be monitored as well as the frequency of sampling and the duration of the monitoring have to be adjusted to the specific case or problem under investigation. Investigative monitoring is characterised by spatial and temporal flexible sampling and can be stopped as soon as the cause of non-compliance has been identified. When a programme of measures is in operation and its effect can be expected to be measurable, a suitable operational monitoring has to be established. In the case of accidental pollution, investigative monitoring can be ceased as soon as the magnitude of the impact of the accidental pollution has been ascertained.

Before starting investigative monitoring, thorough pressure analysis may be required. In particular, it is important to clarify whether point or diffuse sources have to be taken into account as potential cause for non-compliance.

In order to identify the causes of exceedance of EQS in a water body or several water bodies, Member States shall monitor the priority substance(s) or other pollutant(s) of which the water concentration exceeds EQS.

5. TECHNIQUES FOR SAMPLING

5.1. General Remarks on Sampling

The quality of assessments based on the results from the chemical analyses is dependent on the quality of the sampling and on understanding the inherent variability in the media from which samples are taken. The variability of contaminant concentrations in aquatic systems is often difficult to quantify and can often be higher than uncertainties associated with the analyses themselves. Nevertheless, the overall uncertainty needs to be considered in the data evaluation and needs to be addressed in the design of a representative monitoring programme. The design of a monitoring programme includes the selection of sampling points and matrix as well as sampling frequencies as described in Chapter 4. For example in the case of water sampling, the exact position of sampling points including sampling depths depends on local conditions, e.g., parameters such as vertical and lateral mixing, water homogeneity and possibilities to use appropriate sampling equipment (see e.g., ISO 5667-6).

It is vital that all the personnel involved in sampling are sufficiently educated and trained in the procedures applied and fully aware of the risks and consequences of taking inappropriate samples. They should understand the objectives of the monitoring programme, the further treatment of the samples taken and have a certain understanding of the hydro-geochemical processes in the water body. The sampling should include a routine sampling report sufficiently detailed to document the sampling performed and include observations relevant for the assessment of the monitoring results.

QA/QC procedures are necessary to ensure the quality of the sampling activities of a monitoring programme, including care to preserve sample integrity (see ISO 5667-14 and other guidelines). Quality assurance of sampling including selection of sample, pre-treatment, sub-sampling, preservation, storage and transport is essential for the quality of final results of the chemical analyses. Quality control of the sampling should include measures that enable estimation of sampling precision. Other measures could be participation in sampling inter-comparison trials.

5.1.1. Existing Guidance Documents

Guidance on sampling techniques may be found in the ISO Standard on Water Quality – Sampling 5667 (www.iso.org), the guidelines of the OSPAR Convention (www.ospar.org) for the Joint Assessment and Monitoring Programme (JAMP) or the HELCOM COMBINE manual (http://www.helcom.fi/groups/monas/CombineManual/en_GB/main/).

5.2. Water Sampling

	**Look in:** ISO Standard Series 5667, Part 1, 3, 4, 6 and 9 OSPAR JAMP Guidelines: Chlorophyll a in Water, Nutrients and Oxygen Manual for Marine Monitoring in the COMBINE Programme of HELCOM

Water sampling procedures usually include in situ field measurements of physical and chemical parameters, e.g., water flow, temperature, conductivity (salinity), dissolved oxygen, pH, transparency, and fluorescence either in the surface water or in a vertical profile. When the results of these in situ measurements influence the sampling (e.g., the selection of sampling depths) precise guidelines on how to make decisions must be included in the sampling instructions. In stratified water bodies, the densities of phytoplankton and related chemical parameters can change dramatically across a vertical discontinuity. This must be reflected in the sampling strategy (see 4.2) and instructions.

The sampling equipment is selected according to the type of water body and to the sample requirements (e.g., size and integrity) for performing the analyses of the monitoring programme. It must be without risks of contaminating the sample, both from the construction materials of the sampler (adsorption and/or release of compounds) and from the previous use for sampling in other water bodies (memory effects).

Sample containers, transport and storage should not lead to any contamination or changes in the relevant chemical properties of the sample. Some precautions, depending on the nature of the contaminants to be analysed, must be taken to avoid contamination of the sample. Plastic materials except polytetrafluoroethylene (PTFE) must not be used for the samples to be analysed for hydrophobic organic contaminants (e.g., PCBs, PAHs). Samples taken for the analysis of organic contaminants must be stored in glass, PTFE or stainless steel containers. Samples collected for analysis of metals can be stored in closed plastic or glass containers. For mercury, samples must be stored in acid-washed borosilicate glass or quartz containers, as mercury can move through the walls of plastic containers. For organotins, samples are preferably stored in glass containers, but containers of other materials such as polycarbonate or aluminium are also suitable. The type of containers should always be selected after consulting the laboratory performing the chemical analyses, or the containers should be supplied by the laboratory. Depending on the parameter to be determined, specific conditioning and/or cleaning of sample containers prior to use may be required.

Sample preservation is needed in many cases to avoid loss or transformation of substances due to redox processes, degradation of organic matter, and precipitation of metals as hydroxides or evaporation of gaseous or volatile constituents.

If samples are analysed within 24 h and stored in the dark at 1-5 °C, sample composition, and hence, results of chemical analyses will not change significantly. Examples of exceptions are nutrients in low concentrations. Storage of samples at temperatures below -20 °C may allow the sample to be stored for longer time periods. However, freezing is not appropriate for volatile components. It is also necessary to remove suspended matter, algae and other micro-organisms by filtering the sample before freezing to avoid changes in dissolved concentrations of substances caused by ,e.g., disruption of cells. Moreover, the risk of precipitation of, e.g., calcium carbonate at low temperatures and other processes such as co-precipitation and colloid coagulation during freezing should be considered.

The laboratory performing the chemical analyses should agree on the procedures for preservation and storage of samples.

The sampling report should include key parameters such as date, time, location and grid reference, depth, preservation method and a unique identifier, together with any field observation made for inclusion in the reporting of the monitoring results.

5.3. Sampling of Suspended Particulate Matter (SPM)

Analysis of strongly hydrophobic organic substances in SPM can be a suitable surrogate for whole water analysis. The separation of SPM from the water can be accomplished by appropriate filtration (limited to the collection of small amounts of SPM), centrifuging either in the field or in the laboratory or by sedimentation. Commonly, filtration through 0.45 µm glass-fibre depth filters is used. The qualities and quantities of SPM collected by centrifugation, filtration or by using sediment traps differ from each other. None of these techniques allows the collection of the total amount of suspended particles. Therefore, when using SPM for analysis the sampling technique has to be indicated.

Look in:
ISO Standard Series 5667 Part 17

OSPAR JAMP Guidelines for the Estimation of Riverine PAH Inputs into the North Sea and the North-East Atlantic

These guidance documents focus mainly on river sampling but the principles can be adapted for other categories of water body. The following factors are essential in deciding on the sampling regime:

- Horizontal and vertical variations in suspended solids.
- Variations in time and space in suspended solids considering especially seasonal variations, base-flow and storm flow conditions, tidal influence and influence from primary production on suspended solids.
- The volume of sample required to minimize the error producing effects caused by inhomogeneities in the water body and to meet analytical requirements.

The sampling report should also include a descriptive comments field to allow the sampler to record the procedure undertaken on site, the appearance of the water etc.

Regarding sampling containers and sample storage for SPM, see description in chapter 5.4.

5.4. Sediment Sampling[3]

	**Look in:** ISO Standard Series 5667, Part 12, 15 and 19 OSPAR JAMP Guidelines for Monitoring Contaminants in Sediments

As a general principle, the sampling procedure should not alter the properties of the sediment (e.g., by contamination or disturbing the sample). A wide range of sampling devices is available, especially for collecting marine sediments. The choice of equipment should be made depending on the local conditions at the site of sampling, e.g., water depth and type of sediment. Box or other corers, which are capable of sampling the surface sediment without disturbing the sediment structure, are recommended. In case grab samplers are used, all precautions should be taken to limit disturbing the sediment. Retrospective temporal trend studies necessarily involve the collection of samples using a box corer or large-diameter gravity corer, or an equivalent device. Alternatively, for shallow or tidal waters, hand coring may be appropriate.

As suggested above, it is good practice to complete a sampling report, which may include a general description of collected samples including colour, homogeneity (presence or absence of stratification), presence or absence of animals (indication of bioturbation), surface structures, odour and any visible contamination (e.g., oil sheen).

The sub-sampling of sediments should preferably be performed immediately after sampling. Some precautions, depending on the nature of analysed contaminants, must be taken to avoid contamination of the sample. Samples taken for the analysis of organic contaminants must be stored in glass, polytetrafluoroethylene (PTFE) or stainless steel containers. Sediments collected for analysis of metals can be stored in closed plastic or glass containers. For mercury, samples must be stored in acid-washed borosilicate glass or quartz containers, as mercury can move through the walls of plastic containers. For organotins, storage of samples is preferably done in amber glass bottles, but containers of other materials such as polycarbonate or aluminium are also suitable. If the monitoring programme requires analysis of the fine sediment fraction, the sample should be split using appropriate sieving techniques.

Samples which are analysed within 48 h after sampling should be stored at 1-5 °C in the dark (short-term storage). For long-term storage, samples should be stored frozen, at – 20 °C or below, or dried. Freeze-drying samples at low temperature (e.g., < 10 °C) is the preferred alternative to freezing, if it can be ensured that analytes do not evaporate to a substantial degree.

5.5. Biota Sampling[3]

	**Look in:** OSPAR JAMP Guidelines for Monitoring Contaminants in Biota Manual for Marine Monitoring in the COMBINE Programme of HELCOM

Fish, mussels and seabird eggs are commonly used for monitoring of contaminants in the aquatic environment.

The natural variability within biota samples should be reduced by an appropriate sampling design, keeping in mind that age, size, sex and sexual maturity status are criteria to keep homogeneous in a given class of the sampled biota. Biota sampling should only take place when fish and bivalves are in a stable physiological state, and outside the normal period of spawning.

Fish should be collected from areas characterised by relatively low natural variability. Shellfish should preferably be collected from sub-tidal regions, or as near to the same depth and exposure (i.e. in terms of light and wave action) as possible in order to reduce variability in contaminant uptake.

Fish can be sampled from either research vessels or commercial vessels. In both cases, several precautions must be taken to reduce contamination. Clean containers should be available on deck to hold the samples temporarily before they are taken to the ship's laboratory. Personnel should wear clean gloves, free of the contaminants to be analysed, when collecting mussels by hand and when fish are taken from the net. Where appropriate, biota samples should be rinsed with water to remove any material adhering to the surface. When collecting mussels by ship, a commercial mussel dredge can be used.

Freezing of samples will degrade soft tissues. Therefore, sub-samples of particular tissue for analysis should be drawn immediately after catching the fish and immediately deep-frozen. Mussels should be depurated and cleaned prior to preservation and analysis. Dissection must be done under clean conditions on a clean bench by trained personnel, wearing clean gloves and using clean stainless steel knives. The use of blades made of ceramics or titanium is recommended to reduce the risk of Cr and Ni contamination. The soft tissue samples should be analysed immediately or stored at temperatures below – 20 °C.

Biological samples to be used for analysis of organic contaminants should be stored frozen e.g., wrapped in pre-cleaned alumina foil in suitable containers of glass, stainless steel or alumina. Plastic material, except PTFE, must not be used.

For metal analysis, biota samples should be wrapped separately in suitable material (e.g., polyethylene or PTFE) and frozen. Sub-samples (e.g., liver) should be stored in suitable acid-cleaned containers, preferably of glass, and frozen or freeze-dried immediately.

6. TECHNIQUES FOR ANALYSIS

Article 8, Paragraph 3 of the WFD requires that "technical specifications and standardised methods for analysis and monitoring of water status shall be laid down in accordance with the procedure laid down in Article 21". Moreover, Annex V.1.3.6 of the WFD states that the standards for monitoring of quality elements for physico-chemical parameters shall be "*any relevant CEN/ISO standards or such other national or international standards which will ensure the provision of data of an equivalent scientific quality and comparability*".

The strengths of such methods are that they are well established and have often been subjected to collaborative trials to give an illustration of their interlaboratory comparability and applicability. They may not represent the current state of the art in all cases, and usually, represent a compromise in performance that is tailored to a number of different users' goals and operational needs.

In general, performance-based methods shall be used in surveillance and operational monitoring. They shall be described clearly, properly validated[11] and where possible leave laboratories the flexibility to select from several options. Irrespective of what method is applied in chemical monitoring certain minimum performance criteria have to be met, which are laid down in the Final Draft "Commission Directive laying down, pursuant to Directive 2000/60/EC of the European Parliament and of the Council, technical specifications for chemical analysis and monitoring of water status", and discussed in the framework of the EAQC-WISE project[12].

According to this draft commission Directive the laboratories may select any analytical method of their choice for the purpose of monitoring under Article 8 and Annex V of the Directive 2000/60/EC provided they meet the minimum performance criteria set out in this document or by the national competent authorities.

Laboratories can consult chapter 6.5 and Annex II to identify suitable methods for monitoring of priority substances and other pollutants. Available certified reference materials relevant to WFD monitoring[13] are listed in Annex III. The Annex III was elaborated within the EU-project EAQC-WISE[12] .

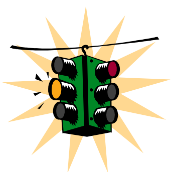
[11] see e.g., the protocols for method validation developed within the NORMAN network, funded under the 6th RTD Framework Programme, European Commission, http://www.norman-network.com.
[12] EAQC-WISE project, funded under the 6th RTD Framework Programme, European Commission, http://www.eaqc-wise.net/
[13] Bercaru, B. Gawlik, F. Ulberth, C. Vandecasteele (2003) Reference materials for the monitoring of the aquatic environment - a review with special emphasis on organic priority pollutants. Journal of Environmental Monitoring 5, 697-705.

6.1. Method Performance Criteria

Look in:
Final Draft "Commission Directive laying down, pursuant to Directive 2000/60/EC of the European Parliament and of the Council, technical specifications for chemical analysis and monitoring of water status"

Minimum performance criteria have been defined for the limit of quantification (LOQ) and the measurement uncertainty U (expanded uncertainty of measurement). They are, where possible, linked to the EQS. In the following chapters 6.1.1/6.1.2 guidance will be given on how to determine/estimate these parameters in a pragmatic way.

If no suitable analytical method is available that meets these minimum performance criteria for a particular priority substance, e.g., tributyltin compounds or short-chain chloroalkanes, Member States shall ensure that monitoring is carried out using best available techniques not entailing excessive costs. The use of more resource intensive methodologies, if these can provide the needed performance, at reduced frequencies, is encouraged in these cases.



Look out!
The mandate M/424 for standardisation adressed to CEN for the development or improvement of standards in support of the Water Framework Directive including methods for the analysis of tributyltin compounds, polybrominated diphenyl ethers, polynuclear aromatic compounds, C_{10}-C_{13} chloroalkanes, and organochlorine pesticides in water has been adopted.

6.1.1. Uncertainty of Measurement[14,15,16,]

According to ISO guide 99[17], measurement uncertainty has been defined as *'a non-negative parameter characterising the dispersion of the quantity values being attributed to a measurand, based on the information used'*.

Measurement uncertainty (U_m) is typically expressed as a laboratory result ± the measurement uncertainty.

U_m should normally be expressed as the combined expanded uncertainty using a coverage factor k = 2 where k is a numerical factor used as a multiplier of the combined standard uncertainty in order to obtain an expanded uncertainty. This provides a confidence level of approximately 95 %.

[14] Nordtest Report TR537. Handbook for calculation of measurement uncertainty in environmental laboratories, 2nd Edition, 2004.
[15] EURACHEM/CITAC Guide: "Quantifying Uncertainty in Analytical Measurement", 2nd Edition, 2000
[16] ISO/IEC "GUM" (with BIPM, IFCC, IUPAC, IUPAP, OIML): "Guide to the expression of uncertainty in measurement", 1993.
[17] ISO guide 99 International vocabulary of metrology - Basic and general concepts and associated terms (VIM), ISO/IEC 2007

The ability to provide a measurement uncertainty is a requirement of ISO 17025, and hence, is necessary for laboratories providing analytical results for the WFD. The knowledge of the measurement uncertainty is also important to confirm that the limit of quantification is equal to or less than that required.

It should be noted that whichever method is used to obtain a value for the measurement uncertainty, the value obtained will always only represent an estimate of the true spread of possible results. The method selected for estimating the measurement uncertainty should be chosen so as to include as many principal sources of contributing errors as possible.

Detailed guidance on the statistical and practical approaches available for estimating the measurement uncertainty can be obtained from the references below.

In general, two possible approaches to estimating measurement uncertainty can be used, either separately or as complementary techniques.

Bottom-up Approach

Firstly, a detailed analysis of the contributing errors from each of the methodological elements can be undertaken. This requires a stepwise analysis of each of the principal causes of measurement uncertainty in the analytical process followed by an estimation of their individual contribution of possible error. Examples of the potential principal causes of error are measurements of mass and volume, instrumental variability and the imperfect correction of systematic errors. Potential sources of data to inform this estimation of measurement uncertainty are within laboratory calibration records for subsidiary equipment such as glassware and balances, instrument repeatability data, data on calibration standard purity etc. This general overall approach of summing individual errors can lead to an underestimation of the measurement uncertainty due to the risk of overlooking an important contributing element. However, knowledge of the magnitude of the contributing errors from each step or process in the analytical method can be helpful to identify the significant errors and target any improvement activities at the most significant sources of error contributing to the overall measurement uncertainty.

Top-down Approach

The second approach of estimating measurement uncertainty is to use data from the analysis of certified reference materials, routine control samples, or interlaboratory trials. Care should be taken to ensure that the control samples include all the analytical steps for the test method. As part of this consideration, any significant bias component to the overall error that is not included within the control samples should also be accommodated into the calculation. Any bias indicated from interlaboratory trials should also be included into the overall estimate of measurement uncertainty.

The measurement uncertainty will vary across the concentration range of the analytical method. Where the range of application of the analytical method is large and there are a number of key threshold values for the analytical results within that range, it may be necessary to estimate the measurement uncertainty at different concentration values. This can be undertaken by dividing the method analytical range into a series of representative sections and estimating the measurement uncertainty for each of them. Alternatively, the measurement uncertainty for any given concentration can be calculated by obtaining values for it at a number of different concentrations, and then, using this data to graphically plot change with concentration and subsequently deriving an equation for change in uncertainty against concentration.

6.1.2. Limit of Detection/Limit of Quantification[18]

6.1.2.1 Limit of Detection

As the concentration of a substance being measured approaches the lower capabilities of the analytical system, it becomes increasingly difficult to distinguish the sample response from background noise. The analyst's confidence that the measurand is actually present diminishes and the consequent risk of reporting a false positive value or failing to detect the presence of a measurand increases.

Therefore, by convention analytical results below this lower confidence limit are referred to as less than the limit of detection. There has historically been a range of definitions for limit of detection. However, the limit of detection is now commonly defined as the concentration of a substance for which there is an adequately high probability of detection when making a single analytical measurement.

It is important to recognise that the value obtained by either calculation will only ever be an estimate of the 'true' limit of detection. If only a few replicates are used in the following calculations, the uncertainty in the value obtained for the limit of detection can be very high. Undertaking more measurements increases the confidence in the limit of detection value obtained, but typically 10 or 11 degrees of freedom are taken as satisfactory. For example, if a limit of detection is calculated with 11 degrees of freedom, an observed limit of detection of 1 could correspond to a 'true' value of any value between 0.7 and 2.0.

Therefore, caution should be used when comparing values for limit of detection from different laboratories or methodologies as an apparently 'better' limit of detection may not be significantly different from an alternative.

Calculation of the Limit of Detection

The limit of detection may be calculated as follows:

$$LOD = 3 * sbl$$

where sbl is the standard deviation of the blank in the signal domain.

A number of separate analyses are undertaken of a real sample containing concentrations of the measurand at or near the blank level and the total standard deviation of the blank corrected results calculated. In order to obtain a reasonable estimate of the LOD, it is preferable to base the calculation on 10 or more measurements of the signal response for the blanks.

[18] WRC report NS30 (1989) A Manual on Analytical Quality Control for the Water Industry. ISBN 0902156853

Chromatographic Analyses
Measurement of blank concentrations in some analytical techniques can be difficult as the instrumental software or hardware may impose peak detection threshold values or peak smoothing algorithms etc., which suppress small signals. This occurs most often for chromatographic methods. When this situation is encountered, it is normal to artificially increase the signal using one of the following methods:

- Use a real sample containing a very low, but measurable concentration of the analyte.
- Fortify a sample that contains no analyte to a very low, but measurable concentration.
- Dilute a sample extract containing a higher concentration of the analyte to achieve the required very low but measurable concentration.

It should be noted that when uncorrected blank signals are used to calculate the limit of detection, increasing the absolute concentration of the blank as above will inevitably produce a higher value for the estimate of the limit of detection.

6.1.2.2 Limit of Quantification
Within the normal range of application of an analytical method, as the concentration of a substance undergoing measurement decreases, there is a tendency for the uncertainty in the results obtained to increase. In principle, it is possible to quote any analytical result and an associated uncertainty of measurement. However, at the lower reaches of an analytical system's capability the uncertainty of measurement increases to a degree such as to make interpretation of the subsequent data difficult. Therefore, a limit of quantification is used to express the concentration at which the accuracy is satisfactory for quantitative measurement.

Definition of Limit of Quantification The Limit of Quantification means a stated multiple of the limit of detection at a concentration of the determinand that can reasonably be determined with an acceptable level of accuracy and precision. The limit of quantification can be calculated using an appropriate standard or sample, and may be obtained from the lowest calibration point on the calibration curve, excluding the blank;
LOQ should be determined experimentally following the procedure given in 6.1.2.1.

6.2. Water Analysis

According to the European Parliament legislative resolution of 17 June 2008 on the Council common position with a view to the adoption of a directive of the European Parliament and of the Council on environmental quality standards in the field of water policy and amending Directives 82/176/EEC, 83/513/EEC, 84/156/EEC, 84/491/EEC, 86/280/EEC and 2000/60/EC (11486/3/2007 – C6-0055/2008 – 2006/0129(COD)), EQS are expressed as total concentrations in the whole water sample except for cadmium, lead, mercury and nickel. The EQS for metals refers to the dissolved concentration measured in the liquid (dissolved) fraction of a water sample obtained by filtration through a 0.45 µm filter.

This implies reporting monitoring results except for metals as whole water concentrations. Whole water data may be generated by analysis of the whole water sample, or by separate analyses of the liquid and SPM fractions.

Unfortunately, most available analytical methods have not been validated for water samples containing substantial amounts of SPM. This can result in incomplete extraction of hydrophobic organic contaminants adsorbed to SPM, and thus, to an underestimation of the whole water concentration. Specific information whether methods can be applied to the analysis of SPM containing samples can be found in the substance guidance sheets (Annex II).

The SPM content of the water sample is not critical for the analyses of polar and highly water soluble compounds such as some pesticides (e.g., alachlor, atrazine, simazine, diuron, isoproturon) and volatile compounds (benzene, dichloromethane, 1,2-dichloromethane, trichloroethane, tetrachloroethene, trichloroethene, tetrachloromethane, trichlorbenzene, naphthalene). Those compounds can be analysed in the whole water or in the filtered sample.

In case of hydrophobic compounds, which strongly adsorb to particles, including e.g., pentabromodiphenylether or 5 and 6 ring polycyclic aromatic hydrocarbons special care is required to ensure complete extraction of the particle bound fraction. Separate analysis of SPM and of the liquid could be a good option. If it can be justified, for example by considerations of expected contaminant partitioning, analysis of the SPM fraction as surrogate for whole water may be appropriate. Nevertheless, in water bodies with extremely low SPM content (e.g., < 3 mg/L) the dissolved fraction of those contaminants has to be determined.

Dependent on the SPM content of the sample and its organic carbon content, medium polar compounds can adsorb in varying amounts to SPM. In such cases, both fractions (dissolved and adsorbed concentrations) have to be considered.

For the determination of dissolved metal concentrations water samples have to be passed through a membrane filter of 0.45 µm pore size. In principle and if possible, this filtration should be done in the field to prevent changes during transportation and subsequent storage due to adsorption processes etc. It is essential to ensure that filters are clean and to pre-clean them, if necessary. In addition, filters should be pre-washed with small sample volumes before collecting the filtrate for metal analysis. If possible (in the light of health and safety instructions), the filtrate shall be acidified with nitric acid to ensure that the pH is less than 2. For more information consult the respective substance guidance sheets and the methods referred to therein.

Bioavailable metal concentrations depend on various parameters including pH, Ca and Mg concentrations, as well as dissolved organic carbon concentration. Hence, measuring these parameters in parallel with the metals can assist in the interpretation of results, where appropriate. In case of cadmium, the measurement of hardness is mandatory because EQS values have been derived for five classes of hardness.

6.3. Sediment/SPM Analysis[3]

With the exception of PBDE, there are no standardised methods specifically developed for the analysis of sediments/SPM available for priority substances likely to be found in sediment. However, existing standard methods for soil analysis summarized in Annex I may probably be applied to sediments with or without slight modification.

Comprehensive guidance on the analysis of marine sediments including sample pre-treatment, storage, and normalisation is given in OSPAR JAMP Guidelines for Monitoring Contaminants in Sediments.

	**Look in:** OSPAR JAMP Guidelines for Monitoring Contaminants in Sediments

In general, < 2 mm fraction of the sediment should be analysed for organic contaminants while the less than 63 µm fraction should be analysed for metals. If the specific purpose of the monitoring requires analysis of the fine sediment fraction, the sample should be split using appropriate sieving techniques[19].

The degree of accumulation of a contaminant depends on the sediment and SPM characteristics (grain size, composition and surface properties). It is essential to compare analytical results from sediments and SPM with similar properties or to compare normalised results to assess the degree of contamination. Therefore, particle size analyses, measurements of organic carbon content or measurement of other common normalisation parameters, such as Li and Al are advised. Detailed guidance for sediments on the use of normalizing parameters is given in Annex 5 of the JAMP Guideline for Monitoring Contaminants in Sediments.

For sediments, measurements of the two operationally defined parameters Acid Volatile Sulfides (AVS) and Simultaneously Extractable Metals (SEM) can provide information on the bioavailability of metals, although guidance on the interpretation of AVS is still in preparation in the EU EQS Technical Guidance – Metals section.

6.4. Biota Analysis[3]

At present, formally approved standard methods for the analysis of priority pollutants and other contaminants in biota are scarce and only available for metals, PAH, PCB and some other organic contaminants.

Comprehensive guidance on the analysis of marine biota (seabird eggs, fish, shellfish) including selection of species and suitable tissue, sampling, sample pre-treatment and storage is given in OSPAR JAMP Guidelines for Monitoring Contaminants in Biota.

	**Look in:** OSPAR JAMP Guidelines for Monitoring Contaminants in Biota Manual for Marine Monitoring in the COMBINE Programme of HELCOM

Most organic contaminants accumulate in the lipid tissue of the species studied. Therefore, concentrations should be provided on lipid weight basis as well as weight basis or the lipid

[19] Smedes, F., Davies, I.M., Wells, D., Allan, A., Besada, V.: Quality assurance of sampling and sample handling (QUASH). Interlaboratory study on sieving and normalisation of geographically different sediments; QUASH Round 5 – August 2000. QUASH report, QUASH Project Office, FRS Marine Laboratory, PO Box 101, Victoria Road, Aberdeen, AB11 9DB, GB

content of the sample should be provided together with the analytical results. It is important to state whether total lipids or extractable lipids have been determined and the method for lipid determination should be specified. Whether or not a normalisation should be performed has to be adjusted to the objective of the monitoring.

6.5. Substance Guidance Sheets

According to the Final Draft "Commission Directive laying down, pursuant to Directive 2000/60/EC of the European Parliament and of the Council, technical specifications for chemical analysis and monitoring of water status", laboratories may select any analytical method of its choice for the purpose of monitoring under Article 8 and Annex V of the Directive 2000/60/EC, except for operationally defined parameters, provided they meet the minimum method performance criteria.

To assist Member States in selecting appropriate methods, substance guidance sheets are provided as an Annex II to this guidance document, summarising basic information on physico-chemical properties of each substance and preliminary environmental quality standards expressed as annual average, AA-EQS, or expressed as maximum allowable concentration, MAC-EQS, respectively, for inland and other surface waters. Available EN or ISO standard methods for the analysis in water, and where appropriate, in sediment or biota, are specified including information on sampling, storage and pre-treatment, performance characteristics and a short description of the principle. Where required other analytical methods are mentioned and respective references given. For laboratories wishing to undertake their own method surveys important links to websites providing information on standardised analytical methods are given in Table 1.

6.6. Group Parameters and Definition of Indicator Substances

Some substances of interest are described in generic terms only. These generic substances may be composed of a finite number of isomeric forms where the potential number of different individual isomers can range from 2 (e.g., Endosulfan) to more than 200 (e.g., polybrominated diphenylethers) of which only a few are of environmental relevance. Moreover, it is often difficult or impossible to analyse all those isomers. Hence, analysis of indicator substances representative for the entire group is common practice. Indicator substances, which have to be analysed have been specified in the Position of the European Parliament adopted on 17 June 2008 on the Council common position with a view to the adoption of a directive of the European Parliament and of the Council on environmental quality standards in the field of water policy and amending Directives 82/176/EEC, 83/513/EEC, 84/156/EEC, 84/491/EEC, 86/280/EEC and 2000/60/EC (11486/3/2007 – C6-0055/2008 (Table 2).

Table 2: Components of Group Parameters and Indicator Substances

Priority Substance	Recommended Components	Comments
Chlorpyrifos	Chlorpyrifos–ethyl	
Endosulfan	α-Endosulfan and ß-Endosulfan	Total concentration to be reported.
Pentabromodiphenyl Ether	BDE congener numbers 28, 47, 99, 100, 153, 154	These congeners constitute approximately 85 % of technical Penta – BDE formulations; Total concentration to be reported.
Hexachlorocyclohexane	α, β, γ, and δ-isomer*	Total concentration to be reported.
C10-13 Chloroalkanes	All C_{10} to C_{13} chlorinated paraffins (49 % to 70 % Chlorine)	Total of all isomers to be reported. Measurement will usually be done against a technical mixture.
Nonylphenol	All *4*-nonylphenol isomers present**	Total concentration of all para isomers to be reported.
Octylphenol	para-tert-Octylphenol***	
PAH	Benzo[b]fluoranthene/ Benzo[k]fluoranthene	Total concentration to be reported. Benzo[j]fluoranthene interferes with the determination of either Benzo [b]fluoranthene or Benzo[k]fluoranthene
Trichlorobenzenes (all isomers)	*1,2,3-*, *1,2,4-* and *1,3,5-*trichlorobenzene	Total concentration to be reported.
DDT total	*p,p'*-DDT, *o,p'*-DDT, *p,p'*-DDE, *p,p*'-DDD	Total concentration and concentration of *p,p'*-DDT to be reported.

* The CAS number 608-73-1 refers to technical HCH, hence, all relevant isomers have to analysed for

** Technical nonylphenol consists mainly (~ 90 %) of para-substituted nonylphenols and comprises theoretically 211 isomers; only 4-nonylphenols are of toxicological relevance

*** Octylphenol (CAS No 140-66-9) is a single isomeric compound: 4-(1,1',3,3'-tetramethylbutyl)-phenol (4-tert-octylphenol)

Although it is possible to calculate the value of a group parameter from its individual components, the interpretation of this value as regards EQS compliance may pose several practical difficulties with respect to the generation and interpretation of data. Principal amongst these difficulties is the uncertainty associated with a group parameter. If the group parameter comprises two substances that are present at equal concentrations, and the standard uncertainty of each substance is 10 %, the standard uncertainty of the sum of their concentrations will be 14 %. If, on the other hand, one concentration greatly predominates over the other, the standard uncertainty of the sum remains near to 10 %. If, for a similar example, there are 6 components of the group, the standard uncertainty could vary between 25 % and 10 % depending on whether the concentrations are similar, or if one is much larger than all the others. This dependency of the uncertainty on the number of components comprising a group and on their concentrations requires consideration when deriving requirements on measurement uncertainty for group parameters and their components.

6.7. Results below the Limit of Quantification

For the calculation of annual average concentrations, values below the limit of quantification shall be set to half of the value of the limit of quantification concerned. If the resulting annual average concentration is below the limits of quantification, the value shall be referred to as 'less than limit of quantification'.

This rule does not apply to total sums of a given group of substances. In those cases, results below the limit of quantification of the individual substances/isomers shall be set to zero.

	**Look in:** Final Draft “Commission Directive laying down, pursuant to Directive 2000/60/EC of the European Parliament and of the Council, technical specifications for chemical analysis and monitoring of water status”

7. COMPLEMENTARY METHODS[20,21]

7.1. Introduction

While checking compliance with the WFD provisions is currently based on chemical analysis of spot samples taken in a defined frequency, it is desirable to introduce other techniques for improving the quality of the assessment and to benefit from resource saving developments, as they become available. Currently advanced methods for environmental assessment (referred to as 'complementary methods in this chapter') are under development and evaluation.

[20] This chapter was elaborated in close cooperation with the EU-project SWIFT (www.swift-wfd.com).
[21] Allan, I. J., Vrana, B., Greenwood, R., Mills, G. A., Roig, B., Gonzalez, C. (2006) A “toolbox” for biological and chemical monitoring requirements for the European Union’s Water Framework Directive. Talanta 69, 302-322.

Examples of techniques are:

- In-situ probes for measuring physico-chemical characteristics (e.g., Dissolved Organic Carbon (DOC), pH, temperature, dissolved oxygen)

- Biological assessment techniques (e.g., biomarker analyses, bioassays/biosensors and biological early warning systems, immunosensors, etc.)

- Sampling and chemical analytical methods (e.g., sensors, passive sampling devices, test kits (see e.g., ISO 17381:2003 Water quality - Selection and application of ready-to-use test kit methods in water analysis), GC-MS or LC-MS screening methodologies)

Two types of complementary methods – (1) equipment for measuring physico-chemical characteristics and (2) chemical analytical methods – usually yield direct measures of the quality elements as defined in the WFD.

The third type – biological assessment techniques – are designed to respond to a wide range of (chemical) stressors, and are therefore, not exclusively linked to individual quality elements such as the different priority substances. Although very useful for many monitoring purposes, they cannot be used to check compliance of individual quality elements against an EQS.

These analytical and biological methods, as well as in-situ sampling techniques, are summarised in the table below. This table aims to provide simple guidance in the use of these tools, with a particular focus on typical indicators monitored, the type and relevance of the information obtained and a selection of performance criteria for these tools. Performance criteria tend to depend on the technique or method selected, and more importantly, on the type of information required. For example, performance criteria for the laboratory-based analysis of extracts from passive sampling devices are mostly similar to those for more conventional spot sampling[22]. Additional performance criteria for passive sampling are the result of (i) the requirement for accurate uptake rates to be used in the calculation of time-weighted average contaminant concentrations in water, and (ii) the in-situ field deployment that needs to follow relatively strict protocols[23] to ensure that data obtained are fit-for-purpose. A few examples of these techniques, some of them either well-known (e.g., the measurement of metallothionein in aquatic organisms upon exposure to trace metals) or tested during the SWIFT-WFD project[24] (e.g., the Multi-species Freshwater Biomonitor that allow real-time monitoring of changes in water quality based on physiological and behavioural monitoring of aquatic organisms) are given. These methods may be able to provide additional weight-of-evidence, mostly in cases where additional information on chemical quality or links between chemical and biological data is required. This is particularly important for situations that do not involve only comparisons with EQS (e.g., investigative monitoring). Scenarios for the efficient use of these tools and techniques are also given and support the possible uses described in section 7.2.

7.2. Applications of Complementary Methods in WFD Monitoring

Use of Complementary Methods in the Design of Monitoring Programmes
Complementary methods can be used in the design of monitoring programmes for:

- Identification of problem as well as non-problem areas, e.g., by using screening methods (test kits) or passive sampling devices
- Selection of monitoring points, e.g., in the grouping of water bodies for operational monitoring complementary methods may be used to demonstrate the representativeness of sampling points.
- Selection of quality elements, e.g., the selection of other pollutants that are part of the ecological status. Information derived from bioassays and toxic identification and evaluation (TIE) may be used to select compounds based on ecological relevance.
- Justification of a reduction in sampling frequency, e.g., the use of sensors as screening tools. Sampling for chemical analysis with a validated method is triggered by a response of a sensor above a certain threshold. In that case, validation of the sensor can be limited to a performance criterion for false negative responses.

Use of Complementary Methods in Surveillance and Operational Monitoring
Complementary methods can be used in surveillance and operational monitoring provided that they meet the requirements laid down in the Final Draft "Commission Directive laying down, pursuant to Directive 2000/60/EC of the European Parliament and of the Council, technical specifications for chemical analysis and monitoring of water status".

Complementary methods may be used in surveillance monitoring to detect long-term changes. Biological assessment techniques can be used as a sum parameter to screen for the presence of substances in ecologically relevant concentrations. Passive samplers could be used alongside spot sampling in order to corroborate or contradict spot sampling data. This would be important weight-of-evidence for water bodies where contaminant concentrations are expected to show large temporal variation or when the contaminant source fluctuates.

Passive samplers (e.g., Semi-Permeable Membrane Devices (SPMD), Polar Organic Chemical Integrative Samplers (POCIS), Diffusion Gradient Thin Films (DGTs), Chemcatcher) are exposed in the aquatic environment for several days or up to weeks to yield time-integrated average concentration of organic contaminants or heavy metals. Passive sampling is less influenced by short-term fluctuations in concentrations than spot sampling. Since one of the primary objectives of the WFD is the assessment of the average concentrations of pollutants in water bodies, the determination of time-integrated concentrations using passive samplers seems to be a promising approach. Some of the passive samplers have been validated and provide high sampling rates (litre/day) for various contaminants (e.g., organic compounds of medium hydrophobicity, heavy metals), and thus, allow quantification of extremely low pollution levels in water[23]. This is a first step towards an internationally recognized standard.

Passive sampling can also be combined with ecotoxicology, where the extracts from the passive monitors are passed through multiple toxicological tests in a laboratory. This will enable assessment of the effects of a mixture of contaminants from an environmental monitoring point over a period of time. This integration of exposure and effects monitoring will facilitate more cost effective monitoring programmes as well as forming the basis of a risk based pollution control strategy.

Difficulties encountered include bio-fouling, back-calculating to water concentration and calibration. Thus, further research and validation is required before using this technology for compliance checking.

Passive samplers sample the freely-dissolved bioavailable water concentrations. Results may, therefore, deviate from the total water concentrations measured in spot samples. It may be possible, if average values for the levels of DOC, SPM and TOC content of the SPM are known, to use partitioning theory and $LogK_{oc}$-$logK_{ow}$ relationships to estimate the total concentrations with uncertainties for all assumptions made accounted for.

Use of Complementary Methods in Investigative Monitoring

The main goals of investigative monitoring are to identify the reason for any failure to achieve environmental objectives, in circumstances where the reason is unknown and to ascertain the magnitude and impact of accidental pollution.

For both purposes, test kits including, e.g., immunoassays specific to certain priority substances or other pollutants allow fast screening of large number of samples and can be cost-effective tools to identify pollution sources as well as to characterise the extent of accidental pollution.

Passive sampling devices might be of use in identifying sources of pollution, in particular, if extremely low levels have to be detected or when the source of pollution is not constant.

In case of MAC-EQS exceedance, investigative monitoring should be used to ascertain this non-compliance in more detail. Both, spot sampling and time-integrated measurements may not detect acutely toxic spikes of seasonally-variable compounds like pesticides; the use of *in situ* bioassays may be beneficial. These biological early warning systems also have the potential to help identify compounds that may need to be included in future risk assessments.

Table 3: A list of complementary methods relevant to WFD chemical monitoring including method performance criteria

Technique	Analytical Methods			*In-situ* Sampling Techniques		Biological Methods		
	Lab	**On-site**	***In-situ***	**Biomonitoring**	**Passive sampling**	**Direct toxicity assessment**	**Biological Early warning system**	**Biomarkers**
Examples	Immunoassay (e.g., atrazine), test kits, hand-held sensors (e.g., Palmsens)			MusselWatch programmes	Semi-permeable membrane device (SPMD), Chemcatcher	Daphtoxkit®	Mosselmonitor®, multi-species freshwater biomonitor	Measurement of metallothionein synthesis
Measurement	Analyte (operationally-defined) concentration or ranges of concentrations, general physico-chemical characteristics			Indicator of exposure to bioavailable analytes	Time-weighted average & operationally-defined analyte concentrations (truly dissolved and labile fractions for organic and metal contaminants, respectively)	(Non)-specific (e.g., genotoxicity) acute/chronic toxicity in water/sediment	Real-time monitoring of acute toxicity in an organism	Chemical and biological indicators of non-specific or specific exposure or effects of contaminants in water and sediments
Type of information obtained	Qualitative, semi-quantitative, quantitative			Semi-quantitative, qualitative	Qualitative, semi-quantitative or quantitative	Qualitative	Qualitative	Qualitative
Performance criteria	- LOD - LOQ - Calibration, quantification range				- LOD, LOQ (field) - Bias - Sensitivity		- Levels of false positives and negatives	
Implementation	- Rapid and/or on-site determination of concentrations, or screening of levels - Mapping of an area - Selection of samples for more accurate laboratory-based analysis			- Linking ecological and chemical information - Linking concentration with exposure and effects	- Assess long-term changes and trends in pollutant concentrations - Extrapolate total and total filtered concentrations - Screening for contaminant presence/absence - Metal speciation	- Detect adverse biological effects to indicate where operational or investigative monitoring required	- Early warning of changes in water quality at crucial sites - Detect and assess significant pollutant for updating risk assessments	- Early detection of biological imbalance - Linking ecological and chemical information - Linking concentration with exposure and effects
Applicable to:	Operational & investigative monitoring			Operational & investigative monitoring	Surveillance, operational & investigative monitoring	Operational & investigative monitoring	Operational & investigative monitoring	Operational & investigative monitoring

ANNEX I: List of ISO Standards for soil analysis

ISO 11465:1993	Soil quality - Determination of dry matter and water content on a mass basis - Gravimetric method
ISO 11466:1995	Soil quality - Extraction of trace elements soluble in aqua regia
ISO 11277:1998	Soil quality - Determination of particle size distribution in mineral soil material - Method by sieving and sedimentation
ISO 10694:1995	Soil quality - Determination of organic and total carbon after dry combustion (elementary analysis)
ISO 14869-1:2001	Soil quality - Dissolution for the determination of total element content - Part 1: Dissolution with hydrofluoric and perchloric acids
ISO 11047:1998	Soil quality - Determination of cadmium, chromium, cobalt, copper, lead, manganese, nickel and zinc - Flame and electrothermal atomic absorption spectrometric methods
ISO 14507:2003	Soil quality - Pretreatment of samples for determination of organic contaminants
ISO 14154:2005	Soil quality - Determination of some selected chlorophenols - Gas-chromatographic method with electron-capture detection
ISO 15009:2002	Soil quality - Gas chromatographic determination of the content of volatile aromatic hydrocarbons, naphthalene and volatile halogenated hydrocarbons - Purge-and-trap method with thermal desorption
ISO 16772:2004	Soil quality - Determination of mercury in aqua regia soil extracts with cold-vapour atomic spectrometry or cold-vapour atomic fluorescence spectrometry
ISO 22155:2005	Soil quality - Gas chromatographic quantitative determination of volatile aromatic and halogenated hydrocarbons and selected ethers - Static headspace method
ISO 11264:2005	Soil quality - Determination of herbicides - Method using HPLC with UV-detection
ISO 10382:2002	Soil quality - Determination of organochlorine pesticides and polychlorinated biphenyls - Gas-chromatographic method with electron capture detection

Available Standard Method
EN ISO 10695:2000
Determination of selected organic nitrogen and phosphorus compounds - Gas chromatography methods [*Note: Alachlor is not explicitly mentioned in this standard but the method may also be applied to the analysis of alachlor provided the method has been properly validated for this compound*].

Matrix Drinking waters, ground waters, surface waters and waste waters containing up to 50 mg/L of suspended solids

Sampling *ISO 5667-2:1991*

Pretreatment

Storage

Method Description

Liquid/liquid extraction with dichloromethane or liquid/solid extraction (SPE) on reversed-phase (RP)-C18 material or other adsorbent. Elution of the cartridges with e.g. methanol or acetone.
After concentration, the sample extracts are analysed by gas chromatography, using a nitrogen-phosphorus or mass spectrometric detector.

Limit of Quantification (LOQ): 0.04 µg/L

Method Validation: no data available

Other Analytical Methods

SPE-GC-MS
Separation by gas chromatography, identification and quantification of the analyte by gas chromatography coupled to mass spectrometric detection (GC-MS) using electron impact (EI) mode.
GC-MS fragment ions: m/z 160, 188, 161 and 146 [1-3]
SPE extraction of 500 mL water; LOQ ~ 12 ng/L [1]
SPE extraction of 1 L water; LOQ ~ 3 ng/L [2]
SPE extraction of 200 mL water; LOQ ~ 30 ng/L [3]

GC-NPD
EPA method 507 [4]

LC-ESI-MS/MS
C18 SPE of 50 mL water; MRM 270 > 161.5; LOQ ~ 0.1 µg/L [5]

On-line SPE-LC-MS-MS
On-line SPE of 10 mL samples; MRM 270 > 238; LOQ ~ 47 ng/L [6]

Available Standard Method

No standardised method for the determination of PBDE in water available

ISO 22032:2006
Determination of selected polybrominated diphenylethers (PBDE) in sediment and sewage sludge - Method using extraction and gas chromatography/mass spectrometry

Matrix Sediment

Sampling *ISO 5667-13*

Pretreatment homogenizing, freezing and freeze-drying, grind and sieve it

Storage at 4 °C in the darkness in wide necked bottles

Method Description

ISO 22032:2006 specifies a method for the determination of selected PBDEs representative for penta-, octa-, and decaBDE technical formulations in sediment using gas chromatography/mass spectrometry in the electron impact or electron capture ionisation mode. Extraction of PBDEs from the dried sample by an organic solvent is followed by clean-up of the extract by e.g. multi-layer silica gel column chromatography. For quantification an internal standard calibration is applied.

Limit of Quantification (LOQ): When applying GC-EI-MS, the method is applicable to samples containing 0.05 µg/kg to 25 µg/kg of tetra- to decabromo congeners. Approximately ten times lower concentrations can be quantified when using GC-ENCI-MS.

Method Validation

l Number of laboratories
n_{AP} percental rate of outliers
$\bar{\bar{x}}$ Total mean after elimination of outliers
s_R standard deviation between the laboratories
CV_R reproducibility variation coefficient

Interlaboratory Study 2004/2005

Matrix	*Substance*	*l*	n_{AP} in %	$\bar{\bar{x}}$ in µg/kg	s_R in µg/kg	CV_R in %
Sediment	BDE 47	16	0	362	50.5	14.0
	BDE 100	16	0	93.3	28.96	31.0
	BDE 99	16	0	518	99.6	19.2
	BDE 154	16	0	39.2	9.11	23.2
	BDE 153	16	0	47.7	9.28	19.5

Other Analytical Methods

Numerous studies of PBDEs in environmental samples are based on the determination by gas chromatography/mass spectrometry in the electron impact or negative ion chemical ionisation mode [1].

U.S. EPA Method 527 employs solid-phase extraction with analysis by gas chromatography/ mass spectrometry as described in PEPICH et al. 2005 [2], but MDL is fairly high (0.39 µg/l).

EPA Method 1614, 2007 [3] applies HRGC/HRMS for the analysis of PBDE in water, soil, sediment and tissue. MDL for BDE 99 is 0.00004 µg/l.

Comments

There are a few reports on extremely low levels of PBDEs in surface water samples [4,5]. The authors enriched 100 and 2500 L of water, respectively, on XAD resin. SPME has been proposed to extract selected BDE congeners from water samples by POLO et al. 2004 [6].

Environmental studies conducted primarily in Europe, Japan and North America indicate that these chemicals are ubiquitous in sediment and biota [7].

Application of inductively coupled plasma mass spectrometry (ICP-MS) - Part 2: Determination of 62 elements

Matrix Drinking waters, ground waters, surface waters and waste waters

Sampling *ISO 5667-1, 5667-2 and 5667-3*

Pretreatment For dissolved elements, filter aqueous sample through a 0.45-µm pore membrane filter. Adjust the pH of the filtrate to < 2 with HNO_3.

Storage

Method Description

EN ISO 17294-2:2004 specifies a method for the determination of the cadmium in water (for example drinking water, surface water, groundwater, wastewater and eluates). Taking into account the specific and additionally occurring interferences, these elements can also be determined in digests of water, sludges and sediments.

The detection limits of most elements are affected by blank contamination and depend predominantly on the laboratory air-handling facilities available.

The lower limit of application is higher in cases where the determination is likely to suffer from interferences or in case of memory effects.

Limit of Quantification (LOQ):

Drinking water and relatively unpolluted water: 0.1 µg/L - 1.0 µg/L

Method Validation

l Number of laboratories
n_{AP} percental rate of outliers
$\bar{\bar{x}}$ Total mean after elimination of outliers
s_R standard deviation between the laboratories
CV_R reproducibility variation coefficient

Interlaboratory study 1997 in Germany

Matrix	l	n_{AP} ***in %***	$\bar{\bar{x}}$ ***in µg/L***	s_R ***in µg/L***	CV_R ***in %***
Surface water	37	5.2	5.75	0.491	8.5

Other Analytical Methods

EN ISO 5961:1995 specifies two methods for the determination of cadmium using atomic absorption spectrometry (AAS) in an air-acetylene flame (aspiration of the acidified sample into the flame and measurement of the cadmium concentration at a wavelength of 228.8 nm) and by electrothermal atomization AAS (injection of the acidified sample into an electrically heated graphite tube of an electrothermal atomization atomic absorption spectrometer and measurement of the absorbance at a wavelength of 228.8 nm).

EN ISO 15586:2003 determination using atomic absorption spectrometry with electrothermal atomization in a graphite furnace. The detection limit of the method for each element depends on the sample matrix as well as of the instrument, the type of atomizer and the use of chemical modifiers. For water samples with a simple matrix (i.e. low concentration of dissolved solids and particles), the method detection limits will be close to instrument detection limits. The minimum acceptable LOQ for a 20 µL sample volume are specified.

EN ISO 11885:1997 specifies a method by inductively coupled plasma atomic emission spectroscopy.

Method Description

Determination of the sum of SCCP in technical mixtures with chlorine contents 49 % to 67 % independent of the chlorine content and independent of the C-number distribution pattern of the congeners. No recognition of the chlorine content is necessary.
Extraction of the whole water sample by liquid-liquid-extraction by an organic solvent, alternatively by solid phase extraction. After concentration and clean up, capillary gas chromatography of the approximately 6300 congeners at a relatively short column within a short retention range. Detection of selected mass fragments by mass spectrometry in the selected ion monitoring mode using negative ion chemical ionisation (NCI). The selection of the mass fragments is specific for the variety of technical mixtures as well as for the chlorine content and C-number distribution patterns in environmental samples.
Alternative selections of mass fragment combinations for quantification are given in this standard too. The chromatogram is to be integrated over the full retention range of the SCCP. The quantification of the sum of SCCP is performed after calibrating by a multiple linear regression model with solutions of different technical mixtures and internal standardisation.
The method works with at minimum three different defined standard mixtures, which resemble the C-number distribution and the chlorine content of different technical mixtures. This reflects the fact that the variety in respect of chlorine content and C-number distribution of technical SCCP-mixtures as well as of SCCP in environmental samples cannot be described by a single defined standard. The selection of the mass fragments for quantification and the special calibration allow a quantification of the sum of SCCP independently of chlorine content and C-number distribution within an expanded measurement uncertainty of 35% to 45%.

Method Validation

no data available

Other Analytical Methods

GC-ECNI-HRMS in the SIM mode at an ion source temperature of 120°C [1]. The molecular compositions of commercial SCCPs and of SCCP-containing extracts were determined by monitoring the two most intensive ions in the [M-Cl]- cluster, one for quantification and the other for confirmation for the following formula groups:

C10 (Cl5 to Cl10), C11 (Cl5 to Cl10), C12 (Cl6 to Cl10), and C13 (Cl7 to Cl9), and assuming that integrated signals are proportional to molar concentrations weighted by the number of chlorine atoms in the formula group. Quantification was achieved by selecting the biggest peak corresponding to [M-Cl]- ion in the most abundant formula group present in the sample and correcting for variations in the formula group abundances between standard and sample. The analytical detection limit was 60 pg of injected SCCP at a signal-to-noise ratio of 4:1, while LOQ was 23 ng/g.

Short-column (62 cm) GC-ECNI- LRMS at an ion source temperature of 100°C using methane as reagent gas [2]. Detection limits in the full- scan mode ranged from 10 to100 pg depending on carbon chain length of the n-alkane and on the degree of chlorination. The method was applied to the analysis of SCCP in fish samples.

Metastable atom bombardment ionisation (MAB) and high resolution mass spectrometry [3]. The detection limits were estimated to be between 10 and 100 pg/L. The MAB method has been applied to the analysis of high-volume water samples.

GC-MS/MS electron ionisation (EI) for fast determination of the sum of short medium chain chlorinated paraffins [4]. Collision-induced reactions of m/z 91 → 53 (LOQ = 0.15 ng/µL), 102 →65 (LOQ = 0.2 ng/µL), and 102 → 67 (LOQ = 0.1 ng/µL) were used to quantify the total short- and medium-chain PCA content of pooled fish liver samples.

Quantification procedure using GC-ECNI-MS, which is independent of the chlorine content of the reference standard used for calibration [5]. The authors calculated the total response factors for seven standard CP mixtures of various chlorine contents (51-70%) from the relative total CP areas and found a linear correlation between the total response factors of CP mixtures and their chlorine contents (R2= 0.9494). Using this correlation, total response factors according to the chlorine content of the SCCPs present in the sample can be calculated and used for quantification.

SPE and carbon skeleton analysis after simultaneous catalytic dechlorination and hydrogenation by gas chromatography with mass spectrometric detection seems to be promising option for routine analsis of of SCCPs in water even though the method has not yet been fully validated [6,7]

Comments

Although some work has been conducted on development of selective and sensitive methods for SCCP analysis in recent years, for the time being, no fully validated procedure is available that could be recommended for routine monitoring of SCCPs in environmental samples.

SCCP concentrations in environmental samples analysed by GC-ECNI-MS can vary widely (by a factor of ten) depending on chlorine content of the standard used for quantification [8].

Method Description

EN ISO 15680:2003 specifies a general method for the determination of volatile organic compounds (VOCs) in water by purge-and-trap isolation and gas chromatography (GC).

Detection is preferably carried out by mass spectrometry in the electron impact mode (EI), but other detectors may be applied as well.

Limit of Quantification (LOQ): 0.01 µg/L

Method Validation

no data available

Other Analytical Methods

EN ISO 10301:1997 specifies two methods for the determination of highly volatile halogenated hydrocarbons in water using gas chromatography with e.g. electron capture detector after: a) the extraction by an organic solvent or using, b) a head-space method (LOQ: 100 µg/L).

The EPA Method 1624 is designed to determine the volatile organic pollutants in water amenable to purge and trap gaschromatography-mass spectrometry.

Huybrechts et al. 2003 give a review of gas chromatography-based methods for analysis of volatile organic compounds in estuarine waters with special emphasis on monitoring [1].

Purge and trap GC-MS
SIM-GC-MS detection of the ions 62, 98, 64; LOQ ~ 2 ng/L [2]
(Modification of EPA method 524.2:VOCs in Water Using GC-MS, http://www.accustandard.com/asi/pdfs/epa_methods/524_2.pdf,)

Gas-chromatographic determination of a number of monocyclic aromatic hydrocarbons, naphthalene and several chlorinated compounds using purge-and-trap and thermal desorption

Matrix drinking water, ground water, surface water, seawater and (diluted) waste water

Sampling *ISO 5667-1, 5667-2 and ISO 5667-3*

Pretreatment

Storage at 4 °C air tight and no direct sunlight, analysis within 5 days

Method Description

EN ISO 15680:2003 specifies a general method for the determination of volatile organic compounds (VOCs) in water by purge-and-trap isolation and gas chromatography (GC).

Detection is preferably carried out by mass spectrometry in the electron impact mode (EI), but other detectors may be applied as well.

Limit of Quantification (LOQ): 0.01 µg/L

Method Validation

l Number of laboratories
n_{AP} percental rate of outliers
$\bar{\bar{x}}$ Total mean after elimination of outliers
s_R standard deviation between the laboratories
CV_R reproducibility variation coefficient
n.a. = not available

Interlaboratory study

Determination of selected plant treatment agents in water by high performance liquid chromatography with UV detection after solid-liquid extraction.

Matrix Drinking and ground water

Sampling

Pretreatment

Storage

Method Description

The plant treatment substances in the water sample are extracted by solid-liquid extraction (SPE) on reversed-phase (RP)-C18 material, eluted with a solvent, and then separated, identified and quantified by high performance liquid chromatography (HPLC) using UV detection.

Limit of Quantification (LOQ): 0.1 µg/L

Method Validation

l Number of laboratories
n_{AP} percental rate of outliers
$\bar{\bar{x}}$ Total mean after elimination of outliers
s_R standard deviation between the laboratories
CV_R reproducibility variation coefficient

Interlaboratory trial

Matrix	*l*	*n_{AP} in %*	*$\bar{\bar{x}}$ in µg/L*	*s_R in µg/L*	*CV_R in %*
Drinking water	33	0	0.1026	0.0299	29.1
Ground water	32	5.1	0.2815	0.0570	20.2

Other Analytical Methods

Liquid Chromatography - Mass Spectrometry
Identification and quantification of diuron (and other pesticides) by liquid chromatography coupled to (tandem) mass spectrometric detection (LC-MS-MS) using positive electrospray ionization (ESI)
LC-MS fragment ions: m/z 233 [1,2]
LC-MS-MS transitions: 233 > 72 and 46 [3,4,5]

LOQ ~ 1 ng/L (depending on the SPE enrichment factor)

Liquid Chromatography – Diode Array Detector
Sea water analysis: Off-line SPE – LC-DAD; LOQ ~ 0.01 µg/L [6]

Gas Chromatography - Mass Spectrometry (after derivatisation)
Phenylurea herbicides require a derivatisation step to prevent the degradation of these thermolabile compounds in the GC injector; LOQ ~ 1 ng/L [7]
SPE-derivatisation-GC-MS; LOQ ~ 50 ng/L [8]

Comments

The EN ISO 11369 HPLC-UV method is only applicable for drinking and ground water, not to the analysis of contaminated surface water. GC-MS determination of phenylurea herbicides is difficult due to the necessary derivatisation step. LC-MS-MS seems to be the method of choice.

Determination of certain organochlorine insecticides, polychlorinated biphenyls and chlorobenzenes - Gas chromatographic method after liquid-liquid extraction

Matrix Drinking, ground, waste and surface water

Sampling

Pretreatment

Storage

Method Description

*EN ISO 6468:1996 d*escribes a method for determination of certain organochlorine insecticides, polychlorinated biphenyls (PCBs) and chlorobenzenes (except the mono- and dichlorobenzenes) in drinking water, ground water, surface waters and waste waters. The method is applicable to samples containing up to 50 mg/L of suspended solids.

Limit of Quantification (LOQ): 0.001 up to 0.01 µg/L

Method Validation

l Number of laboratories
n_{AP} percental rate of outliers
$\overline{\overline{x}}$ Total mean after elimination of outliers
s_R standard deviation between the laboratories
CV_R reproducibility variation coefficient

Interlaboratory study (Extraction of β-Endosulfan with Hexane)

Matrix	*l*	n_{AP} *in %*	$\overline{\overline{x}}$ *in ng/L*	s_R *in µg/L*	CV_R *in %*
Surface water	14	6.6	21.2	14.4	67.9

Other Analytical Methods

SPE extraction of 500 ml water with 200 mg SDB, elution with ethyl acetate; GC-MS determination
LOQ for α-endosulfan ~ 11 ng/L [1]

SPE-GC-NCI-MS
C18-SPE, 100 mL, LOQ for α- or β-endosulfan ~ 25 ng/L [2]

The LOQ of these alternative SPE-GC-MS methods may be low enough if good equipment and well trained personnel are available. The uncertainty however is rather high (depends on required U whether this method will be feasible).

Comments

Technical endosulfan is a mixture of two stereoisomers, α- and β-endosulfan (in a ratio of 7:3). In the environment in particular in soil the metabolite endosulfan-sulfate is also present.

By the SPE extraction of higher water volumes lower LOQs could be achieved.
New research results show that sufficient LOQs in the low ng/L or even pg/L range can be achieved with negative chemical ionization (NCI) GC-MS, using SPE of 1 or 10 L water [3].

Matrix Drinking waters, ground waters, surface waters and waste waters

Sampling *ISO 5667-1, 5667-2 and 5667-3*

Pretreatment For dissolved elements, filter aqueous sample through a 0.45-µm pore membrane filter. Adjust the pH of the filtrate to < 2 with HNO_3.

Storage

Method Description

EN ISO 17294-2:2004 specifies a method for the determination of the lead in water (for example drinking water, surface water, groundwater, wastewater and eluates). Taking into account the specific and additionally occurring interferences, these elements can also be determined in digests of water, sludges and sediments. The working range depends on the matrix and the interferences encountered.

Limit of Quantification (LOQ):
Drinking water and relatively unpolluted water:
0.1 up to 1 µg/L

Method Validation

l Number of laboratories
n_{AP} percental rate of outliers
$\bar{\bar{x}}$ Total mean after elimination of outliers
s_R standard deviation between the laboratories
CV_R reproducibility variation coefficient

Determination of selected alkylphenols - Part 1: Method for non-filtered samples using liquid extraction and gas chromatography with mass selective detection

Matrix Drinking, ground and surface water

Sampling

Pretreatment

Storage

Method Description

Method for the determination of 4-nonylphenols (mixture of isomers) in non-filtered samples of drinking water, ground water and surface water.

Extraction of nonylphenol from the acidified water sample with toluene. Cleaning of the extract, if necessary with silica. Gas chromatographic separation and identification of the alkylphenol by mass spectrometry without derivatisation (mass fragments m/z 135 and 107). Quantification with an internal standard (^{13}C p-n-NP; m/z 113).

Limit of Quantification (LOQ): 0.02 to 0.2 µg/L

Method Validation

l Number of laboratories
n_{AP} percental rate of outliers
$\bar{\bar{x}}$ Total mean after elimination of outliers
s_R standard deviation between the laboratories
CV_R reproducibility variation coefficient

Interlaboratory study 2002

Surface water	11	26.7	0.0828	0.016	18.8

Other Analytical Methods

Solid-phase extraction
Extraction of alkylphenols from water with solid-phase extraction (SPE) using C18 or polymeric adsorbents. Elution with methanol, acetone, ethylacetate, or dichloromethane [2-6].

Liquid Chromatography - Mass Spectrometry
Identification and quantification of the analytes by liquid chromatography coupled to (tandem) mass spectrometric detection (LC-MS-MS) using negative electrospray ionization (ESI).
LC-MS fragment ion: m/z 219 [2]
LC-MS-MS transitions: 219 > 133 and 219 > 147 [3,4]; LOQ ~ 5 ng/L
Internal standard: 4n-NP; transition 219 > 106

GC-MS after derivatisation
Several derivatisation techniques for alkylphenols prior to GC-MS determination have been reported.
E.g., the phenol group can be converted to a pentafluorobenzoylate ester (LOQ ~ 0.05 ng/L) [5], or silylated using bis(trimethylsilyl)trifluoroacetamide (BSTFA) (LOQ ~ 1 ng/L) [6], or methyl-N-(trimethylsilyl)trifluoroacetamide (MSTFA) [7].

Comments

Technical nonylphenol consists of 211 differently branched nonyl chains isomers; it consists mainly (~ 90 %) of 4-nonylphenol. Only recently, it was recognized that for a correct risk assessment, isomer-specific toxicological studies and analysis are important because the estrogenic effect of the individual nonylphenol isomers is heavily dependent on the structure of the alkyl side chain. It is estimated that in biological and environmental relevant matrices approximately 50 – 80 isomers are present [8,9]. Chromatographic separation of all isomers is not possible (at the time being); it might become feasible in the future with two-dimensional GC [8]. Therefore (for now), the sum of the different nonylphenol isomers should be analysed.
When using liquid chromatography (LC), the nonylphenols have to get chromatographically separated from the ethoxy carboxylate metabolites (NPECs) because they produce the same MS ions.
Nonylphenols are relatively polar compounds, and therefore GC-MS without derivatisation can give rise to poor chromatographic peaks. Thus, nonylphenols are often derivatized prior to GC-MS.

Internal standard: 4n-NP; transition 219 > 106

GC-MS after derivatisation
Several derivatisation techniques for alkylphenols prior to GC-MS determination have been reported. E.g., the phenol group can be converted to a pentafluorobenzoylate ester (LOQ ~ 0.05 ng/L) [5], or silylated (LOQ ~ 2.6 ng/L) [6].

Comments

The term *octylphenol* represents a large number of isomeric compounds of the general formula $C_8H_{17}C_6H_4(OH)$. The octyl group may be branched in a variety of ways or be a straight chain. Of these potential isomers, 4-*tert*-octylphenol (CAS No. 140-66-9) is the most commercially (and toxicologically) important [7]. It has the MS-MS transistion 205 >133.

Another analytical standard is available: 4-octylphenol (CAS No. 1806-26-4). This standard contains linear octylphenol; it shows the characteristic MS-MS transistion 205 > 106.

Determination of certain organochlorine insecticides, polychlorinated biphenyls and chlorobenzenes – Gas chromatographic method after liquid-liquid extraction

Matrix Drinking, ground, surface and waste waters

Sampling

Pretreatment

Storage

Method Description

Liquid-liquid extraction of organochlorine insecticides, chlorobenzenes and PCBs by an extraction solvent. After concentration and clean-up the sample extracts are analysed by gas chromatography, using an electron-capture detector (GC-ECD).

The method is applicable to samples containing up to 50 mg/L of suspended solids.

Limit of Quantification (LOQ): ~ 0.001 – 0.01 µg/L

Method Validation

no data available

Other Analytical Methods

Gas chromatography - mass spectrometry

GC-MS determination of the ions 250, 215, 180

GC-ECD

EPA methods 505 (GC-ECD) [1] and 625 (GC-MS) [2]: Liquid-liquid extraction of 1 L water with dichloromethane.

LOQ ~ 3 ng/L

GC- triple-quad MS-MS [3]

SPE extraction of 100 mL water (elution with ethyl acetate / DCM) followed by GC- triple-quad MS-MS. Precursor ions 248 and 250, product 142; LOQ = 25 ng/L.

With NCI and the extraction of bigger water volumes, a lower LOQ might be achieved.

Comments

If released to water, pentachlorobenzene will adsorb strongly to sediments and will bioconcentrate in fish. It will be subject to evaporation with a half-life of 6.5 hours estimated for evaporation from a river 1 m deep, flowing at 1 m/sec and a wind velocity of 3 m/sec. The volatilization half-life from a model pond, which considers the effects of adsorption, can be estimated to be about 60 days. It will not be expected to significantly biodegrade or hydrolyze.

Gas chromatographic determination of some selected chlorophenols in water

Matrix Drinking, ground, rain, waste, sea and surface water

Sampling

Pretreatment

Storage

Method Description

This European Standard describes the gas chromatographic determination of 19 chlorophenols in water.

The methods consists of acetylaction of the chlorophenols with acetic anhydride followed by liquid/liquid extraction with hexane and determination by gas chromatography (GC) and electrone capture detection (ECD) or mass selective detection (MSD).

Limit of Quantification (LOQ): 0.1 µg/L (Extraction volume:50 mL)

Method Validation

l Number of laboratories
n_{AP} percental rate of outliers
$\bar{\bar{x}}$ Total mean after elimination of outliers
s_R standard deviation between the laboratories
CV_R reproducibility variation coefficient

Interlaboratory study November 1996

Matrix	l	n_{AP} *in %*	$\bar{\bar{x}}$ *in µg/L*	s_R *in µg/L*	CV_R *in %*
Drinking water	12	22.2	0.11	0.028	24
Surface water	13	7.1	0.20	0.042	21

Other Analytical Methods

Gas Chromatography - Mass Spectrometry

Characteristic ions for MS detection (of acetate): 266, 264, 268, 270 (DIN EN 12673).

Silyl derivatisation GC-MS

Derivatisation with Bis(trimethylsilyl)trifluoroacetamide (BSTFA); MS quantification ions 323, 321, 93.
Dynamic concentration range: 1-1500 µg/L (without enrichment)

Solid-phase extraction

SPE with styrene-divinylbenzene (SDB) cartridges at pH 2.6; elution with 4 mL methanol; recovery ~ 90 % [2].

SPME-GC-MS

SPME from 2 mL sample volume; scan MS acquisition; claiming a LOQ of ~ 5 ng/L [3]

Derivatisation SPME-GC-MS

Derivatisation with acetic anhydride in 22 mL headspace vials followed by SPME and GC-MS determination (scan mode); LOQ ~ 3 ng/L [4].

SPE-LC-MS

LC-MS of Pentachlorophenol is difficult due to bad ionisation of the hydroxy group. However, off- and on-line SPE-LC-MS methods have been reported.

On-line SPE extraction of 100 mL river water (pH 3) using LiChrolut EN precolumns; elution with the water-acetonitrile-methanol gradient; LC-APCI-MS analysis; LOQ in SIM mode ~ 0.1 ng/L [5]

On-line SPE extraction of 10 mL river (pH 2.5) water using polymeric adsorbents; LC-APCI-MS analysis; LOQ in SIM mode ~ 5 ng/L [6]

Off-line SPE with PS-DVB membrane extraction disk of 500 mL tap water, elution with acetonitrile; LC-APCI-MS with post-column addition of diethylamine; SIM ions 263, 265, 267; LOQ ~ 20 ng/L [7].

Comments

The SPME-GC-MS and SPE-on-line-LC-MS methods have lower LOQ but are not standardized.
Other derivatisation reagents such as pentafluorobenzoyl chloride can be used prior to GC analysis.

Available Standard Method
EN ISO 17993: 2003
Determination of 15 polycyclic aromatic hydrocarbons (PAH) in water by HPLC with fluorescence detection after liquid-liquid extraction

Matrix Drinking, ground, waste and surface water

Sampling

Pretreatment

Storage

Method Description

EN ISO 17993:2003 specifies a method using high performance liquid chromatography (HPLC) with fluorescence detection for the determination of 15 selected polycyclic aromatic.

Limit of Quantification (LOQ):
Drinking and ground water: > 0.005 µg/L
Surface water: > 0.01 µg/L

Method Validation

l Number of laboratories
n_{AP} percental rate of outliers
$\overline{\overline{x}}$ Total mean after elimination of outliers
s_R standard deviation between the laboratories
CV_R reproducibility variation coefficient

National interlaboratory study for spiked drinking water 1996 (German)

Substance	***l***	***n_{AP} in %***	***$\overline{\overline{x}}$ in pg/L***	***s_R in pg/L***	***CV_R in %***
Benzo[a]pyrene	33	3.1	20.43	4.17	20.4
Benzo[b]fluoroanthene	33	3.1	27.41	4.719	17.2
Benzo[k]fluoroanthene	32	3.2	10.87	2.382	21.9

Benzo[g,h,i]perylene	32	6.2	25.21	5.941	23.6
Indeno[1,2,3-cd]pyrene	29	12	26.31	4.417	17.9

Other Analytical Methods

EPA 8270c [1] claims detection limit of 10 µg/L which is obviously too high. Other analytical methods based on this standard using modern GC/MS equipment however may attain the required low LOQs.

Comments

The methods do not attain low enough LOQs and uncertainties for compliance checking with the AA-EQS for the sum of *Benzo[b]fluoroanthene and Benzo[k]fluoroanthene as well as the sum of Benzo[g,h,i]perylene and Indeno[1,2,3-cd]pyrene.* In addition, not enough validation data are available regarding the analysis of surface water samples in particular samples containing substantial amounts of SPM.

A new ISO standard for the determination of PAH in water using gas chromatography with mass spectrometry detection in under development (ISO/CD 28540)

Determination of selected organic nitrogen and phosphorus compounds - Gas chromatography methods

Matrix Drinking waters, ground waters, surface waters and waste waters containing up to 50 mg/L of suspended solids

Sampling

Pretreatment

Storage

Method Description

Liquid/liquid extraction with dichloromethane or liquid/solid extraction (SPE) on reversed-phase (RP)-C18 material or other adsorbent. Elution of the cartridges with e.g. methanol or acetone.
After concentration, the sample extracts are analysed by gas chromatography, using a nitrogen-phosphorus or mass spectrometric detector.

Limit of Quantification (LOQ):

Liquid/liquid extraction method: 0.5 µg/L
Liquid/solid extraction method: 0.012 µg/L

Method Validation

l Number of laboratories
n_{AP} percental rate of outliers
$\bar{\bar{x}}$ Total mean after elimination of outliers
s_R standard deviation between the laboratories
CV_R reproducibility variation coefficient

Interlaboratory study 1993 for liquid/solid extraction

Available Standard Method

EN ISO 17353:2005

Determination of selected organotin compounds - Gas chromatographic method

Matrix Drinking, surface and waste waters containing not more than 2g/L of suspended material.

Sampling

Pretreatment

Storage

Method Description

Method for the identification and quantification of organotin compounds and/or cations in water.
Compounds:
Monobutyltin cation (MBT) $BuSn^{3+}$
Dibutyltin cation (DBT) Bu_2Sn^{2+}
Tributyltin cation (TBT) Bu_3Sn^{+}
Tetrabutyltin (TTBT) Bu_4Sn

Organotin compounds in water are ethylated with sodium tetraethyl-borate ($NaBEt_4$) and extracted with hexane. The extract can be cleaned with silica. After concentration, the tetra-substituted OTC are separated by capillary gas chromatography and detected with a suitable system (MS, FPD, AED). The concentration is determined by calibration over the total procedure using an internal standard mixture.

Limit of Quantification (LOQ): 0.010 – 1 µg/L

Method Validation

l Number of laboratories
n_{AP} percental rate of outliers
$\bar{\bar{x}}$ Total mean
s_R standard deviation between the laboratories
CV_R reproducibility variation coefficient

Interlaboratory study 1998 in Germany

Matrix	*l*	*n_{AP} in %*	*$\bar{\bar{x}}$ in ng/L*	*s_R in µg/L*	*CV_R in %*
Spiked surface water	11	8.3	388.2	92.16	23.7

Other Analytical Methods

LLE-EI-GC-MS
100 mL seawater, pH 5.4, derivatisation with $NaBEt_4$, hexane extraction; LOQ ~ 0.8 ng/L [1].

GC-NCI-MS
LOQ 0.1 ng/L [2].

Liquid phase microextraction (LPME) – GC-MS-MS
4mL water sample; 4-fluorophenyl derivatisation; LOQ 0.36 ng/L [3].

LLE-GC-FDP

1 L sea water, pH 5.5, ethylation in aqueous phase with $NaBEt_4$, iso-octane/n-pentane extraction; LOQ 0.01 ng/L [4].

LLE-LC-MS

At pH 4 using hexane-ethylacetate (70:30); ion-trap LC–APCI-MS; m/z 323 and 307; LOD 35 µg/L for TBT [5].

GC-ICP-MS

Extraction of 1 L sample at clean room conditions. Derivatisation followed by GC-ICP/MS, LOQ ~0.01 ng/L [6,7]

Comments

Only tributyltin cation is required for WFD monitoring. In the environment different anions (OH-, Cl-, Br-, acetate) are associated with TBT. Analytical methods are assumed to derivatise all forms.

EQS values for TBT refer to the tributyl-cation, hence result shall be expressed in the same way.

Care has to be taken when comparing result with data from scientific literature because some authors express results as µg Sn /L.

Comments

If released to water, trifluralin is expected to biodegrade under both aerobic and anaerobic conditions and to undergo direct photolytic degradation. It is expected to bioconcentrate in fish and aquatic organisms and adsorb strongly to sediment and suspended organic matter. It may also volatilize from water to the atmosphere. If released to the atmosphere, trifluralin is expected to undergo a rapid gas-phase photolysis.

ANNEX IV: Case Studies

Background information
Title/Name of case study: Pesticides in Surface Water Bodies from Agricultural Sources (Pesticide Program).
Type of case study: Monitoring to check the chemical and ecological status compliance (operational and investigative monitoring).
Reporting Institution: Ministry of the Environment (Spain).
Web-Link: www.mma.es
Main sources for further information; literature: *Analysis of pesticides and metabolites in Spanish surface waters by isotope dilution gas chromatography/mass spectrometry with previous automated solid-phase extraction. Estimation of the uncertainty of the analytical results.* Planas et al. Journal of Chromatography A, 1131 (2006) 242-252.
Objective of case study - background information: Development of the methodology for monitoring the pollution caused by pesticides from agricultural sources. Analysing pesticides is necessary to check the good chemical and ecological status compliance. The pesticides included in the monitoring program must be all the priority substances discharged and "other pesticides" discharged in significant quantities. It is not easy to select the "other pesticides" to analyse due to high number of possible compounds, changes in pesticides use, pesticide fate, etc. To solve this, the surveillance of pesticide pollution from agricultural activities may combine 2 types of analytical methodologies. Type 1: Standardized techniques with high level of QA/QC to monitor EQS compliance (legally binding EQSs or calculated EQSs). Type 2: MS characterization to determine new pesticides not included in common lists in order to incorporate them in the selected compounds to monitor in the future. This combined methodology is used to monitor pesticides in water bodies potentially at risk of failing to meet the pesticides EQS due to pressure from agricultural sources.
Contribution to…
Specific contribution linked to WFD monitoring programmes Operational and investigative monitoring design.
Description *Monitoring points*: water bodies potentially at risk of pesticides pollution from agricultural sources. *Matrix:* Water *Frequency*: 8 sampling/year *Methodology and substances* Using Isotope dilution GC/MS with previous automated SPE 10 pesticides from Priority Substances List , 04 pesticides from List II with national legally binding EQSs 05 metabolite pesticides 13 pesticides commonly used or detected in waters Using MS characterization of the all the pollutants present in the sample Unknown pesticide presents in the sample

Experiences gained - Conclusions - Recommendations **Experience gained:** Determination of the level of pollution from pesticides of water bodies at risk due to agricultural pressures. Development of a Methodology with high QA/QC data. Determination of new pollutants to be included in the Pesticides Program. **Conclusion**: A method based on isotope dilution GC/MS with automated SPE extraction was developed for the analysis of 32 pesticides and metabolites in surface water samples. Trueness was in the range 80-120% for 29 pesticides, precision below 15% for 25 compounds, method detection limit ranged from 1 to 9 ng/g and expanded uncertainties were < 40% for 24 pesticides. 93 Spanish surface water samples collected during summer and autumn 2004. Highest concentration and occurrence were found for atrazine, simazine, alachlor, terbutylazine and metoachlor included in the Priority List and/or Spanish Relevant List. New pesticides were detected using MS characterization technique, the pollutant molinate and imazalil and are included in the future pesticide program. Pesticides concentrations and occurrence are higher in the summer than in the autumn period. In summer, four pesticides were found in more than 50% of the analysed samples and four compounds were detected above the concentration level of 1 µg/l (atrazine, terbutylazine, 3,4-dichloroaniline and fenitrothion), while in autumn percentage of detection was bellow 50% for all pesticides, only one compound (terbutylazine) exceeded 1 µg/l. **Recommendations**: The surveillance of pesticides in water from agricultural activities needs the combination of 2 types of techniques. Standardized analytical methods with a high level of QA/QC to monitor specific pesticides, at least all the pollutants included in the Priority List and/or other National Relevant List in order to monitor the EQS compliance, and hence Chemical status. And the application of screening techniques to detect new pesticides from diffuse sources not included in common Lists in order to monitor ecological status compliance.
Outlook - Next steps – Accessibility of results/information

Background information
Title/Name of case study: Conversion of pollutant concentrations measured in suspended particulate matter (SPM) into total concentrations in the whole water sample.
Type of case study: Routine operation since 1990 in the water quality monitoring program of the international Rhine Commission (ICPR) for compliance checking of annual data of lipophilic pollutants with water quality targets.
Reporting Institution: International Commission for the Protection of the Rhine (ICPR)
Web-Link: http://www.iksr.de/fileadmin/user_upload/Dokumente/Berichte/IKSR_Bericht_Nr_143d.pdf
Objective of case study - background information – In surface waters a number of the priority substances are adsorbed to SPM from 50 close to 100 percent. The water quality targets of the ICPR (analogous the EQS) for organic priority substances are expressed as total concentrations, that is the dissolved portion plus adsorbed portion of the substance in the whole water sample. For some organic priority substances the AA-EQS are very low, and the respective detection limits of the recommended analytical methods are insufficient. The objective is to support compliance checking with whole water EQS (or ICPR water quality targets) by conversion of SPM determinand concentration.
Contribution to support compliance checking with EQS
Specific contribution linked to WFD monitoring programmes Surveillance monitoring design; specific monitoring of pollutants adsorbed to suspended particulate matter; compliance checking of SPM determinand concentration with whole water EQS.
Characterisation For organic micropollutants like PCB, TBT, PAH or hexachlorobenzene, the ICPR had developed water quality targets for whole water. For reasons of the analytical method, surveillance of the quality targets was performed by sampling and analyzing these pollutants in suspended particles. Sampling by centrifuge allows collecting the suspended material from several 1,000 litres of water within a few hours. Thus, a sufficient amount of SPM can be gained for chemical analysis, what corresponds to an enrichment from several 100 (or 1,000) litres of water. The amount of water centrifuged is recorded. **Course of procedure:** The concentration of contaminants is determined in µg/kg dw and converted to whole water by means of the SPM content (in mg/L): $C_{Ti} = (Si \times C_{si}) \times 10^{-6}$ C_{Ti} = total contaminant content on the day of sampling in µg/L Si = SPM content on the day of sampling in mg/L C_{si} = contaminant content in SPM on the day of sampling in µg/kg. This applies to substances that are adsorbed at SPM by more than 90 %. For substances that are adsorbed by 50 % at SPM, the value is multiplied by the factor 2: $C_{Ti} = 2\,(Si \times C_{si}) \times 10^{-6}$

Other factors might be selected for a particular substance, if the partition coefficient is known. The mean value (50- or 90-percentile in ICPR procedure) is calculated from the C_{Ti} values. Values below the limit of detection (limit of quantification) are included in the mean-value calculation (arithmetic mean) by the numerical value of the limit of detection. Then, the value of the arithmetic mean is indicated as “less than”.
Experiences gained - Conclusions - Recommendations **Experience gained:** The ICPR member states have successfully applied this method at selected sampling sites since 1990. The error that results from the arbitrary definition of the conversion factor for adsorption between 50 and 90 percent is negligible against the other errors in trace analyses. But for EQS compliance checking procedure it is possible to define the adsorbed portion for each priority substance in 10-percent steps (50, 60, 70, 80, 90 or 100 percent). **Conclusion**: The collection of the SPM from several 100 (or 1,000) litres of surface water allows the compliance checking of the EQS for priority substances, which are partially or not dissolved in the water because of their hydrophobic and lipophilic properties. Sampling by centrifuge is time- and labour-intensive and should be applied in surveillance monitoring only at selected sampling sites at large rivers. But it is no problem to meet the minimum performance criteria for the quality of analytical results – also for low EQS values (e.g. tributyl tin). The results of the contaminant concentrations in SPM can be used for comparisons with the EQS, and - after a hydrological interpretation - they are also suitable for trend analyses. **Recommendations**: - For selected priority substances and for selected monitoring sites at large rivers the described procedure is suitable for compliance checking with EQS and for trend analyses. Special attention should be given to the following micropollutants: Pentabromodiphenylether, C10-13 chloroalkanes, Fluoranthene, Hexachlorobenzene, Pentachlorobenzene, PAH (Benzo(a)pyrene, Benzo(b)fluoranthene, Benzo(k)fluoranthene, Benzo(g,h,i)perylene, Indeno(1,2,3-cd)pyrene), Tributyltin and Trifluralin. - the result of each measurement (spot sample) is converted into the total determinand concentration by means of the SPM content of the water and according to the percent factor of the adsorbed portion of contaminants; - No further effort is necessary for analytical techniques to obtain a limit of quantification half of the EQS.
Outlook - Next steps – Accessibility of results/information

Background information
Title/Name of case study: Comments Concerning the National Swedish Contaminant Monitoring Programme in Marine Biota
Type of case study: Monitoring activities within the Swedish contaminant programme in marine biota
Reporting Institution: Environmental Protection Agency (Sweden)
Web-Link: www.naturvardsverket.se
Main sources for further information; literature: Comments Concerning the National Swedish Contaminant Monitoring Programme in Marine Biota, 2006
Objective of case study - background information: The data of concern in this report represent the bioavailable part of the investigated contaminants i.e. the part that has virtually passed through the biological membranes and may cause biological effects. The main objectives of the monitoring program in marine biota could be summarised as follows: - to estimate the levels and the normal variation of various contaminants in marine biota from several representative sites, uninfluenced by local sources, along the Swedish coasts. The goal is to describe the general contaminant status and to serve as reference values for regional and local monitoring programmes - to monitor long term time trends and to estimate the rate of found changes. - to estimate the response in marine biota of measures taken to reduce the discharges of various contaminants - to detect incidents of regional influence or widespread incidents of 'Chernobyl'- character and to act as watchdog monitoring to detect renewed usage of banned contaminants. - to indicate large scale spatial differences - to explore the development and regional differences of the composition and pattern of e.g. PCB's, HCH's and DDT's as well as the ratios between various contaminants.
Contribution to…
Specific contribution linked to WFD monitoring programmes Surveillance monitoring design and operational monitoring design as soon as EQS are developed for biota.
Description Substances monitored: Metals, for example Hg, Cd, Pb and Cu and organic substances, for example PCB, DDT, Lindane, brominated flameretardants and dioxins. Sampling area: The sampling sites are located in areas regarded as locally uncontaminated and, as much as possible, uninfluenced by major river outlets or ferry routes and not too close to heavy populated areas. Collected specimens: For many species adult specimens are less stationary than sub-adults. To increase comparability between years, young specimens are generally collected. Only healthy looking specimens with undamaged skin are selected. The collected specimens are placed individually in polyethene plastic bags, deep frozen as soon as possible and transported to the sample preparation laboratory.

Number of samples and frequency: In general 20 individual specimens from the Baltic sites (reported to HELCOM) and 25 from the Swedish westcoast sites (reported to OSPARCOM) are analysed annually from each site/species. For guillemot eggs and perch, 10 individual specimens are analysed. Organo-chlorines in blue mussels are analysed in pooled samples containing about 50 individual specimens in each pool. Since 1996, samples from 12 individual specimens are analysed which is proposed in the revised guidelines for HELCOM and OSPARCOM.

Experience gained:
Continuous development of design for both a spatial and temporal monitoring programme and also increased knowledge of choice of matrix. The importance of quantifying objectives.

Conclusion:
Herring is the most commonly used indicator species for monitoring contaminants in biota within the BMP (Baltic Monitoring Programme) in the HELCOM convention area and is sampled by Finland, Estonia, Poland and Sweden. Herring muscle tissue is fat and thus very appropriate for analysis of fatsoluble contaminants i.e. hydrocarbons.

Cod is among the 'first choice species' recommended within the JAMP (Joint Assessment and Monitoring Programme) and BMP (Baltic Monitoring Programme). The cod liver is fat and organic contaminants are often found in relatively high concentrations. For that reason, it is also a very appropriate matrix for screening for 'new' contaminants.

Mussels are one of the most common used organisms for monitoring contaminants in biota. Adult mussels are sessile and hence it is easier to define the area the samples represent, compared to fish.
Blue mussel is among the 'first choice species' recommended within the JAMP (Joint Assessment and Monitoring Programme).

Recommendations:
It is very important that the objectives of the monitoring are quantified before designing a monitoring programme. When the objectives are defined the choice of sampling location, matrix, sampling method and analytical procedure could cause problems if the proper guidelines are not followed.

Outlook - Next steps – Accessibility of results/information

Background information
Title/Name of case study: Screening of Industrial and Consumer Chemicals in Finland (VESKA 1)
Type of case study: Screening to select sites and substances for surveillance monitoring of WFD
Reporting Institution: Finnish Environment Institute SYKE
Web-Link: http://www.ymparisto.fi
Main sources for further information; literature:
Objectives of case study: To study the occurrence and concentrations of the substances chosen by risk assessment in the aquatic environment close to emission sources To produce information for the purpose of emission source identification. To develop the analytics used to examine harmful substances and to build up cooperation network between laboratories. To develop a risk assessment method that can be used to estimate the circulation of the studied compounds in nature and to minimize the expenses needed for their monitoring. To set a criterion that could be used to preclude or add substances to a more detailed monitoring plan.
Contribution to…
Specific contribution linked to WFD monitoring programmes Supply data for national surveillance monitoring programme 2006-2008
Description The study was carried out in the vicinity of twelve industrialized cities in Finland, in water systems downstream municipal sewage treatment plants. Concentrations were measured in sludge and waste water samples (1-3 occasions) and surface water (1-3 occasions), sediment (once, surface 2-3 cm) and fish (4-10 specimen pooled, Northern pike, *Esox lucius*) muscle samples. Organotin compounds (both butyl and phenyl –forms) were found in all matrices, often exceeding EQS or "benchmark" values. This will trigger more research, monitoring and management activities MBT and DBT were found in sediments also below inland sewage treatment plants, indicating sources other than antifouling paints (stabilizer in plastics). TPhT indicated bioaccumulation: found less than TBT in sediments but more in fish Alkylphenols, phthalates, organotin compounds, HCH, HCB and VOC-compounds were found in treated sewage water. Out of these, only DEHP and alkylphenols were found in excess of surface water EQS proposals. In surface waters, only nonylphenol ethoxylates were found at the (national) EQS-level. Several substances were not detected (other alkylphenols, chlorobenzenes and volatile organic compounds). PAHs, PBDE, organotins and phthalates were, however, not measured in surface water phase. In sediments, organotins, PAHs, HCHs and dibutylphthalate were most commonly found.
Experience gained:

Conclusion: Simultaneous screening of several substance groups might not be cost-efficient for industrial and household chemicals with several, poorly known sources. On national level, surveillance monitoring will be started for alkylphenols, phthalates and PAHs in water (10 sites/year). First year (mid 2007- mid 2008) results will determine the need of continuation (rotation, cessation). Sediment and biota monitoring continues (5-15 sites, 2-6 yr rotation) for lipophilic substances. **Recommendations**: In addition to analytical problems at low concentrations, natural conditions in Northern Europe (lake-richness, low temperature, low particulate matter, low degradation, low population/water volume) would favour sediment and/or biota over water, in monitoring many industrial and household chemicals presently on the Priority Substances list (e.g. PBDE, HCB, SCCP, some PAHs, DEHP, TBT). Effect-based monitoring should be developed and brought into the guidance for impact monitoring locations.
Outlook - Next steps – Accessibility of results/information New groups of substances will be screened in sewage effluents and waste deposit leachates. The impact monitoring of selected compounds will start gradually along source identification and the renewal process of the permissions (industrial and municipal STPs) with statutory monitoring.

Background information
Title/Name of case study: Pesticide Screening in Finnish Surface Waters (VESKA 2)
Type of case study: Screening to select sites and substances for surveillance monitoring of WFD
Reporting Institution: Finnish Environment Institute (SYKE)
Web-Link: http://www.ymparisto.fi/download.asp?contentid=49817&lan=EN
Main sources for further information; literature:
Objectives of case study: To study the occurrence and concentrations of agricultural pesticides in Finnish surface waters. To produce information for identification of emission source. To develop a risk assessment method that can be used to minimize the expenses of later monitoring.
Contribution to…
Specific contribution linked to WFD monitoring programmes Supply data for national surveillance monitoring programme 2006-2008
Description *Monitoring points*: water bodies (streams and rivers) potentially at risk of pesticide pollution from agricultural sources *Matrix*: surface water and the top of bottom sediment (0-1 cm) *Duration:* 2004 - 2005 *Frequency* - at one intensive site: weekly (May-Oct 2004) + monthly in winter (2004-2005) - intermediate sites: monthly (Apr/May-Sep/Oct) - areal screening sites: twice (Jun/Jul + Jul/Aug in 2005). *Analysed substance*: - 100 compunds from water samples using :multi-residue methods (GC-MS and LC-MS-MS) (including all pesticides in the EU Priority list and four of the six pesticides in the national list of pesticides) - Tribenuronmethyl (a low-dose herbicide in the national list) from part of water samples using a specific analysing method - The 14 pesticides analysed from sediment samples were selected basing on partitioning coefficients (from the EU and national lists of priority substances and other potential pesticides). *Number of samples:* 190 water samples + 31 sediment samples The study was carried out in two parts. The objective of the pilot year 2004 was to find the best timing for surface water sampling and to assist in the selection of the sampling sites for a survey for following year. In the second year (2005) the main objective was areal representativeness, but most of the sites were sampled only twice at the time of expected high concentrations. In 2004 the focus was in upstream sites (catchment areas: 1-100 km^2) close to fields. Surface water was collected in an intensive site and in 6 other agricultural streams. Additional samples were collected once from 6 rivers (Sep/Oct). The pilot year indicated that agricultural land use percent was more important factor to explain pesticide detections than catchment area. In 2005, sampling sites were selected from watershed register using agricultural land use percent as the

main criterion: 35 agricultural sites and five reference sites from non-agricultural areas (catchment areas of the sampling points: .50 - 37 000 km^2). In addition, six rivers and two of the smaller streams sampled during the pilot year were sampled monthly (May-Oct) in 2005.

Pesticides in water samples (70 (in 2004) + 120 (in 2005) + quality assurance samples):
The number of different pesticides detected was 24 in 2004 and 46 in 2005. Detected concentrations were mainly low (traces). In 2005, one or more herbicides were detected in 90% of water samples. Phenoxy acid herbicides were most frequently found compounds. This may be explained by the volume of they use in Finland. Only following few exceedings of EQS values were observed during the screening, although the sampling was focused in the expected concentration peaks and in the areas of high pesticide loadings:

- Endosulfansulphate was detected in one site (3 detections /3 sampling times) (max 0.02 µg/l = quantification limit), while suggested EQS-value is 0.005 µg/l.
- The detected peaks of MCPA concentration exceed national EQS value (1.6 µg/l) in several sites (max 8.8 µg/l), but concentrations were still lower than MacQS (15 µg/l).
- In single samples the concentrations of low-dose herbicides (thifensulfuronmethyl, tribenuronmethyl) were higher than Swedish "target values". However, the Finnish national EQS of tribenuronmethyl was not exceeded.
- Insecticides were detected seldom, which is inline with the sold amounts of them. Pirimicarb was found in one site and its concentration was higher than Norwegian limit value.

Pesticides in sediment samples (31 + a parallel sample):
In 2005, the top of bottom sediment (in all sites where possible) was sampled and 14 substances were analysed and 6 detected from sediment samples samples. Atrazine (forbidden in 1991) was detected in more than half of the sediment samples, prochloraz in every third sample, and the others in single samples. Currently there are no confirmed sediment EQS values for pesticides, but the earlier proposed values were exceeded in case of atrazine, prochloraz, endosulfan and its metabolite endosulfansulphate.

Conclusion:
Simultaneous screening of several substances was cost-efficient for pesticides. High number of different pesticide compounds, mainly herbicides and their metabolites were detected. Concentrations exceeded seldom levels of potential environmental threat.

The time and site of sampling have significant effects on the results. No watershed specific information about pesticide usage is available. Agricultural land use percent was a good tool in selecting sampling sites, but further information about the type of agriculture (e.g. typical crops) would help in finding the risky sites.

The intensive agricultural land use fraction is usually rather low in big Finnish catchments and pesticides are diluted in water from non-agricultural areas in big rivers while pesticides may occasionally pose local problems in some small streams close to fields.

Outlook - Next steps – Accessibility of results/information
For year 2007 the statutory pesticide monitoring is planed to be performed in 8 rivers and in one stream (10-12 samples/site). Later (in 2008-) it will be reasonable to include some upstream sites to monitoring program.

Background information
Title/Name of case study: French National Monitoring Network (RNO) Réseau National d'Observation de la qualité du milieu marin
Type of case study: A 30 years Chemical monitoring network (surveillance and operational monitoring)
Reporting Institution: **IFREMER** (Institut français de recherche pour l'exploitation de la mer) French Research Institute for Exploitation of the Sea
Web-Link: www.ifremer.fr and www.ifremer.fr/envlit/surveillance/rno.htm
Main sources for further information; literature: Annual bulletin may be downloaded at : **www.ifremer.fr/envlit/surveillance/rnopublis.htm**
Objective of case study - background information: 1. Assessment of the levels and trends of the chemical contamination of the French coastal seas. 2. To meet OSPAR and Barcelona Conventions monitoring obligations
Contribution to…
Specific contribution linked to WFD monitoring programmes Surveillance and Operational Monitoring
Description **Chemical contaminants monitored :** - metals : Ag, Cd, Cr, Cu, Hg, Ni, Pb, V, Zn - organochlorinated compounds: DDT compounds, HCH isomers, PCB congeners - PAH's : 16 US-EPA PAH's and some alkylated PAH's **Strategy of monitoring :** The RNO is largely based on bivalve molluscs (mussels and oysters) which are used as quantitative indicators of contamination. **Some 90 sampling points are sampled twice a year for metals and once a year for organic contaminants**. Analyses are carried out at a single laboratory, the Ifremer Center of Nantes. An aliquot of the samples is systematically archived for possible controls at a later date or the retrospective search of other contaminants (the bank contains more than 8000 samples, since 1981). The contaminants are also measured in the sediments. The first centimetre of the surface sediments can integrate several years of contamination. A yearly sampling cruise is carried on 1/10 of the French maritime frontage, the whole French littoral being covered every 10 years. The contaminants measured are the same than in biota, in addition to descriptive and normalization parameters (grain size, organic carbon, carbonates, aluminium, iron, lithium and manganese). Some sediment cores are collected to reconstruct the history of the contamination over several decades.
Experience gained: Direct monitoring in water is not used any longer because it is too expensive and not reliable. Indeed, the operational difficulties to collect valid samples (i.e. uncontaminated and representative) for analyses of substances present in water at trace levels are too great. First, collecting uncontaminated samples needs a care difficult to reach in routine monitoring. Secondly, the spatial and temporal representativeness of samples collected in Water Bodies affected by tides and currents, are too low. This is our first-hand

experience of direct measurements of contaminants in water which was carried out between 1979 and 1984 and abandoned for the reasons above. This is coherent with the OSPAR Convention monitoring programme which is also based on biota and sediment.

Conclusion:

To assess the levels of contamination by metals and organic hydrophobic substances, it is highly preferable to use accumulative matrixes that present higher levels and allow temporal integration of the natural water variability.

Recommendations:

Within the frame of the WFD, Surveillance Monitoring should be advantageously carried out in sediments for the metals and hydrophobic substances. One survey by Management Plan (6 years) would be sufficient to assess the quality of the Water Bodies.

Operational Monitoring needs to assess temporal trends of the contamination and should be carried out in biota (mussels as a first choice). One survey per year (synchronous with biological life cycle of the biota) would make possible to evaluate the trends.

Outlook - Next steps – Accessibility of results/information

Ifremer developed a Web site including a broad section devoted to marine monitoring (**www.ifremer.fr/envlit/surveillance**). It is possible to view and to download the data of contaminants in molluscs for each sampling point.

Background information
Title/Name of case study: What Concentrations of Hazardous Substances Do We Find in the Environment? Results from the Swedish Screening Programme 2003-2004
Type of case study: Screening
Reporting Institution: Environmental Protection Agency (Sweden)
Web-Link: www.naturvardsverket.se
Main sources for further information; literature: What concentrations of hazardous substances do we find in the environment? Results from the Swedish Screening Programme 2003-2004 Report 5524, February 2006.
Objective of case study - background information: For the purpose of obtaining information regarding the concentrations of newly discovered persistent organic pollutants (POPs), as well as other potential problem substances used in society, the national environmental monitoring scheme was supplemented by a screening programme a few years ago. In this programme, one or more selected substances are measured on one or more occasions during a single year and in different media, such as sewage, fish or air. Screening was initiated on a small scale in 1996-97 and has gradually increased in scope since then. The reason for including a substance in the screening programme may be that it is used on a large scale, that it has been prioritized in various international contexts, or that it has attracted national attention for other reasons.
Contribution to…
Specific contribution linked to WFD monitoring programmes Data for substances those are not included in the regular monitoring programme.
Description The screening studies have been modelled on the **DPSIR** strategy. This strategy analyses environmental problems based on **D**rivers such as those created by industry, **P**ressures on the environment such as polluting discharges that harm the **S**tate of the environment, which in turn results in an **I**mpact on human health and the environment, whereby we try to find **R**esponses or actions to deal with the problems. *A screening study consists of the following closely-connected parts:* Choice of substance Preparatory theoretical study Measurement study Evaluation
Experience gained: The primary purpose of the screening is not to support research on new POPs, but to comply with requirements on reporting of certain substances in various EU directives and international conventions. Many of these substances are of no relevance for Sweden, and the screening could help to show this so that resources do not have to be wasted on measurement of these substances.

Draw attention to new environmental pollutants. Informing the public without frightening them is important, but perhaps even more important is furnishing data to those who work with chemical risk reduction, i.e. various public authorities.

Conclusion:
Further studies should be made of the following substance groups
Organophosphates
Bisphenol A
α- and β-endosulfan
Siloxanes
Chloro- and bromostyrenes

The following substance group should be subjected to another screening study in a few years
Adipates

The following substance groups do not have to be followed regularly
Chlorinated paraffins
Limonene
Mirex
Isocyanates

Recommendations:
Will be based on the results obtained for each substance/group.

Outlook - Next steps – Accessibility of results/information
Data are available on the Internet from the environmental monitoring scheme's data host for screening.

Background information
Title/Name of case study: Monitoring Using Passive Sampling Devices to Improve Trace Metal-Related Risk Assessments
Type of case study: Complementary monitoring by *in-situ* deployment of passive sampling to help reduce the uncertainty associated with infrequent grab sampling for compliance monitoring
Reporting Institution: University of Portsmouth (UK), Bureau de Recherche Géologique et minière (Fr) As part of the EU-funded FP6 project *Screening Methods for Water Data information in support of the implementation of the WFD (SWIFT-WFD)*
Web-Link: none
Main sources for further information; literature: *Evaluation of the performance of the Chemcatcher and DGT passive sampling devices for monitoring heavy metals in water* Allan IJ, Knutsson J, Guigues N, Mills GA, Fouillac A-M and Greenwood R, (in preparation) *(2007)*
Objective of case study - background information: Demonstration of the applicability of passive sampling to increase confidence in measures of water quality provided by infrequent spot (bottle) sampling campaigns. Grab or bottle sampling followed by filtration at 0.45µm is to be used for compliance checks (AA-EQS & MAC-EQS). Whilst monthly spot samples provide a precise estimate of concentrations of contaminants at the time of sampling, there is uncertainty concerning conditions prevailing in the periods between sampling events. This is of particular concern where concentrations are known to fluctuate or where there are significant or potential natural or anthropogenic pressures. One possible solution to this problem is to deploy passive samplers to provide time-weighted average (TWA) concentrations of concentrations of contaminants in the period between grab samples. This may confirm or contradict the data from the routine monitoring campaigns, and should help to reduce the possibility of making erroneous decisions in risk assessments required in the implementation of the WFD. In this application the TWA concentrations of metals estimated using DGT and Chemcatcher samplers were compared with estimates based on spot sampling in the Meuse River (Eijsden, The Netherlands). In this trial 2 different grab sampling procedures were used at relatively high frequencies (one to three times per week) and metal analyses conducted in two different laboratories in a pilot-scale inter-organisational comparison that incorporated both the analytical determination and the sampling step.
Contribution to…
Specific contribution linked to WFD monitoring programmes Surveillance and operational monitoring tasks
Description *Matrix:* Water *Passive sampling:* Use of the Diffusive Gradient in Thin Film (DGT) and Chemcatcher sampling devices following guidelines provided in the BSI Publicly Available Specification 61, and analysis of sampler extracts by ICP-MS in an university research laboratory. *Sampler exposure:* Consecutive and/or overlapping 7, 14, 21 and 28 day periods *Grab sampling protocol 1:* Routine weekly sampling, transport of the sample to the laboratory followed by filtration (0.45 µm) and ICP-MS analysis. *Grab sampling protocol 2:* Sampling every two or three days, on-site filtration (0.45 µm) and analysis by ICP-OES in an accredited laboratory.

Experience gained:
There was good agreement between the results for cadmium, copper, nickel and zinc provided by the two types of samplers, despite differences in their working principles. High and fluctuating concentrations of cadmium (between proposed MAC-EQS and AA-EQS thresholds) were detected by passive sampling during the first 14 day exposure period. This was confirmed by the relatively high frequency of grab sampling used in this trial, but may have been missed if only conventional sampling rates had been used. Extra information, on speciation of the metals, was provided by the samplers, and this was consistent with predictions obtained using equilibrium speciation modelling with visual MINTEQ (NICA-Donnan model).

Conclusion:
Reliability and consistency of TWA metal concentrations measured by passive sampling were shown when compared with 2 distinct grab sampling protocols in a procedure that included uncertainty both on the sampling and analytical measurement steps. This provided representative information on average concentrations. On the other hand an estimate based on a single grab sample could have provided misleading information since for instance levels of Cd varied over a factor of five during the trial.

Recommendations:
Passive sampling devices should be deployed following BS PAS 61 guidelines and manufacturer's specifications for period up to 14 to 20 days to achieve representative sampling. This should be combined with grab sampling to reduce monitoring uncertainty to manageable levels.

Outlook - Next steps – Accessibility of results/information
These results will be published in detail in a peer-reviewed scientific journal.

A desirable extension of this work would be to increase the duration of the trial to two or three years in order to provide a reliable, long-term comparison between the average concentrations of contaminants estimated by routine grab sampling, and passive sampling. This would establish the utility of the two methods either on their own or in combination to quantify trends in trace metal concentrations over time. Since the two methods measure different (operationally defined, and water body specific) fractions of metals, relationships between the concentrations in filtered bottle samples and those measured by passive samplers need to be established.

Other future developments may include testing and optimising combinations of grab and passive sampling in order to improve sampling representativeness while ensuring a reduction in monitoring costs.

Foreword

Activities to support the implementation of the Water Framework Directive are under way both in Member States and in the European Commission. The EU Member States, Norway and the European Commission have jointly developed a common strategy for supporting the implementation of the Directive 2000/60/EC, "establishing a framework for Community action in the field of water policy" (the Water Framework Directive). The main aim of this strategy is to allow a coherent and harmonious implementation of the Directive. The focus is on methodological questions related to a common understanding of the technical and scientific implications of the Water Framework Directive.

In the context of this common implementation strategy (CIS), a series of working groups and joint activities have been launched for the development and testing of non-legally binding Guidance Documents. A strategic co-ordination group oversees these working groups and reports directly to the Water Directors of the European Union and Commission that play the role of the overall decision body for the Common Implementation Strategy.

As a result of a four year discussion initiated by the Water Directors and assisted by a Drafting Group, several documents have been prepared to identify some key issues and make recommendations related to environmental objectives and exemptions.

Now this previous work is brought together in one consolidated document to give a full overview on the issue of environmental objectives and exemptions. This document compiles previously agreed interpretations on issues related to environmental objectives and exemptions and does not add any new issues. The previously agreed documents will stay available on Circa[1] as background documents for this consolidated guidance document.

Table of contents

1 INTRODUCTION - A GUIDANCE DOCUMENT: WHAT FOR?

On 23 October 2000, the "Directive 2000/60/EC of the European Parliament and of the Council establishing a framework for the Community action in the field of water policy" or, in short, the **EU Water Framework Directive** (or even shorter the WFD) was adopted. By means of this Framework Directive, the EU provides for the management of inland surface waters, groundwater, transitional waters and coastal waters in order to prevent and reduce pollution, promote sustainable water use, protect the aquatic environment, improve the status of aquatic ecosystems and mitigate the effects of floods and droughts.

The environmental objectives are defined in Article 4 - the core article - of the Water Framework Directive (WFD). The aim is long-term sustainable water management based on a high level of protection of the aquatic environment. Article 4.1 defines the **WFD general objective** to be achieved in all surface and groundwater bodies, i.e. good status by 2015, and introduces the principle of preventing any further deterioration of status. There follow a number of **exemptions** to the general objectives that allow for less stringent objectives, extension of deadline beyond 2015, or the implementation of new projects, provided a set of conditions are fulfilled.

As for many of the challenging concepts under the WFD, the text of the directive provides the framework and gives the general orientation but there is scope for differences in understanding and application. So from the first day of the implementation it was clear that the use of exemptions needed to be explained further and the rules for application had to become clearer.

Under the Common Implementation Strategy (CIS) of the WFD several working groups for various topics have been set up[2]. The issue of exemptions was firstly addressed in the working group on economics (WATECO) where a first indication of how to deal with exemptions related to disproportionate costs is given. The WATECO guidance document, endorsed by the Water Directors, in particular started to discuss exemptions in the light of disproportionate costs.

In June 2005, the Water Directors (WD) endorsed a paper on the environmental objectives under the WFD (WFD). This document introduced key elements regarding the environmental objectives of the WFD. At the end of 2006, the Water Directors endorsed a Policy Paper on the application of Article 4.7 for new modifications. In November 2007, a third document dealing with the exemptions on extension of deadlines (4.4), the setting of less stringent objectives (4.5) and temporary deterioration (4.6) was endorsed by the Water Directors. Finally, a specific paper with conclusions on disproportionate costs was endorsed by the Water Directors in June 2008[3].

In addition to the agreed documents, information on case studies and practical examples was exchanged at various occasions. Information related to a workshop held in Berlin in 2005 and in Copenhagen in 2008 can be found at the Circa website[4].

---

[2] See http://circa.europa.eu/Public/irc/env/wfd/library?l=/framework_directive/guidance_documents

[3] All papers can be found at http://circa.europa.eu/Public/irc/env/wfd/library?l=/framework_directive/thematic_documents/environmental_objectives

[4] See http://circa.europa.eu/Public/irc/env/wfd/library?l=/framework_directive/implementation_conventio/objectives_exemptions and http://circa.europa.eu/Public/irc/env/wfd/library?l=/framework_directive/implementation_conventio/disproportionate

After this, all existing earlier agreed papers are brought together into one consolidated document, resulting in this guidance document. Chapter 2 recalls the requirements of the WFD related to the environmental objectives and the exemptions. Chapter 3 reflects on key issues for the interpretation of the exemptions. In paragraph 3.2, horizontal issues which are applicable to two or more exemptions are addressed. In addition to these horizontal issues, paragraph 3.3 until 3.5 included address some specific issues related to each exemption.

This guidance document intends to provide earlier agreed information in a complete way, and may be useful for water managers involved in preparing the river basin management plans, as well as to the public interested in the (draft) river basin management plans (RBMP) and the related process of objectives setting.

2 RECALL OF WFD REQUIREMENTS IN RELATION TO ENVIRONMENTAL OBJECTIVES

2.1 General introduction

The environmental objectives and the exemptions are set under Article 4 of the WFD. The subsequent paragraphs aim at describing Article 4, mainly the exemptions, in a summarised way and in the order presented in the Directive.

Article 4 WFD sets out the **"environmental objectives"** mainly in Article 4.1. The **main environmental objectives** in the Directive are manifold and include the following elements (for details see Article 4.1, (a) surface waters, (b) groundwaters and (c) protected areas):

- ***No deterioration*** of status for surface and groundwaters and the protection, enhancement and restoration of all water bodies;
- Achievement of *good status* by 2015, i.e. good ecological status (or Potential) and good chemical status for surface waters and good chemical and good quantitative status for groundwaters;
- ***Progressive reduction of pollution*** of priority substances and ***phase-out*** **of** priority hazardous substances in surface waters[5] and prevention and limitation of input of pollutants in groundwaters;
- ***Reversal*** of any significant, upward ***trend*** of pollutants in groundwaters;
- Achievement of Standards and objectives set for ***protected areas*** in Community legislation.

It is important to note that where more than one of the objectives relates to a given body of water, the most stringent shall apply (Art. 4.2), irrespective of the fact that all objectives must be achieved.

It is important to understand that the normative definitions for the environmental objective of "good status" are described in the Directive in great detail in Annex V. However, the development of specific numerical criteria and classification schemes including class boundaries is described only as regards the process. Taking into account the results of the intercalibration exercise Member States are obliged to set detailed values defining the status for each water body.

For **heavily modified and artificial water bodies**, Article 4.1 point (a) indent (iii) sets out "specific objectives" for these specific water bodies. In Article 4.3, strict criteria for the designation of artificial or heavily modified water bodies are described.

In order to achieve the specific objectives for heavily modified and artificial water bodies (i.e. good ecological potential and good chemical status), the provisions for designation (see Article 4.3), contain elements of comparing the consequences of achieving the 'good ecological status' to a number of aspects including economic considerations. Moreover, the assessment of "good ecological potential" is linked to the possible mitigation measures[6].

There has been a debate whether these requirements should be interpreted as "alternative objectives" or "exemptions". **It has been agreed that artificial and heavily modified water bodies do not constitute a conventional objective or exemption. They are a**

[5] Pollution of "other pollutants" than PS and PHS need to be reduced by Member States in accordance with Article 11 (3) (k) WFD.

[6] See Guidance Document No. 4 on "Identification and Designation of HMWB and AWB" for more detail. http://europa.eu.int/comm/environment/water/water-framework/guidance documents.html

specific water body category - with its own classification scheme and objectives - which is related to the other exemptions in requiring certain socio-economic conditions to be met before it comes to play.

An integral part of the environmental objectives set out in Article 4 are the so-called exemptions. Article 4.4, 4.5, 4.6 and 4.7 describe the conditions and the process in which they can be applied. These exemptions range from small-scale temporary exemptions to mid- and long term deviations from the rule "good status by 2015[7]", and include the following aspects:

- **the extension of the deadline** , in other words, good status must be achieved by 2021 or 2027 at the latest (Article 4.4) or as soon as natural conditions permit after 2027;
- the achievement of **less stringent objectives** under certain conditions (Article 4.5);
- the **temporary deterioration** of the status in case of natural causes or "force majeur" (Article 4.6);
- **new modifications** to the physical characteristics of a surface water body or alterations to the level of bodies of groundwater, or failure to prevent status deterioration of a body of surface water (including from high status to good status) as a result of new sustainable human development activities (Article 4.7).

Common to all these exemptions are strict conditions to be met and a justification to be included in the River Basin Management Plan.

Comparing the criteria for applying the various exemptions (or "exemption tests"), there are some similarities between them. Thus, it should be discussed how and when to apply particular exemptions and whether there is a certain sequence or hierarchy when applying them together (see chapter 3 for more details).

Finally, paragraphs 8 and 9 of Article 4 introduce two principles applicable to all exemptions,

- first, exemptions for one water body must not permanently exclude or compromise achievement of the environmental objectives in other water bodies
- second, at least the same level of protection must be achieved as provided for by existing Community law (including those elements to be repealed).

2.2 Scope of article 4.4 and 4.5

Under certain conditions, the WFD permits the assignment of a less stringent objective or the extension of the timescales for achieving a particular objective:

Art 4.4
The deadlines established under paragraph 1 may be extended for the purposes of phased achievement of the objectives for bodies of water, provided that no further deterioration occurs in the status of the affected body of water when all of the following conditions are met:

(a) Member States determine that all necessary improvements in the status of bodies of water cannot reasonably be achieved within the timescales set out in that paragraph for at least one of the following reasons:

(i) the scale of improvements required can only be achieved in phases exceeding the timescale, for reasons of technical feasibility;
(ii) completing the improvements within the timescale would be disproportionately expensive;
(iii) natural conditions do not allow timely improvement in the status of the body of water.

[7] or "good ecological potential by 2015 " for HMWB and AWB.

(b) Extension of the deadline, and the reasons for it, are specifically set out and explained in the river basin management plan required under Article 13.

(c) Extensions shall be limited to a maximum of two further updates of the river basin management plan except in cases where the natural conditions are such that the objectives cannot be achieved within this period.

(d) A summary of the measures required under Article 11 which are envisaged as necessary to bring the bodies of water progressively to the required status by the extended deadline, the reasons for any significant delay in making these measures operational, and the expected timetable for their implementation are set out in the river basin management plan. A review of the implementation of these measures and a summary of any additional measures shall be included in updates of the river basin management plan.

Art 4.5
Member States may aim to achieve less stringent environmental objectives than those required under paragraph 1 for specific bodies of water when they are so affected by human activity, as determined in accordance with Article 5(1), or their natural condition is such that the achievement of these objectives would be infeasible or disproportionately expensive, and all the following conditions are met:

(a) the environmental and socioeconomic needs served by such human activity cannot be achieved by other means, which are a significantly better environmental option not entailing disproportionate costs;

(b) Member States ensure,
— for surface water, the highest ecological and chemical status possible is achieved, given impacts that could not reasonably have been avoided due to the nature of the human activity or pollution,
— for groundwater, the least possible changes to good groundwater status, given impacts that could not reasonably have been avoided due to the nature of the human activity or pollution;

(c) no further deterioration occurs in the status of the affected body of water;

(d) the establishment of less stringent environmental objectives, and the reasons for it, are specifically mentioned in the river basin management plan required under Article 13 and those objectives are reviewed every six years.

2.3 Scope of article 4.6

Article 4.6 differs from articles 4.4 and 4.5 in that it relates to events which "could not reasonably have been foreseen".

Art 4.6.
Temporary deterioration in the status of bodies of water shall not be in breach of the requirements of this Directive if this is the result of circumstances of natural cause or force majeure which are exceptional or could not reasonably have been foreseen, in particular extreme floods and prolonged droughts, or the result of circumstances due to accidents which could not reasonably have been foreseen, when all of the following conditions have been met:

(a) all practicable steps are taken to prevent further deterioration in status and in order not to compromise the achievement of the objectives of this Directive in other bodies of water not affected by those circumstances;

(b) the conditions under which circumstances that are exceptional or that could not reasonably have been foreseen may be declared, including the adoption of the appropriate indicators, are stated in the river basin management plan;

(c) the measures to be taken under such exceptional circumstances are included in the programme of measures and will not compromise the recovery of the quality of the body of water once the circumstances are over;

(d) the effects of the circumstances that are exceptional or that could not reasonably have been foreseen are reviewed annually and, subject to the reasons set out in paragraph 4 (a), all practicable measures are taken with the aim of restoring the body of water to its status prior to the effects of those circumstances as soon as reasonably practicable, and

(e) a summary of the effects of the circumstances and of such measures taken or to be taken in accordance with paragraphs (a) and (d) are included in the next update of the river basin management plan.

Hence it is not used for setting alternative objectives during the improvement planning process - rather it is used after the event, as a "defence" to justify why an objective which was set in a river basin management plan has not been met. This justification must be provided in the following (update of the) river basin management plan. Details are discussed in section 3.4.

2.4 Scope of article 4.7

Article 4.7 sets out circumstances in which failure to achieve certain of the WFD objectives are permitted.

Art 4.7.
Member States will not be in breach of this Directive when:

- failure to achieve good groundwater status, good ecological status or, where relevant, good ecological potential or to prevent deterioration in the status of a body of surface water or groundwater is the result of new modifications to the physical characteristics of a surface water body or alterations to the level of bodies of groundwater, or

- failure to prevent deterioration from high status to good status of a body of surface water is the result of new sustainable human development activities

and all the following conditions are met:

(a) all practicable steps are taken to mitigate the adverse impact on the status of the body of water;
(b) the reasons for those modifications or alterations are specifically set out and explained in the river basin management plan required under Article 13 and the objectives are reviewed every six years;
(c) the reasons for those modifications or alterations are of overriding public interest and/or the benefits to the environment and to society of achieving the objectives set out in paragraph 1 are outweighed by the benefits of the new modifications or alterations to human health, to the maintenance of human safety or to sustainable development, and
(d) the beneficial objectives served by those modifications or alterations of the water body cannot for reasons of technical feasibility or disproportionate cost be achieved by other means, which are a significantly better environmental option.

Note that Article 4.7 does not provide an exemption if deterioration caused by inputs of pollutants from point or diffuse sources drives the water body to a status below good.

If the resulting development is not causing a deterioration of status on the water body scale, art. 4.7 does not have to be used (for example if replacing one activity by another).

Details on how Art 4.7 can be applied are provided in section 3.5.

3 KEY ISSUES IN THE PROCESS OF JUSTIFYING EXEMPTIONS

3.1 General Introduction

When discussing exemptions it should be taken into account that the WFD is an environmental directive and exempting from its objectives should not be the rule but exceptional. It is important that before considering the application of exemptions for a certain water body, all relevant requirements from existing EU legislation for the protection of water have to be fulfilled. Nevertheless "exemptions" are an integral part of the environmental objectives set out in Article 4 and the planning process.

Member States are encouraged to keep the analysis for applying exemptions as simple as possible, but as detailed as necessary. The level of information should be determined by the complexity of the decision and the possible consequences of taking the wrong decision.

When consensus is reached between all relevant stakeholders in an early stage of the decision-making process, the efforts for data gathering may be reduced. Thus, early consensus may help to reduce analytical efforts but does not replace an economic analysis.

In the following section the key issues to use exemptions are outlined in more detail. First, some horizontal issues related to the exemptions in general are set out (in paragraph 3.2), followed by specific issues for Article 4.4 and 4.5 (in paragraph 3.3), Article 4.6 (in paragraph 3.4) and Article 4.7 (paragraph 3.5).

3.2 Horizontal issues

3.2.1 Scale

Member States have to set objectives for individual water bodies. As reflected in the 2010 reporting sheets, Member States are asked to report each water body for which the objective will not be good status by 2015; the alternative objective related to the affected quality element, and the reasons for this.

It is however recognised that different scales (national, basin, sub-basin, water body) may be appropriate for different assessments or different aspects of the same assessment. For example, transboundary issues have to be assessed on a transboundary scale. However, the choice of the scale should be justified by the provisions of the WFD and if the information used to justify an exemption is gathered at a more aggregated level it needs to be clear that the aggregated information is relevant for the concerned water body or group of water bodies.

Furthermore, Article 4.8 specifies that when applying an exemption to a water body, "a Member State shall ensure that the application does not permanently exclude or compromise the achievement of the objectives of this Directive in other bodies of water within the same river basin district and is consistent with the implementation of other Community environmental legislation." Regarding the link between water bodies, it is clear that there cannot be an automatic mechanism for justifying exemptions in an adjacent water body on the basis of an assessment carried out for another water body. This does not necessarily imply that the reasons (e.g. water uses or significant pressures) for justifying an exemption must always be located within the water body for which the exemption is sought for.

3.2.2 Protected areas

It is generally understood that the exemptions in Article 4.4 and 4.5 and 4.6 are applicable to all environmental objectives in Article 4.1, thus also to Article 4.1(c), which describes the objectives for protected areas. But Article 4.9 is clear in its obligation that when applying the exemptions of Article 4, the same level of protection should be given as in existing Community legislation. This means that exemptions from the WFD environmental objectives cannot be used to deviate from objectives and obligations set by other pieces of EU legislation.

For example, a new development is proposed that would cause deterioration of status and a failure to achieve the objectives for a Natura 2000 site. In such a case, in order to fulfil both the WFD and the Habitats Directive:

- The relevant conditions set out in Article 4.7 of the WFD for allowing deterioration of status would have to be met to the extent that it is a water body; and
- The conditions set out in Article 6 of the Habitats Directive (92/43/EEC) for allowing a failure to achieve a Natura 2000 site's objective would have to be met.

3.2.3 Management of uncertainties

Uncertainty is an inevitable feature of objective setting in general, and will therefore be a feature of the first set of river basin plans[8]. Uncertainties should be taken into account in deciding the appropriate action. This action may include further investigation, monitoring and assessment to reduce uncertainties and this could contribute to the justification for the phasing of measures across cycles. Uncertainty will reduce over the medium to long term but will always be present. There can be uncertainty about:

- Whether, and to what extent, a water body is adversely impacted and what and/or who causes the impact;
- The impact of policies already in place or planned and various trends and developments, including innovation and technical change;
- The effectiveness of measures in addressing an adverse impact on a water body (note that this will have an effect on the certainty of the benefits as well);
- The assessment of the achievement of good status[9];
- The costs associated with measures;
- The benefits resulting from improvements to the status of water bodies, particularly the calculation of the non-marketable benefits.

These uncertainties will also relate to the analysis for applying exemptions, and will have substantial impact on cost and benefit estimates. There are a number of things which can be done, and should be done, to reduce uncertainties or to deal with them in the decision-making process. For example:

- Choose reversible measures, measures that can be easily adapted, measures that can be carried out iteratively or measures with low risk and costs, and high return[10]. Where

[8] See also Guidance nr 13 on Classification of Ecological Status on: http://circa.europa.eu/Public/irc/env/wfd/library?l=/framework_directive/guidance_documents

[9] A number of uncertainties are addressed by the Directive's requirements to apply the 'one out - all out' principle and to set physico-chemical Standards characterising the good Status and to use hydro-morphological parameters to define the high Status. The pressure - Status - impact relations are well researched and understood for most of those non-biological parameters. Furthermore, uncertainties associated with the assessment of water body Status are addressed in the CIS ECOSTAT work programme 2007-2009.

[10] These measures are often referred to as 'no-regret measures'.

there is significant uncertainty, the risk of incurring disproportionate costs can be reduced by choosing measures that can be readily and iteratively added to, or adapted, in the future on the basis of information on their effects and the associated benefits. However, these kinds of measures are not necessarily the ones that are most acceptable to stakeholders.

- Estimating and recording the level of uncertainty is needed to take into account uncertainty in objective setting.
- Weigh the benefits in such a way that the additional uncertainty of benefits relative to costs is taken into account. The same logic should apply where costs are more uncertain than benefits, though this is likely to be less common in practice.
- Actions need to be taken to reduce uncertainty (e.g. by research programmes), although these actions need to be proportional. The findings of the Article 5 reports are an important basis for addressing knowledge gaps and identifying follow-up actions.
- Efforts to reduce uncertainty should be proportional to the difficulty of the decision at hand and the implications of making a wrong decision. However, there is no point attempting to reduce uncertainty if doing so does not clarify the decision at hand. It may be better to act on the basis of principle, for example the precautionary principle and/or the polluter pays principle and/or, where possible, on the basis of consensus.
- There needs to be a balance between the risk of failing to meet objectives and the risk of failing to use the most cost-effective means of achieving those objectives, with priority being given to minimising the risks of the first.

For example, the effectiveness of diffuse pollution measures may be more uncertain than the effectiveness of point source pollution measures. Conversely, the costs of diffuse pollution measures may be less than the costs of point source pollution measures.

3.2.4 Technical infeasibility

In principle, only issues of a technical nature should be taken into account in applying the technical infeasibility test - as referred to in Article 4.4 and 4.7 - and not cost issues. Although cost savings may be associated with extending the deadline for achieving good status, such savings are not relevant in deciding whether making the improvements by the deadline would be technically infeasible.

Technical infeasibility is justified if:

- No technical solution is available;
- It takes longer to fix the problem than there is time available;
- There is no information on the cause of the problem; hence a solution cannot be identified.

In practice, the greater the effort expended in trying to overcome practical issues of a technical nature, the greater the likelihood that technically feasible ways of making the improvements will be found. This means that consideration of the costs and benefits will need to be considered alongside technical feasibility. Where the benefits resulting from an improvement would be substantial, a much higher degree of effort to find a technically feasible option is likely to be appropriate than where the benefits of an improvement are expected to be low.

Further guidance can be provided by the term 'best available technique (BAT)' which is defined in the IPPC-directive (96/61/EC)[11], although in the cases where going beyond BAT might be technically feasible, these options should be explored.

Article 4.5 refers to the term 'infeasible', which includes technical infeasibility, but which could also refer to situations where addressing a problem is out of the control of a Member State.

3.2.5 Disproportionate costs

The term disproportionate costs (or disproportionately expensive) is used in Article 4.4, 4.5 and 4.7 of the WFD. Below, some principal issues related to these terms are addressed.

3.2.5.1 General introduction of the terms 'disproportionate costs'

'Disproportionality', as referred to in Article 4.4 and 4.5, is a political judgement informed by economic information, and an analysis of the costs and benefits of measures is necessary to enable a judgement to be made on exemptions. It was already concluded in the WATECO guidance that, given the uncertainty around estimates of costs and benefits one should bear in mind that,

- Disproportionality should not begin at the point where measured costs simply exceed quantifiable benefits;
- The assessment of costs and benefits will have to include qualitative costs and benefits as well as quantitative;
- The margin by which costs exceed benefits should be appreciable and have a high level of confidence;
- In the context of disproportionality the decision-maker may also want to take into consideration the ability to pay of those affected by the measures and some information on this may be required.

From the logic of the WFD is becomes clear that an assessment of disproportionate costs only makes sense after a combination of the most cost-effective solutions has been identified. Most importantly, for all cases where an exemption is applied, all measures that can be taken without involving disproportionate costs should still be taken to reach the best status possible.

In cases where exemptions are considered the consequences of non-action (i.e. foregone benefits) need to be weighed against the specific costs of the measures.

3.2.5.2 Costs of measures required under other Community legislation

The costs of measures required under existing Community legislation already agreed at the time of the adoption of the Directive cannot be considered when deciding on disproportionate costs. Without prejudice to the transitional arrangements in the Accession Treaties, this also applies to Member States which joined the EU in 2004 and 2007.

---

[11] 'best available techniques' shall mean the most effective and advanced stage in the development of activities and their methods of Operation which indicate the practical suitability of particular techniques for providing in principle the basis for emission limit values designed to prevent and, where that is not practicable, generally to reduce emissions and the impact on the environment as a whole. For further details, see http://ec.europa.eu/environment/air/legis.htnrfstationary

3.2.5.3 Affordability issues

Affordability (or ability to pay for a certain measure) can be one element for justifying the decision on a time extension (i.e. application of Article 4.4), if based on a clear explanation:

- of the non-availability of relevant alternative financing mechanisms which would not result in affordability issues,
- of the consequences of non-action in deciding on an extension of the deadline,
- of steps to resolve the affordability issues in the future.

Non-action by one player does not automatically lead to non-action by other players within the same sector.

Furthermore, Member States may phase the implementation of measures to spread the costs of the implementation, but there is the need for clear and demonstrable action in the first cycle.

When affordability arguments are used to extend the deadline, the possibility to use relevant **alternative financing mechanisms** should be fully considered. The alternative financing mechanisms could include distribution of costs among polluters and users, use of the public budget (at different levels), private investment, EU and international funds, etc. These relevant alternative financing mechanisms should be considered at the appropriate scale.

On the role of affordability in setting less stringent objectives, no guidance can be provided at this stage. For some Water Directors affordability could play a role in setting less stringent objectives, as both Article 4(4) and 4(5) use the same terminology 'disproportionately expensive'. They indicated that in practice affordability arguments may be used less frequently in Article 4(5) than in Article 4(4). Some other Water Directors argued that affordability can not be used as an argument for setting less stringent objectives as the context of 'disproportionate expenses' is different in 4(5) from the context in Article 4(4) as it concerns setting lower objectives permanently (subject to revision every 6-years). These Water Directors consider that application of this provision requires it to be set out clearly that the costs outweigh the benefits of achieving the targets.

On the role of constraints of the public budget as a reason for extending the deadline, no guidance can be provided at this stage either. Most Water Directors indicated that constraints of the public budget may be used as a reason for extending the deadline as there are limits to the available budget for water management. The Commission indicated that in its views the adoption of the WFD by the Council and the European Parliament entails obligations for Member States to make available the necessary means for its implementation.

3.2.5.4 Prioritisation approaches in the context of disproportionate costs

The Water Directors agreed that a proportionate selection of the different analyses (cost-benefit analysis, benefits assessment, assessment of the consequences of non-action, distribution of costs, social and sectoral impacts, affordability, cost-effectiveness etc) is useful to inform decision making.

It was also agreed by the Water Directors that prioritisation approaches for ranking measures that are considered technically feasible can be the first operational steps in the assessment of cost disproportionality, but that a justification of an extension of the deadline following these approaches should respect the relevant provisions of the WFD. The results of prioritisation have to be developed on or transformed to the water body level when relevant.

It was emphasised that prioritisation takes place on different geographic / administrative levels (e.g. MS, River Basin, Region, sub unit, water body) and should consider the different basic conditions in the area. The prioritisation process should take into account a set of relevant criteria, for example:

- synergies with other directives, e.g. habitat directive, flood risk management directive
- cost-efficiency / benefits of measures
- consequences of non-action
- certainty / uncertainty ("no regret measures")
- measures which could be implemented short term
- urgency of problem to be solved(severe consequences/high cost of non action: e.g. protection of drinking water supplies)
- existence of available financing mechanisms
- acceptance by the public

Prioritisation criteria and results should be transparent and should be disclosed to the public. The prioritisation approach should also give information on the further timescale to reach the environmental objectives.

3.2.6 Alternative means

In both Article 4.5 and Article 4.7, the necessity is mentioned to assess 'alternative means'. In Article 4.5 this refers to alternatives to serve the environmental and socioeconomic needs served by a certain human activity, which are a significantly better environmental option not entailing disproportionate costs. In Article 4.7 it is indicated that it is necessary to demonstrate that the beneficial objectives served by the modifications or alterations of the water body cannot for reasons of technical feasibility or disproportionate cost be achieved by other means, which are a significantly better environmental option.

Those means or alternatives solutions could involve alternative locations, different scales or designs of development, or alternative processes. Alternatives should be assessed in the early stages of development and at the appropriate geographical level (EU, national, RBD) against a clear view of the beneficial objectives provided by the modification.

For projects under its scope, the use of the requirements of the EIA Directive can help to assess the different possible alternatives.

3.2.7 Transboundary context

In international river basin districts within the EU, exemptions need to be coordinated. This obligation to coordinate the requirements for the achievement of the environmental objectives is indicated in Article 3.4 and 3.5.

Exemptions can be applied in cases where a certain Member State cannot resolve the reasons for not achieving the environmental objectives because they lay outside the competence and jurisdiction of the Member State. In these cases, a country causing the problem should be obliged to provide enough information for justification of the application of exemptions for the affected Member State.

Frequent information exchange between Member States, and between an EU Member State and a country outside the EU, is crucial when applying exemptions in a transboundary context. This includes information on intermediate objectives and the expected evolution for the water bodies where exemptions are applied. This enables affected Member States to adapt their own planning process.

In cases where the reasons for not achieving good status cannot be resolved by a Member State since they are outside the competence and jurisdiction of the Member State, the WFD includes the provision of Article 12 on the involvement of the Commission to solve the issue.

The key issue in both applying the exemption and invoking Article 12 is the demonstration of evidence that Member States have taken all reasonable actions to fulfil the legal obligations.

More information on the transboundary context is included in Annex II: Exemptions in a transboundary context

3.2.8 Public participation and transparency

Active participation at an early stage should be encouraged not only because of legal requirements, but it can also be used to get a better insight in factors influencing the application of exemptions (such as costs and benefits and technical feasibility). Further, it might also give an early indication of acceptability and create a basis of understanding of a certain decision on objective setting. However, public information and consultation do not guarantee acceptance of a range of (feasible) measures.

As a minimum, the public should be given insight in the reasons for applying exemptions (eg. as mentioned in Article 4(a) i, ii and iii) per water body for which an exemption is applied.

Public information and consultation is not only an obligation of WFD Article 14 and other legislation, also Article 4(4) and 4(5) and the related recitals require that the following information should be provided in the river basin management plans[12]:

- the reasons for an extension of the deadline should be specifically set out
- the reasons for the establishment of less stringent environmental objectives should be specifically mentioned;
- a summary of the measures to bring the bodies of water *progressively* to the required status;
- the reasons for any significant delay in making the measures operational;
- the expected timetable for the implementation of the measures (that are delayed);
- the appropriate, evident and transparent criteria used for applying exemptions

It is agreed that:

- there is the need for clear and demonstrable action in the first cycle;
- when applying the 'disproportionality justification', the reasons, underlying data and assessments should be made public;
- if affordability arguments are used, an explanation that there are no relevant alternative financing mechanisms available;
- an explanation of how consequences of non-action are taken into account and what action will be taken to address these reasons, so that in the future a time extension is no longer needed.

[12] See 4.4(b):'Extension of the deadline, and the reasons for it, are specifically set out and explained in the river basin management plan required under Article 13' and 4.4(d):' A summary of measures required under Article 11 which are envisaged as necessary to bring the bodies of water progressively to the required status by the extended deadline, the reasons for any significant delay in making these measures operational, and the expected timetable for their implementation are set out in the river basin management plan.' and 4.5(d):' the establishment of less stringent environmental objectives and the reasons for it, are specifically mentioned in the river basin management plan required under Article 13 and those objectives are reviewed every six years', including reasons why 'the environmental and socioeconomic needs served by such human activity cannot be achieved by other means, which are a significantly better environmental option not entailing disproportionate costs' (4.5(a)).

3.2.9 Link with Strategic Environmental Assessment and Environmental Impact Assessment

Both in applying Article 4.4/4.5 and in applying Article 4.7, the question may arise regarding how a link to the Environmental Impact Assessment (EIA)[13] and/or Strategic Environmental Assessment (SEA)[14] can be best made.

Some measures to improve status may fall within the scope of the EIA Directive and hence require an EIA (see Figure below). Furthermore, the EIA Directive gives a list of some of the environmental factors to consider in assessment of environmental costs and benefits which should be a starting point.

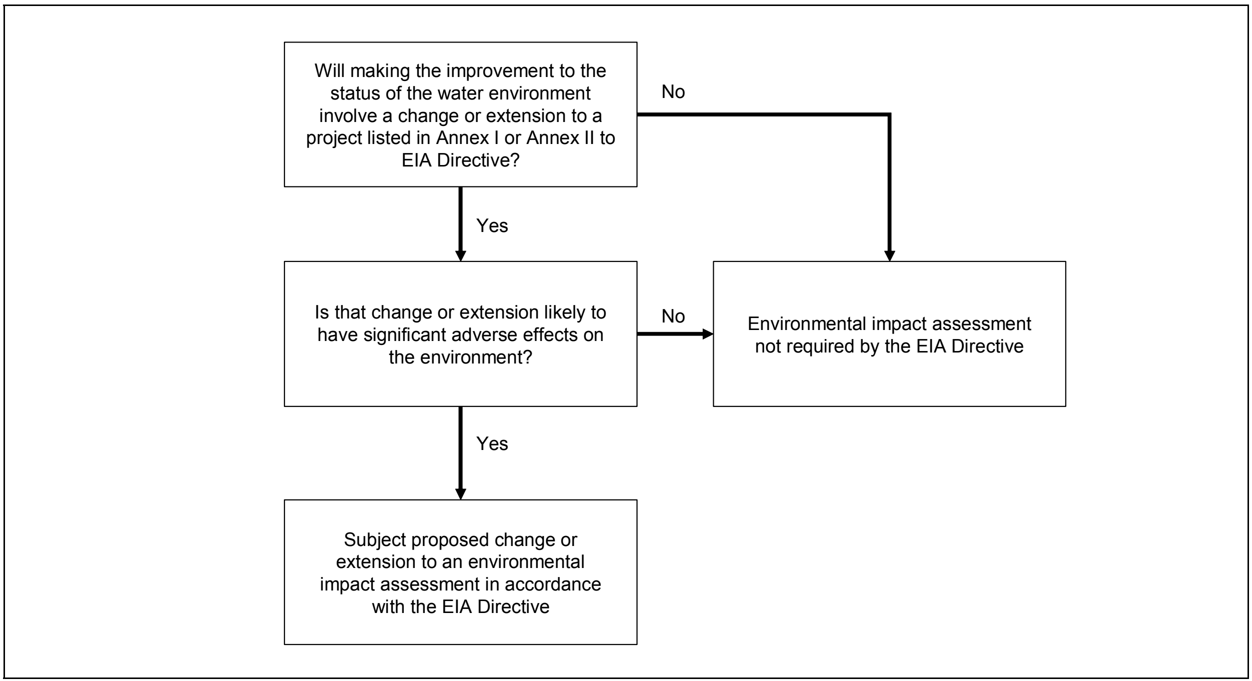

Figure 0: Link between EIA and measures under the WFD

Information from an already carried out SEA or EIA should be used as much as possible in exemptions tests. However, a formerly carried out EIA is not a blank cheque for application of the WFD exemptions.

The assessment of whether the criteria and conditions set out in **Article 4.7** are met needs to be carried out in the planning stage. Thus, it makes sense to incorporate such an evaluation into the environmental impact assessment which has to be done for most of these types of projects. However, even if certain projects are not covered by the EIA Directive, article 4.7 may apply. For plans and programmes affecting the environmental objectives of the WFD, the evaluation in accordance to 4.7 should be incorporated into the SEA[15].

In summary, the planning of "new modifications" requires the carrying out of an assessment of the environmental impacts which demonstrates, at least, that the criteria and conditions of Article 4.7, but also 4.8 and 4.9, are met.

---

[13] Directive 85/337/EEC

[14] Directive 2001/42/EC

[15] See guidance document on the implementation of the SEA Directive, available at http://europa.eu.int/comm/environment/eia/sea-support.htm

3.3 Key issues for Article 4.4 and 4.5

3.3.1 Relationship between Article 4.4 and 4.5

The relationship between Article 4.4 and Article 4.5 is not a hierarchy in the sense that Member States must prove that one is ruled out before considering another. Member States are free to apply either exemption, provided the relevant exemption tests are met. However, the conditions for setting less stringent objectives require more information and in-depth assessment of alternatives than those for extending the deadline. For this reason, there should be a stepwise thinking process for considering what sort of exemption may be most appropriate (see Figure 1).

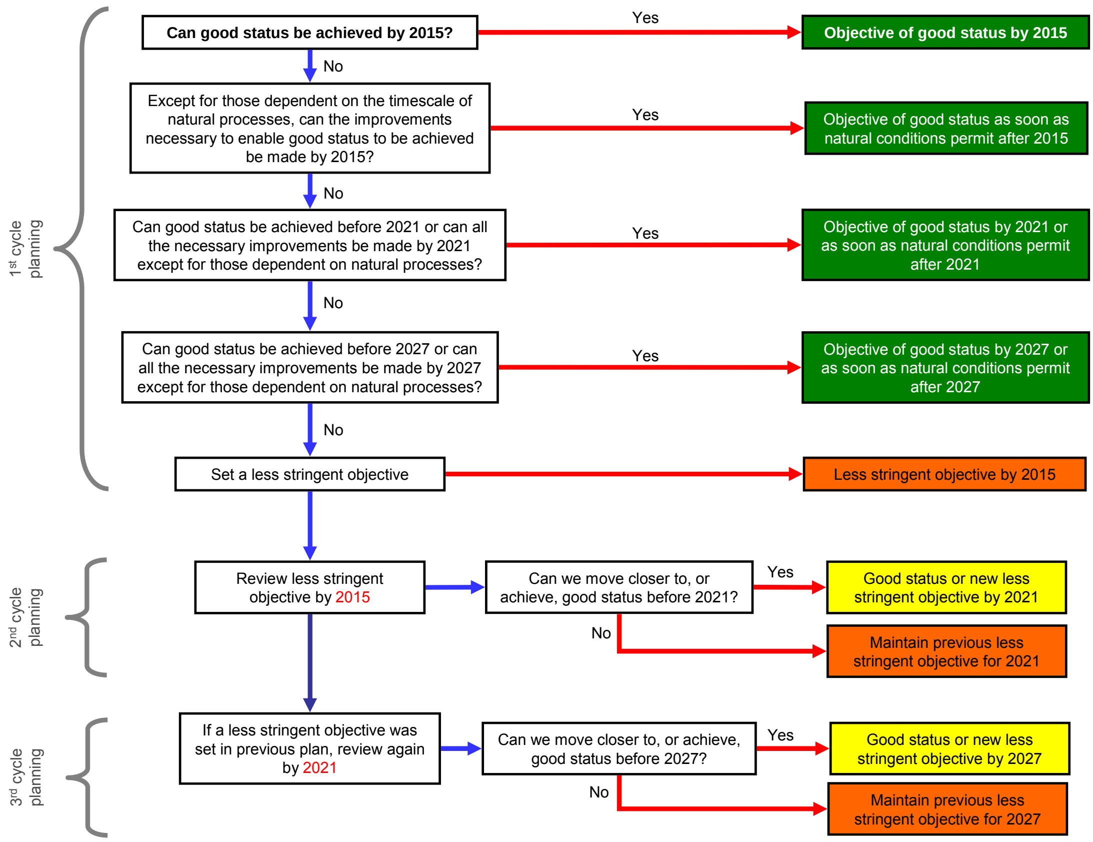

Figure 1: Stepwise thinking process for the considerations of exemptions from good status. The orange boxes refer to Art 4.5, the green except the first box to Art 4.4. For water bodies designated as heavily modified or artificial, references in the Figure to 'good status' should be taken to mean 'good ecological potential and good surface water chemical status[16]. Note, if the objective of "good status" is aimed for (green boxes), the achievement of "good status" needs to be confirmed by monitoring data.

[16] All information needed for the decision on exemptions should be on the desk before starting the stepwise process, especially the economic data and assessments, as these make it possible to test the proportionality of costs, which is one assumption for the achievement of good status

3.3.2 Internal logic of Article 4.4

Figure 2 summarises the principal tests involved in deciding whether the application of an extended deadline is appropriate. Other tests also need to be considered before applying an extended deadline. These include meeting the conditions specified in paragraphs 8 and 9 of Article 4 of the Directive.

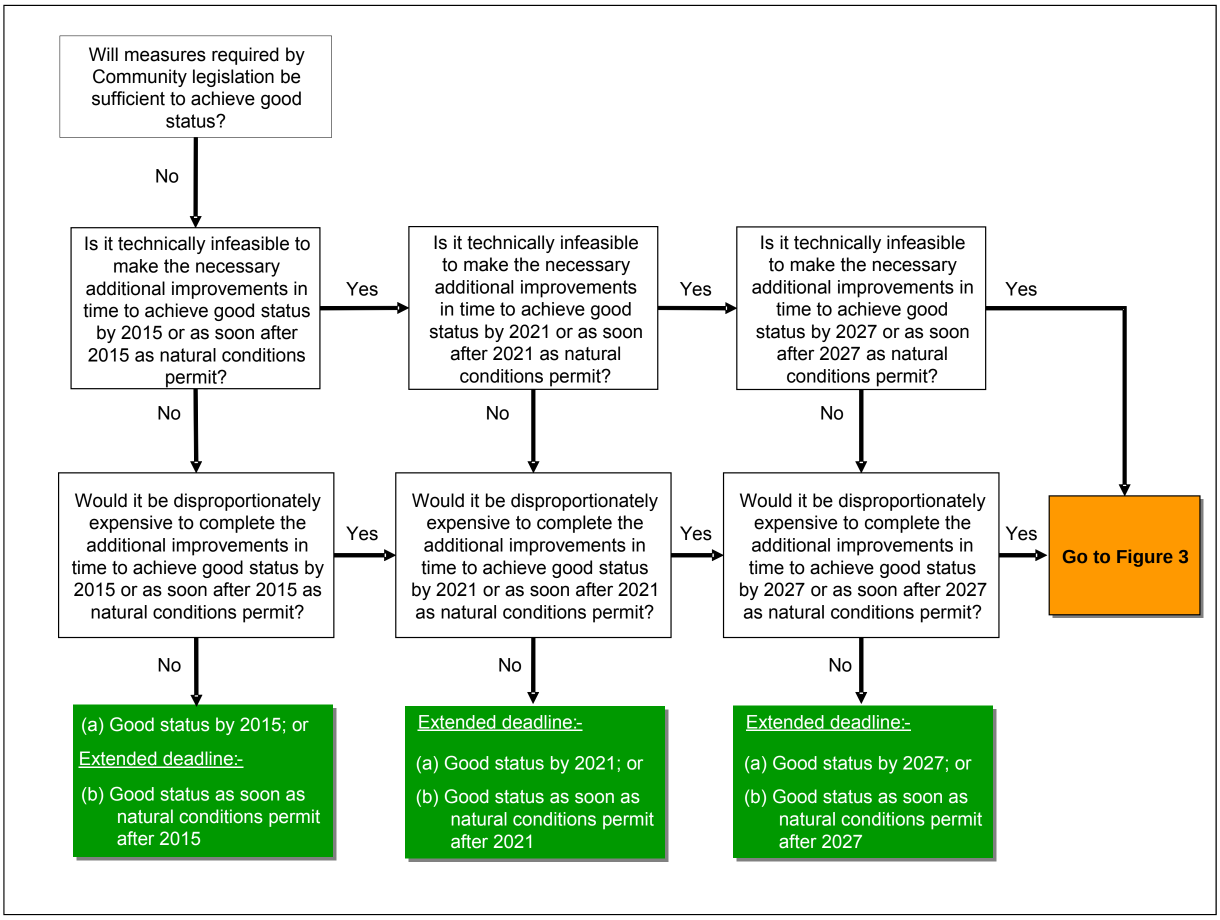

Figure 2: Internal logic of Article 4.4 - References in the Figure to good status should be interpreted as references to good ecological potential and good chemical status when dealing with heavily modified or artificial water bodies.

The Figure represents the internal logic of Article 4.4 as a step-wise linear process. However, in practice Member States may apply the process in a more iterative manner. For example, where it is technically infeasible to achieve good status by 2015 because there is no known technique for doing so (see above), consideration of the other tests illustrated in Figure 2 will not be relevant. Instead, the application of a less stringent objective (see Figure 3 below) could be considered. In contrast, if achieving good status by 2015 is technically infeasible because of technical constraints on the timing of making the measure operational, consideration of whether the measure could be implemented in time to achieve good status by 2021 or 2027 would be relevant in order to decide if an extended deadline might be applicable.

The tests should not be applied in relation to any improvements to the status of water bodies that are required by other Community legislation (see above). Exemptions may only be applied in relation to the additional improvements that would be necessary to achieve good status once compliance with relevant Community legislation has been achieved.

Where an exemption for an extended deadline is applied, a summary of the measures envisaged as necessary to achieve good status by the extended deadline and the expected timetable for their implementation must be set out in the RBMP. A review of the implementation of these measures and a summary of any additional measures must be included in updates of the RBMP. In the second and third planning cycle, Figure 2 should be used by leaving out the first column boxes referring to 2015.

The tests require consideration of the measures needed to address the pressures on the water body and so create the conditions necessary for the achievement of good status. It should be borne in mind that the rate of recovery of the water body to good status once such conditions have been established may be delayed because of natural conditions. Where natural conditions are preventing the timely achievement of good status by 2015, Article 4.4 provides that the deadline may be extended until such time as the water body recovers to good status.

Some changes of the institutional framework for putting alternative financing mechanisms in place, or addressing other administrative or legal constraints, may need time. In some cases, pursuing these changes within the first management cycle may lead to disproportionate costs. In cases where certain procedural requirements need to be fulfilled to take measures, the deadline for achieving the environmental objectives may need to be extended. In all cases where administrative or legal constraints occur, a description of the constraints has to be given in the RBMP as well as an explanation of how these constraints will be addressed in the future.

3.3.3 Internal logic of Article 4.5

Figure 3 is intended to illustrate the process of checking whether a less stringent objective is applicable and, if so, the process for identifying what the less stringent objective should be.

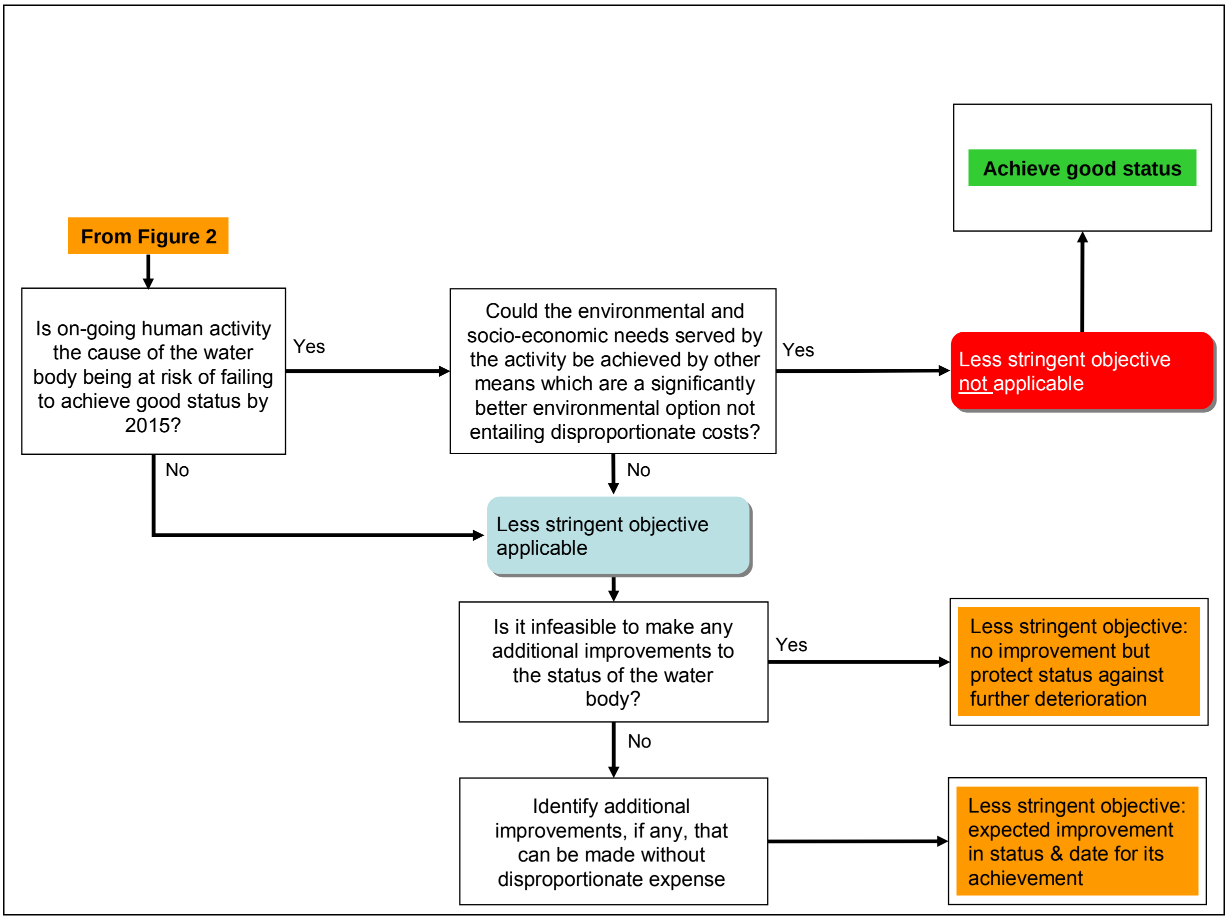

Figure 3: Internal logic of Article 4.5 - References to status should be interpreted as references to ecological potential and chemical status when dealing with heavily modified or artificial water bodies.

Figure 3 should be read in conjunction with Figure 2. According to the step-wise approach, it assumes that the tests indicated in Figure 2 have already been applied.

The Figure illustrates the process for the first cycle. The application of any less stringent objective must be reviewed in each subsequent planning cycle. When reviewing a less stringent objective, the internal logic illustrated in Figure 3 still applies. However, references in the Figure to 2015 should be treated as references to the deadline relevant to the planning cycle concerned (e.g. 2021; 2027; etc).

Before setting a less stringent objective, Member States must decide whether the environmental and socio-economic needs served by any activity that is preventing the achievement of good status could instead be provided by other means which are a significantly better environmental option not entailing disproportionate costs. Where the achievement of good status is being prevented by impacts resulting from human activities which have now ceased (e.g. historically contaminated land or sediment), this test will not be relevant.

If the test for other means is failed (i.e. if an 'other means' exists), an exemption cannot be applied and the objective for the water body will remain to aim to achieve good status. Member States are free to choose how they then achieve good status. They are not obliged to implement the identified other means of providing the benefits served by the activity as part of those measures.

In principle, a less stringent objective should represent the condition expected in the water body once all measures that are feasible and not disproportionately expensive have been taken. For example, this could mean that a less stringent objective is for the majority of the quality elements to be protected at, or restored to, values consistent with good status even though the overall status may be worse than good because of remaining impacts on other quality elements. A 'less stringent objective' does therefore not mean that (a) the other quality elements are permitted to deteriorate to the status dictated by the worst affected quality element or (b) the potential for improvement in the condition of other quality elements can be ignored.

In some cases it may be technically infeasible or disproportionately expensive to make any improvements in the status of a water body within the period covered by the relevant river basin management plan or update. In such cases, Member States must nevertheless prevent further deterioration of status, subject to the application of paragraphs 6 or 7 of Article 4 of the Directive. It should be noted that the term "infeasible" used in Article 4 (5) is broader than the term "technical feasibility" used in Article 4 (4).

The achievement of a so called "less stringent objective" may require the implementation of measures that are as stringent, if not more so, than the measures that are required for water bodies for which the objective is good status.

3.3.4 Application of new exemptions in subsequent planning cycles

On the basis of new knowledge gathered in the subsequent planning cycle, it may be necessary and appropriate in some cases to apply a new exemption under article 4.4 or 4.5 in the next update of the river basin management plan. For example, suppose a Member State finds that a water body will not achieve the objective set for it because the measures the Member State implemented are proving less effective than expected. If bringing the achievement of the objective back on track would be infeasible or disproportionately expensive, an extended deadline up to 2027 or a less stringent objective may be applied, as appropriate. Along the same lines, it is possible to apply a less stringent objective in a subsequent planning cycle for a water body for which an extension of the deadline was applied in an earlier planning cycle or it could be concluded that an exemption is not necessary anymore for the second or the third planning cycle.

The internal logic of Article 4.4 and 4.5 illustrated in Figures 2 and 3 above applies equally where the application of new exemptions is being considered in subsequent planning cycles. However, references in the figures to the deadlines for achieving objectives will change accordingly.

3.3.5 Natural conditions

The term 'natural conditions' is used both in Article 4.4 and 4.5 and refers to the conditions which dictate the rate of natural recovery. It recognises that it may take time for the conditions necessary to support good ecological status to be restored and for the plants and animals to recolonise and become established. It also recognises that due to varying natural hydrogeological conditions, groundwater bodies may take time to reach good chemical status. Climate change can also change the natural conditions over time.

3.4 Key issues for Art 4.6

Article 4.6 provides, under certain conditions, an exemption for temporary deterioration of the status of bodies of water in certain circumstances, which are exceptional or could not reasonably have been foreseen. In order to apply Art 4.6 a common understanding of the different terms below is needed, as well as a common understanding of the terms extreme floods and prolonged droughts.

- *Temporary deterioration:* The length of a temporary deterioration (Article 4.6) is linked to the length of the circumstances of natural cause, which are exceptional or could not reasonably have been foreseen and the practicability[17] of the measures that can be taken to restore the status of the water bodies.
- *Natural cause:* 'Natural cause' refers to events like floods and droughts which give rise to situations which cause us to make use of the water environment in ways that results in its deterioration of status (e.g. by taking emergency action to save life and property during floods; by supplying the public with drinking water during prolonged drought; by having pollutants to be washed into the water environment by floods). It is essential for proper river basin management planning and the application of Article 4(6) to make a distinction between the natural cause itself and the effects of management practices. WFD Article 4.6 deals with circumstances of natural cause which are exceptional or could not reasonably have been foreseen.

3.4.1 Extreme floods

The term 'extreme floods' recognises that, whilst it is possible to have some knowledge of the quantitative range of numerical flows and levels that might occur and the possible frequency of flood events, it will not be possible to foresee all flood events or to extrapolate all of their consequences in terms of environmental and other impacts.

The new Flood Risk Management Directive[18] introduces a EU-wide *"framework for the assessment and management of flood risks, aiming at the reduction of the adverse consequences for human health, the environment, cultural heritage and economic activity".* This includes the setting up of preventive measures which can contribute to the prevention of deterioration of status as provided for by the WFD. Thus, a closely coordinated and coherent implementation of both Directives will maximise synergies in the achievement of their objectives.

Despite all required preventive measures, however, some flood events will lead to "temporary deterioration" for which it is justified to apply the exemption set out by Article 4.6 WFD[19]. The identification of such an event can finally only take place after its occurrence. However, Member States should have assessment strategies in place in which they make use, to the maximum possible extent, of the implementation of the Floods Directive.

For example, the Floods Directive introduces three categories in Article 6.3 for the purposes of mapping floods:

a) floods with a low probability, or extreme events scenarios;
b) floods with a medium probability (likely return period > 100 years);
c) floods with a high probability, where appropriate.

It is most likely that "extreme flood" events falling under category (a) will require the application of a "temporary deterioration". However, floods with a higher probability of

---

[17] Practicable is related to 'technical feasible, not disproportionately expensive and without natural conditions preventing the improvements' (Article 4.4(a)).

[18] Directive 2007/60/EC of 23 October 2007 of the European Parliament and of the Council on the assessment and management of flood risks.

[19] This does not, however, include those cases of coastal flooding where deterioration, as a result of coastal erosion, may be permanent.

occurrence may also be regarded as "extreme floods" in circumstances where the impacts of such floods are equally exceptional or reasonably unforeseen.

In no way does the application of exemptions under the WFD give a Member State a possibility to make an exemption from the obligation of implementing all aspects of the Directive on the assessment and management of flood risks.

3.4.2 Prolonged droughts

A drought - contrary to water scarcity- is a natural unpredictable phenomenon. The appearance of a drought is not generated by human activities. However, the impacts of a drought episode may be exacerbated by mismanagement practices. Mitigation and prevention measures can be taken in order to reduce, and potentially avoid, the consequences of a drought when it occurs, but no measures can avoid a drought.

Although not always easy in practice, Member States will have to differentiate between the effects of prolonged droughts, which are purely natural phenomena, and the effects of human activities.

'Prolonged' droughts should be clearly distinguished from non-prolonged droughts. The conditions of a prolonged drought, i.e. the circumstances that are exceptional or that could not reasonably have been foreseen, should be demonstrated, as normal dry hydrological conditions should be addressed in the reference conditions. Relevant indicators identified at EU level are necessary to facilitate the common understanding of a 'prolonged drought', similar to criteria to define 'extreme floods'. More information is provided in Annex III.

3.5 Key issues for Art 4.7

Under Art 4.7 exemptions can be applied for **new modifications** and **new sustainable human development activities.** Before explaining the main principles of applying Art 4.7 some common definitions are provided:

- New modifications: Article 4.7 has a considerable impact on new developments and modifications. Modifications to the physical characteristics of water bodies mean modifications to their hydro-morphological characteristics. The impacts may result directly from the modification or alteration or may result from changes in the quality of water brought about by the modification or alteration. For example, hydropower plants, flood protection schemes and future navigation projects are covered by this provision. Also the hydro-morphological characteristics of impoundment created for hydropower and water supply can dictate the oxygen and temperature conditions resulting in a deterioration of ecological status in the impounded water and in the downstream river. These may be different from those in a natural water body.

  The impacts of those modifications and alterations may be limited to the water bodies in which modification works are undertaken; or extend to water bodies beyond those in which the modification works are undertaken. For example, the abstraction of water from a body of groundwater may cause adverse impacts in an associated surface water body.

- New sustainable human development activities: The Directive does not give a definition of those activities. In general, such activities cannot be defined per se through a set of criteria or policies but are framed by the relevant decision making process requirements within an open ended and iterative procedure. The exact definition for an activity falling under sustainable development will thus depend on the time, scale, involved stakeholders and information available. Relevant process requirements are provided in the WFD itself, the Strategic Environment Assessment, Environmental Impact Assessment and "Aarhus" Directives and should be guided by the principles of the EC Treaty, being the *"polluter pays principle, the precautionary principle and preventive action, and the principle of rectification of pollution at source"'.* Guiding principles on sustainable development can be found in the Renewed EU Sustainable Development Strategy (EU SDS), which was adopted by the Council in June 2006[20]. Furthermore, the decision making process should follow the principles of "good governance", including policy coherence, social inclusion and transparency and make best use of the availability of alternatives. A generic approach for small business developments affecting the same water body may be considered when applying the second point of 4.7.

- Deterioration of status or potential: The ecological status (or the potential) of a water body is expressed in terms of “classes” (e.g. high, good, moderate, poor or bad). Ecological status and potential classes are established on the basis of specific criteria and boundaries in accordance with the annex V of the WFD. In the context of Article 4.7, the objectives of preventing deterioration of ecological status (or the potential) refer to changes between classes rather than within classes. Member States do not, therefore, need to use article 4.7 for negative changes within a class.

- Temporary effects: Fluctuations in the condition of water bodies can sometimes occur as a result of short-duration human activities, such as construction or maintenance works. If the condition of each affected water body is adversely affected for only a short period of time and recovers within a short period of time[21] without the need for any restoration measures, such fluctuations will not constitute deterioration of status. The application of Article 4.7 will not be required.

  For example, temporary impacts due to the establishment of the modification during the building phase are not required to be addressed if no deterioration of status or potential could be expected thereafter in the water body or parts of the water body.

  Article 4.6 provides, under certain conditions, an exemption for temporary deterioration of the status of bodies of water in certain circumstances, which are exceptional or could not reasonably have been foreseen. An exemption under Article 4.7 will be unnecessary in those cases in which an Article 4.6 exemption is applicable.

- Small size projects: The size of the project is not the relevant criteria to trigger article 4.7. The relevant approach is to assess if a given project, whatever its importance is, will result in deterioration of the status of a body of surface water or groundwater or prevent the achievement of good ecological status, good ecological potential or good groundwater status or from high status to good status of a body of surface water. Thus, projects of any size may fall under article 4.7. However, for small projects not falling within the scope of the EIA Directive (85/337/EEC) a generic approach can be used in order to reduce the assessment burden.

In addition to the explanations above, the conditions under which Article 4.7 can be applied are presented in the figure below in a stepwise approach. This flow chart aims to be a practical tool when considering application of Article 4.7.

In comparison to the exact text of the Directive (art 4.7) c), the order of Box 3 and 4 have been changed. This is done for two reasons. Firstly, the considerations in Box 2 and 3 may result in adaptations of the project. This is not the case for the considerations from Box 4 onwards.

[20] Available at: http://register.consilium.europa.eu/pdf/en/06/stlO/stl0117.en06.pdf

[21] No definition will be given of 'short period of time'. However, the frequencies mentioned for the monitoring programmes (Annex V 1.3.4 and 2.2.3) can serve as an indication.

Secondly, Box 3 refers to the process of looking for alternatives, which should be done at an early stage of drafting the project, when better alternatives are available.

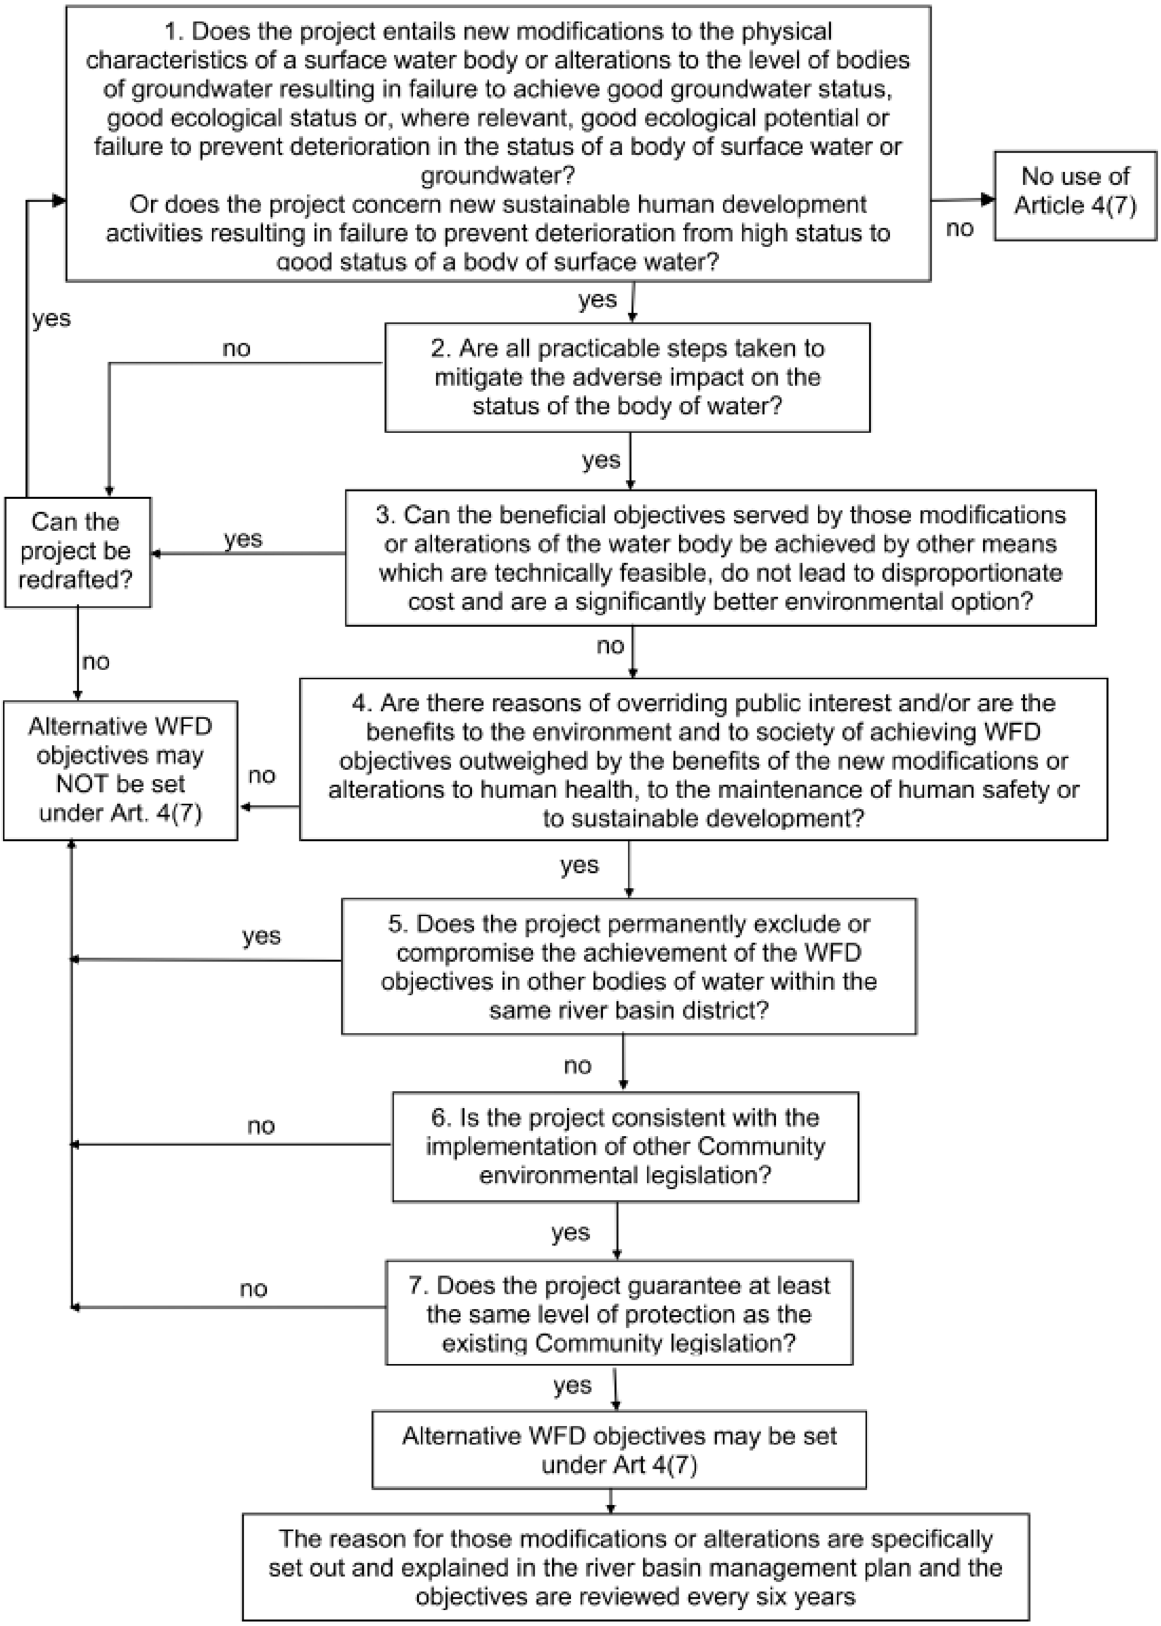

Figure 4: Example for an iterative approach, which should allow the re-assessment of the potential identification of a sustainable development activity done at the beginning.

Like all WFD exemptions, article 4.7 does not apply when the provisions of articles 4.8 and 4.9 are not fulfilled. In other words, use of the exemptions is allowed when they guarantee at least the same level of protection as existing Community legislation and provided that they do not permanently exclude or compromise the achievement of the wider objectives of the WFD under Article l in other bodies of water within the same river basin district.

In the following paragraphs, the different conditions of the Article 4.7 assessment are explained in more detail.

3.5.1 Practicable steps to mitigate adverse impacts

As indicated in box 2 in figure 5, all practicable steps have to be taken to mitigate the adverse impact on the status of the water body. As article 4.7 requires only mitigation, it is at first important to make a clear distinction between:

- Mitigation measures, which aim to minimise or even cancel the adverse impact on the status of the body of water, and
- Compensatory measures, which aim is to compensate in another body of water the "net negative effects" of a project and its associated mitigation measures.

Article 4.7 does not require compensatory measures.

The notion of "steps" addresses potentially a wide range of measures in all phases of development, including maintenance and operation conditions, facilities' design, restoration and creation of habitats.

The wording "all practicable steps", in analogy with the term "practicable" used in other legislation, suggests those mitigation measures should be technically feasible; do not lead to disproportionate costs; and are compatible with the new modification or sustainable human development activity.

3.5.2 Overriding public interest

As indicated in box 4, when applying Article 4.7, the reasons for those modifications or alterations are of overriding public interest. This concept is also used in the Habitats Directive (92/43/EEC) and other EC law. Though there is no case law from the European Court of Justice on the application of this concept to the Habitats Directive, the European Commission's "Methodological guidance on the provisions of Article 6.3 and 6.4 of the Habitats Directive 92/43/EEC: Assessment of plans and projects significantly affecting Natura 2000 sites"[22], may bring some clarification. It is reasonable to consider that the reasons of overriding public interest[23] refer to situations where plans or projects envisaged prove to be indispensable within the framework of:

- Actions or policies aiming to protect fundamental value for citizen's lives (health, safety, environment);
- Fundamental policies for the state and the society;
- Carrying out activities of an economic or social nature, fulfilling specific obligations of public services.

---

[22] Some consideration to defining "Overriding public interest" can be found at http://europa.eu.int/comm/environment/nature/nature_conservation/eu_nature_legislation/specific_articles/art6/index_en.htm

[23] Note that the consideration of "overriding public interest" only applies to the first part of Article 4.7 c, not to the second part.

Furthermore, public participation will contribute considerably in determining overriding public interest[24].

3.5.3 Benefits of the new modification versus benefits to the environment

In Box 4, it is asked whether the benefits to the environment and to society of achieving the objectives set out in paragraph 4.1 (of the Directive) are outweighed by the benefits of the new modifications or alterations to human health, to the maintenance of human safety or to sustainable development. The benefits of achieving the environmental objectives of Article 4 include:

- In case of deterioration of status, those benefits and opportunities foregone as a result of the deterioration of status (e.g. loss of biodiversity); and
- In case of failure of reaching good status or potential, those benefits that would be provided if the achievement of good status or good ecological status were not prevented (e.g. drinking water supply is not longer possible).

The "water costs" (negative benefits) have to be put in balance with the potential benefits and other costs (increased use of other natural resource, including global impacts) of the new modifications and alterations to human health, to the maintenance of human safety or to sustainable development. Thus, other categories of possible benefits and costs will have to be considered and -if possible- calculated.

In conclusion, an analysis of the costs and the benefits of the project adapted to the needs of the Directive is necessary to enable a judgement to be made on whether the benefits to the environment and to society of preventing deterioration of status or restoring a water body to good status are outweighed by the benefits of the new modifications or alterations to human health, to the maintenance of human safety or to sustainable development.

This does not mean that it will be necessary to monetise or even quantify all costs and benefits to make such a judgement. The appropriate mix of qualitative, quantitative and, in some cases, monetised information should depend on what is necessary to reach a judgement and what is proportional and feasible to collect.

3.5.4 Article 4.7 and the designation of heavily modified water bodies (HMWB)

After a new hydro-morphological alteration has occurred, it may be that the water body qualifies for designation as a heavily modified water body in accordance with Article 4.3 in the next planning cycle. There is no requirement that the designation has to wait until the publication of the next River Basin Management Plan. However, **water bodies cannot be designated as HMWBs before the new modification has taken place** because of the anticipation of the significant hydro-morphological alteration.

After the application of article 4.7 and in case of designation of new HMWBs, the step by step approach developed within the HMWB guidance document should be applied without the "provisional identification-step".

[24] See Guidance Document No 8: Public Participation in relation to the Water Framework Directive on http://forum.europa.eu.int/Public/irc/env/wfd/library?l=/framework_directive/guidance_documents

3.5.5 Reporting article 4.7 in the RBMP and public consultation

Annex VII of the WFD describes the information that should be included in the RBMP. Under point A.4, the current status of the water bodies must be assessed as a result of the monitoring programmes. Under point A.5, the environmental objectives established for surface waters and groundwaters must be listed, including identification of the use of the exemptions and the associated information required under Article 4.

The risk of deterioration of status occurring should be assessed at the time a new modification or alteration is being considered. The assessment of risk should be based on the best information available on the status of those water bodies whose status is likely to be affected by the proposed project. Such information should include the latest information from the monitoring programmes required under Article 8 and information obtained from any environmental impact assessment undertaken for the project.

Further, under article 4.7 (b), there is a general provision that "the reasons for those modifications and alterations are specifically set out and explained in the river basin management plan required under Article 13 and the objectives are reviewed every six years". This is a reporting obligation and does not mean that Member States must wait until the publication of the River Basin Management Plan before allowing a new physical modification or new sustainable development activity to proceed. In many cases projects will be developed within the RBMP six-year cycle.

For modifications and alterations within the scope of the Environmental Impact Assessment Directive, Member States must ensure that the public concerned is given the opportunity to express an opinion before the project is initiated.

Even if timing of a project is such that consultation on the RBMPs will not provide the opportunity for interested parties to express their views in advance of those decisions, Article 14 requires Member States to encourage the active involvement of all interested parties in the implementation of the Directive. It is recommended that Member States ensure that such opportunities are provided in relation to projects that are outside the scope of the Environmental Impact Assessment Directive but likely to result in deterioration of status or to prevent the achievement of good ecological Status, good ecological potential or good groundwater status.

The information provided through such consultations will help Member States in reaching a judgement on whether the exemption conditions are met and will reduce the likelihood that interested parties will challenge the subsequent decision.

If a modification or alteration goes ahead in the middle of a river basin planning cycle, the reason for that modification or alteration must be set out in the subsequent (update of the) RBMPs.

4 Conclusions

The work on environmental objectives and exemptions has started in 2005 and has progressed significantly over the past years. It has become evident that Article 4 of the WFD is the heart of this legislation and the crucial element to achieve a high level of protection of our waters as part of a sustainable water management, which also takes account of the social and economic needs and realities. This document brings together the fruitful work under the WFD Common Implementation Strategy on exemptions.

In the mean time, Member States are gaining practical experience with the application of Article 4 and are preparing for the necessary discussions as part of the public consultation. Whilst it is recognised that starting points, strategies and approaches differ across Europe, it is important to make transparent the underlying reasons and data for decision-making and to not use the exemptions as a blanket excuse. In many cases it may be more effective to discuss in a proactive way what measures can be taken to improve the current situation, rather than what arguments and administrative effort can be made to avoid taking any measures.

Thus, where "good status" may not be achieved or "deterioration of the current status" is possible, no action is not an option! This document aims at contributing towards this positive and proactive attitude when implementing the WFD and thereby contributing to sustainable water management.

The process of objective setting does not stop after the first planning cycle but is dynamic and iterative which means that it should be further developed and improved on the basis of experiences in the first RBMP. It is likely that the number of water bodies for which exemptions are applied will be decreasing within the second and third planning cycle but the application will have to be adapted each time.

It may be necessary to continue the work on exemptions in the next years, focusing on practical experiences and cases from the first planning cycle.

ANNEXES

Annex I: Costs & Benefits

An analysis of the costs and the benefits of measures to achieve the objectives of the WFD may be necessary to support the judgement to be made on exemptions from these objectives. Reasonable efforts should be made to collect information on different types of costs and benefits, including the appropriate mix of qualitative, quantitative and monetised information. In addition, available information, for example from the cost-effectiveness assessment, should be used. In all cases, the data should be used in a transparent way showing how the assessments and calculations have been carried out.

Below, more specific information is given on benefits and costs in the framework of the WFD. Useful guidance on types of costs and benefits and how to assess them was also made in the **WATECO guidance**. Please see Section 2 and 3 and Annex D of this guidance document[25].

In addition to the WATECO guidance, **the study on Costs and Benefits associated with the implementation of the Water Framework Directive of** 2007[26] provides useful information on types of costs and benefits and methodology for Cost-Benefit Analyses (CBAs) (mainly Chapter 3). Currently used methodologies for estimating the total costs and benefits of the implementation of the WFD were studied, and recommendations were made on which costs and benefits to include and how to evaluate them. Issues relating to comparison and aggregation of costs and benefits were also outlined.

I.1 Benefits

The environmental objectives set in the WFD shall ensure the long-term protection and the sustainable use of the water resources and prevent further deterioration. The achievements of these objectives will have numerous benefits and socio-economic gains for this and coming generations. When examining the proportionality of costs required for achieving the objectives, these benefits can and should be taken into account. Some examples of such benefits are listed below:

- Protection and enhancement of health and biodiversity of the aquatic ecosystem (in particular since good ecological status requires good quality of the structure and the functioning of this ecosystem).
- Protection of human health through water-related exposure (e.g. through drinking, drinks and food production, bathing and consumption of fish, shellfish and seafood).
- Lower costs for water uses, e.g. water supply or fisheries and more cost effectively achieved improvements by reducing treatment and remediation costs (e.g. drinking water supply, Sediment pollution).
- Improvement of efficiency and effectiveness of water policy based on the "polluters-pays principle" (in particular by adequate water pricing policies and cost-effectiveness assessment of measures, example: reduction of amount of water use per capita).
- Increased cost-effectiveness of water management, in particular of measures to implement and apply, for example the Nitrates, Urban Wastewater Treatment and IPPC Directives.

25 http://circa.europa.eu/Public/irc/env/wfd/library?l=/framework_directive/guidance_documents/guidancesnos1seconomicss/_EN_1.0_&a=d

26 http://circa.europa.eu/Public/irc/env/wfd/library?l=/framework_directive/thematic_documents/economic_issues/benefits_implementation/report_septl2pdf/_EN_1.0_&a=d

- Integrated river basin management - as introduced by the WFD – should help authorities to maximise the economic and social benefits derived from water resources in an equitable manner instead of repeating the mistaken and fragmented approaches of the past, which dealt with problems in a local, and usually temporary, basis. This should translate, *inter alia,* in designing more cost-effective measures to meet the environmental objectives of other EU legislation (see above). Especially for new Member States, the cost-saving potential is great the lessons from the experiences in EU15 are learnt[27].
- Improvement of the quality of life by increasing the amenity value of surface waters (e.g. for visitors, tourists, water-sports users, conservationist) and by increasing its non-use value and all non-market benefits associated.
- Mitigation of impacts from **climate change and security of water supplies** (e.g. by forward planning in river basin management, water demand and supply management and mitigation of flood and drought events)
- Mechanisms to address **conflicts and regional disadvantages** by balancing interests of different water users and creating a level playing field for water users across the EU[28] (in particular by addressing and managing all demands on water resources from drinking water supply, agricultural and industrial uses, navigation, hydropower, etc. in a consistent and comparable way).
- Promotion of sustainable uses thereby **creation of new jobs** (e.g. in ecotourism, fisheries, environmental technologies and nature conservation sector).

Some of these benefits are financial like e.g. the saving of costs for water supply (economic benefits) and therefore can be expressed in monetary terms, or, if the acquisition of the corresponding data requires a disproportionate effort, can at least be estimated. However, on the basis of existing methodologies, it is difficult to attribute a monetary value to many types of environmental and social benefits. The existing Information Sheet on "Environmental and Resource Costs" clarifies many concepts and outlines a few examples of how to measure them in monetary terms. Another useful tool is the "Millennium Ecosystem Assessment Report"[29] which includes substantial information on freshwater ecosystem values as well as more recent study on The Economics of Ecosystems and Biodiversity (TEEB)[30] which quantified the costs of in-action for many ecosystem services. Member States need to make an effort to value or assess social and environmental benefits/costs more appropriately than in the past. Without this, it is likely that many assessments of disproportionate costs, taking place as part of the WFD implementation, will be incorrect.

However, it will not always be necessary to place a monetary value on all costs and benefits. Member States will need to collect sufficient information on costs and benefits to support good decision making, taking into account the costs associated with the collection of the relevant information. There is a need for pragmatic approaches in order to be able to take benefits into account if this monetary information is incomplete or not fully available. Some of these benefits may be assessed by using qualitative information. In other cases, an appropriate alternative may be the application of the "precautionary principle" or it might be possible to make a qualitative assessment of the benefits and to weigh them up against the costs.

More work is required to achieve full assessment of benefits (monetary or not) derived from the implementation of measures under the WFD. It is expected that, e.g. the ongoing

[28] and with non-EU countries sharing a river basin with the EU.

[29] http://www.maweb.org//en/index.asp

[30] http://ec.europa.eu/environment/nature/biodiversity/economics/index_en.htm

work on environmental costs (both within the WFD implementation as well as in a wider context) will improve this situation.

I.2 Costs

While recognising the considerable benefits, achieving the environmental objectives may have additional costs on those water uses or "driving forces" which have a negative impact on the aquatic environment or beneficiaries from improvements and which have not - up until now - contributed to address such impacts (e.g. not paying for the water use). At the moment, these potential costs are not known for various reasons. First, it is impossible to determine the costs before criteria for the environmental objectives are available. The water quality has to be monitored in accordance with the Directive. Only when comparing the monitoring results with the environmental standards (as defined through Annex V WFD) will it be possible to assess the "distance to target" and thereby the required investments. Second, the costs are largely dependent on the choices of instruments and combination of measures that Member States will use. Third, application and enforcement of other water protection legislation, in particular the Urban Waste Water Directive, the Nitrates Directive and the Drinking Water Directive, are inadequate in a number of countries and, thus, costs related to implementing those are easily, but wrongly, added to the costs of implementing the WFD. In the end, it is not always possible to distinguish between the water management costs incurred due to the implementation of the WFD, and the costs which would have been incurred in the absence of the WFD. However, this distinction is crucial for performing the different analysis of costs. The costs of basic measures according to existing EC water related directives (UWWD, IPPC, Nitrate etc.) can not be included in the analysis for justification of exemptions.

Independent of the lack of concrete cost-estimates, the WFD incorporates mechanisms that the socio-economic impacts are properly addressed in the decision-making and that the least cost option is selected. The way that such considerations are addressed in the directive is mainly through the above-mentioned exemptions and the development of the programme of measures as an integral part of the planning process.

If there is sufficient evidence that costs seem to be disproportionate, careful assessment and balanced decision-making on benefits and costs is an integral part of the WFD, in particular through the "exemptions" tests.

Further to the considerations in the objectives, the socio-economic aspects and, in particular the **cost-effectiveness,** is a central part in the development for the Programme of Measures. The Member States should attempt to ensure that the combination of measures for achieving the environmental objectives is resulting in the least cost option after giving sufficient attention and consideration to environmental and resource costs. Such approaches, which should be applied on national or river basin, sub-basin or water body level, leave enough flexibility in order to address issues of concern.

Furthermore, the proposed options including the use of certain exemptions and the proposed programme of measures must be subject to **public participation** in which all interested stakeholders are encouraged to be involved.

The WFD provides for environmental objectives which should be achieved by the most cost-effective combination of measures. Cost-effectiveness assessment and public participation of proposed choices are the key instruments in this process.

Annex II: Exemptions in a transboundary context

II.1 Principles for applying exemptions in a transboundary context

Exemptions may be applied in cases where a certain Member State cannot resolve the reasons for not achieving the environmental objectives because they lay outside the competence and jurisdiction of the Member State. When applying such an exemption, the following principles should be taken account of.

The coordination mechanisms as mentioned in WFD Article 3.4 or Article 3.5 or covered by other pieces of legislation (e.g. air quality) should be in place and have been exploited to the fullest extent to resolve the problem. In this context, the Member States concerned should coordinate their efforts to apply the most cost effective solution to solve the environmental issue for which an exemption may be required. - Furthermore, the Member State has to take all measures on its own territory that will contribute to achieving good status, and that are not disproportionate expensive or technically infeasible.

Finally, the Member State has to demonstrate that the reasons for not achieving the environmental objectives are outside its jurisdiction and its competence. This could for example be done by information provided by the other Member State, and/or by information provided by a monitoring point at the border between the Member States concerned or by other means.

II.2 Reasons for applying exemptions in a transboundary context

Exemptions in a transboundary context could relate to transboundary pollution, but also to hydro-morphological alterations or other transboundary ecological impacts or in the case of extreme events.

Transboundary pollution was specifically discussed in the context of the negotiations of the Commission proposal on environmental quality Standards (EQS) for priority substances[31], in particular for the following issues:

- where EQS are exceeded because the pollution load which is transported from an upstream country (whether this country is a EU Member State or not) through transboundary rivers;
- where EQS are exceeded because long-range transboundary air pollution transports high loads of pollutants (in particular heavy metals and PAHs) into the Member State concerned[32];

In both cases, the exceedance of the EQS *"cannot be resolved by that Member State"* since the sources of pollution are outside the competence and jurisdiction of the Member State. So it appears most likely that in these cases of transboundary pollution, the exemptions (Article 4.4, 4.5 and 4.6) would be applicable. Countries receiving transboundary pollution via marine currents or by atmospheric deposition are also considered downstream (or affected) countries in the context of Section 3.2.7 and this Annex.

[31] COM(2006) 397 final of 17.7.2006; 2006/0129 (COD)

[32] It should be noted that other EU or international legislation or agreements might be applicable to this issue, for example the protocols under the UNECE Convention on Long-range Transboundary Air Pollution.

II.3 Conditions of the exemptions in transboundary context

Similar to applying exemptions in a national context, it needs to be demonstrated if the conditions of Article 4.4 and 4.5 are met. Subparagraph 4.5(a) needs special attention in this case: the application of sub-paragraph (a) is clear in cases where human activities are carried out within a Member State and where an assessment of the environmental and socio-economic needs of the human activities and its alternatives is carried out. In case of transboundary effects, there is no human activity within the Member States' competence that can be compared with another. The human activity causing the pollution or the ecological impacts is outside the jurisdiction of the Member State. Thus, this condition does not apply in case of transboundary pollution or transboundary ecological impacts.

<u>WFD Article 3</u>

WFD Article 3.4 requires Member States to ensure coordination of the requirements for the achievement of the environmental objectives for international river basin districts within the territory of the EU. For international river basin districts partly outside the territory of the EU, the requirement is to 'endeavour to establish appropriate coordination'. It is obvious that this includes the coordination of the application of exemptions. It is of particular relevance that the coordination ensures that all relevant information and data are being exchanged between the Member States and/or other countries. For example, if the upstream Member State intends to apply an exemption on its territory, the downstream country should be informed as soon as possible and access to all information should be guaranteed. The international river conventions and other relevant international agreements play an important role in fostering and improving this information exchange.

<u>WFD Article 12</u>

In case the reasons for not achieving good status cannot be resolved by a Member State since they are outside the competence and jurisdiction of the Member State, the WFD includes the Provision of Article 12 ***"Issues which cannot be dealt with at a Member State level".*** Article 12 provides for:

"1. Where a Member State identifies an issue which has an impact on the management of its water but cannot be resolved by that Member State, it may report the issue to the Commission and any other Member State concerned and may make recommendations for the resolution of it.

2. The Commission shall respond to any report or recommendations from Member States within a period of six months."

Article 12 might be invoked for various situations related to exemptions. It might for example be applied in cases where no information on exemptions is provided, or it might be applied to solve the issue for which an exemptions needs to be applied by a neighbouring Member State. Article 12 could be invoked at the same time when applying the exemption in the drafting phase of the river basin management plan.

The possible reaction by the Commission will vary depending on the issue.

<u>Demonstration of evidence</u>

The key issue in both applying the exemption and invoking Article 12 is the **demonstration of evidence** that Member States have taken all reasonable actions to fulfil the legal obligations.

When applying exemptions, the reasons for this need to be mentioned in the river basin management plan. Furthermore, it is important to inform neighbouring countries as soon as possible on intermediate Steps related to the evidence, the intermediate objectives and the expected evolution, in order to enable the neighbouring country to adapt their own river basin management.

When a Member State is reporting to the Commission under Article 12, it will have to provide information which support their argument and allow the Commission to verify that the non-achievement of an objective is clearly linked to the transboundary pollution or other transboundary effects. In general, such demonstration of evidence can be achieved through an appropriate and targeted monitoring strategy or a comprehensive risk analysis in accordance with Article 5 and Annex II WFD.

Annex III: Background information on prolonged droughts

The 'Drought Management Plan Report, including Agriculture, Drought Indicators and Climate Change' (also DMP report) of the Water Scarcity and Drought Expert Network notes that there are various types of droughts. For the application of exemptions according to WFD Article 4(6), the term to be used is "prolonged droughts". Whilst it will be difficult to find an all encompassing definition for what a "prolonged drought" is, it would be beneficial to enhance the common understanding for the application of the term in the context of the WFD exemptions.

As the WFD indicates in Article 4.6, the Member State may declare a "temporary deterioration" to achieving the objectives of Article 4.1 on the basis of the following conditions:

- It is a result of natural causes or *force majeure* which are exceptional or which could not reasonably be foreseen and which are reviewed periodically (e.g. through a follow up of the Programme of Measures (PoM) and/or Drought Management Plan);
- All practicable Steps are taken to avoid further deterioration (Article 4.6(a));
- Measures taken during the prolonged drought do not compromise the recovery of the water body after the prolonged drought and are included in the PoM (Article 4.6(c));
- Measures to restore the water body are taken as soon as reasonably practicable and are included in the next update of the River Basin Management Plan; (Article 4.6(c) and 4.6(d))
- A summary of effects of the prolonged droughts is included within the RBMP (Article 4.6(e)).

Section 10 of the Paper "Exemptions to the Environmental Objectives under the Water Framework Directive, Article 4(4), 4(5), and 4(6)" already highlights a few issues regarding the exemption under 4(6).

First, 'prolonged droughts' are one of the natural causes for which the exemptions under Article 4(6) may be applied. It is highlighted again that a **drought - contrary to water scarcity - is a natural and unpredictable phenomenon[33].** The appearance of a drought is not generated by human activities. However, the impacts of a drought episode depend on the degree of use of the resource in a particular river basin and may be exacerbated by mismanagement practices (i.e. water resource management that is not sustainable). Some mitigation and prevention measures can be taken in order to (partially) reduce the effects of a drought when it occurs, but no measures can avoid a drought.

Secondly, it is already recognised that Member States will have to differentiate between the effects of prolonged droughts, which are purely natural phenomena, and the effects of human activities, although not always easy in practice. It is essential for proper river basin management planning and the application of Article 4.6 to make a distinction between the natural cause itself and the effects of management practices.

Thirdly, the Exemptions Paper indicates that for the distinction between a "non prolonged drought" and a "prolonged drought", the conditions of a prolonged drought, i.e. the circumstances of natural causes or "force majeure" which are exceptional or could not reasonably have been foreseen should be demonstrated in order to qualify as "prolonged". Normal dry hydrological conditions should be addressed in the ecological reference conditions set by the WFD. The river basin management plans should be able to

---

[33] See also the Communication 'Addressing the challenge of water scarcity and droughts in the European Union' (COM(2007) 414)

cope with non prolonged droughts without resorting to the exemption in article 4(6). Relevant criteria are necessary to facilitate the common understanding of a 'prolonged drought' through an agreed set of indicators (see below), similar to criteria to define 'extreme floods'.

III.1 Identification of a "prolonged drought"

Characteristics of droughts can vary significantly from country to country and between regions and therefore it is not possible to agree on common values of indicators that can be used in all cases.

As the circumstances to declare prolonged drought relate to a natural cause, indicators for prolonged droughts should relate to natural parameters (see 4.6(b)). Although there might be a time lag between the lack of precipitation and decreased water levels, e.g. due to retention effects of soil and vegetation and inertial effects on aquifers, the main parameter to define prolonged drought should be related to lack of precipitation (minus evapotranspiration) during a particular period with respect to average, and should take into account aspects like intensity and duration. It is necessary to distinguish between the drought itself and the effects of water use and management practices.

The drought events that are part of the normal dry hydrological conditions cannot be considered a "prolonged drought" since they are not "circumstances of natural cause *or force majeure* which are exceptional or could not reasonably have been foreseen". Any indicator used to define a prolonged drought and hence to allow triggering the exemption in article 4(6) should be based on a statistical analysis of the deviation of precipitation from the average situation (including intensity and duration), to prove that the circumstances are those of a prolonged drought.

III.2 Management of a prolonged drought

The reason for invoking an exemption under Article 4.6 is that a prolonged drought may affect the status of a water body considerably and during a significant period of time, so that a temporary deterioration may be inevitable even with the application of the best water management practices.

In the case of a prolonged drought, it may be necessary to take exceptional measures, but they must not compromise the recovery of the quality of the water body when the prolonged drought is over. These measures need to be included in the programmes of measures and/or the Drought Management Plan. They also do not exempt from taking all practicable steps to prevent further deterioration in status of the water body (see 4.6 paragraphs (a) and (c)).

Furthermore, during the prolonged drought and afterwards, all measures have to be taken with the aim of restoring the water body to its prior status as soon as reasonably practicable. In this context, practicable measures are those that are technically feasible and not disproportionately expensive. Restrictions on water use by different sectors might be an example of measures that have to be taken.

Managing prolonged droughts implies making decisions on the allocation of reduced resources to both environmental and human activity needs. Unlike in non prolonged droughts, during which the environmental needs should be respected at all times so that the WFD environmental objectives are met, during a prolonged drought, and provided the conditions on article 4.6 are respected, priority needs related to human activity (e.g. drinking water supply) can be temporarily met at the expense of the environmental needs, i.e.

allowing a temporary non- achievement of the environmental objectives. Such decisions have to carefully consider the environmental and socioeconomic aspects in accordance with the conditions in paragraphs 4.6 (a) to (d).

Besides the potential impacts on drinking water, prolonged droughts may cause significant impacts on all water uses, in particular irrigation, hydropower generation, supply of cooling water and other industrial uses, navigation and domestic uses other than drinking water (such as garden sprinkling). Thus, a clear prioritisation of main uses should be established[34] in advance where use restrictions are imposed step-by-step with increased duration, intensity and impact of the drought event. Essential drinking water supplies will be considered a high priority during periods of prolonged droughts, and this should be combined with high priority for an ecological minimum flow.

All drought situations other than a prolonged drought need to be managed without the use of article 4.6, i.e. for water bodies where non-prolonged droughts occur, the environmental objectives should be achieved and no deterioration must take place. Hence the water uses need to be brought in balance with the water availability under these dry hydrological conditions. The impacts of non prolonged droughts need to be taken into account in the definition of the environmental objectives of the RBMP and need to be addressed in the programme of measures and/or the Drought Management Plan. The iterative process of the WFD includes a periodical review of these objectives and associated measures in order to take into account the evolving impacts of these events in time.

In case of water bodies where the extent of human activity is such as to produce a permanent imbalance between available resources and demands, and if the achievement of environmental objectives would be infeasible or disproportionately expensive, the possibility to apply an exemption in article 4.4 or 4.5 might be explored, provided the conditions set out in these articles are fulfilled

III.3 Drought impacts on ecology and other water uses

For management of droughts and for determining if a temporary deterioration occurs in case of a prolonged drought, the impacts of this extreme phenomenon need to be investigated, both on ecology and on different human water uses.

Some examples for impacts on the ecology at a low water level and high water temperature are, in particular:

- changes in fish development and larger numbers of deaths than normal. Some periods of the year are highly critical for fish, such as the reproduction and migration periods.
- increased algae development due to the lack of water in rivers and lakes due to the drought. However, this parameter may be difficult to distinguish from the excess of nutrient releases that cause eutrophication.

The effects of a drought could greatly vary depending on the existing scenarios: basins with storage aquifers directly linked to the water body system, and/or regulating infrastructures (e.g. reservoirs) could be less vulnerable to impacts, while basins without storage capacity could be more rapidly affected. Other factors will undoubtedly influence drought impacts, such as demands and uses of the area. Thus, the different potential impacts caused by droughts should be assessed or, at least estimated, in advance, preferably as part of a drought management plan. Such assessment should consider economic, social and

[34] See also the Communication 'Addressing the challenge of water scarcity and droughts in the European Union' (COM(2007) 414)

environmental impacts in order to inform the necessary decision-making. Such an assessment should also take into account transboundary impacts, disparities between different Member States and distortions of competition between them which may stem from restricting or stopping certain uses.

III.4 Indicators

Three types of indicators can be identified in relation to droughts:

1. Indicators to identify and demonstrate the occurrence of a prolonged drought: natural indicators based on precipitation as the main parameter (where relevant including evapotranspiration, and with statistical series) indicate that it is a 'natural cause *or force majeure',* and that the circumstances are exceptional or could have not reasonably been foreseen.
2. Indicators to prove that the prolonged drought has resulted in a temporary deterioration of one (or several) water body(-ies) as an integral part of the monitoring programmes established under Article 8 and Annex V WFD (these are indicators related to environmental impacts).
3. Indicators to illustrate the socio-economic impacts of the prolonged droughts (drinking water supply, agriculture, industry, etc).

The first and second types of indicators should be used to prove the occurrence of a prolonged droughts and the associated temporary deterioration of water bodies. The second and third types of indicators should be used:

- to take the appropriate measures in order to mitigate the impacts of the prolonged droughts
  and recover the quality of the water bodies, according to 4.6 (c) and (d),
- to draft the annual review of the effects of the prolonged droughts (4.6(d))
- to draft the summary of the effects (4.6(e))

All indicators should be used to inform the water users and the public about the occurrence of droughts, their effects and the management results.

Chapter 3 of the DMP report provides an overview of national indicators related to droughts. The development of such indicators to be used on EU level and the specification on which indicators are consistent for the purpose of applying the exemption related to "prolonged droughts" will be subject of further work carried out by the European Commission, the European Environment Agency and Member States. In all cases, it is a requirement that when applying an exemption and the related indicators that they are to be submitted to a transparent and open process through the public participation (cf. Article 14 WFD).

III.5 Measures to address "prolonged droughts"

When a prolonged drought occurs, measures need to be taken to avoid further deterioration and to restore the water body as soon as reasonably practicable. Examples of such measures could be the following:

- develop early warning System and public Information
- implement preventive measures
- promote water savings
- take all practicable measures to prevent further deterioration
- implement specific mitigation and adaptation measures of article 11 (basic and supplementary) in water management sector as well as in other water

dependant sectors (agriculture, energy, tourism, transport, urban development, industry)

- propose additional measures after the annual review of the effects of circumstances
  that are exceptional or could not have reasonably been foreseen (Article 4.6(d))

When, and where necessary, these measures can be presented in advance as part of a drought management plan (complementing the river basin management plan). Acting on a prolonged drought, requires a rapid adoption of measures, for which the course of action should also be reflected in the RBMP or directly within the specific DMP.

Measures to be taken in case of prolonged droughts as mentioned in 4.6(c) cannot adversely affect other water bodies (see Article 4.8 WFD) and must ensure that the objectives set by other Community legislation are not compromised (see Article 4.9 WFD).

Additional information on the types of measures and possible implementation strategies are described in detail in Chapter 5 of the DMP report.

1 INTRODUCTION

1.1 Purpose of this document

Since 2003 several documents have been agreed defining the information that Member States (MS) should provide the Commission for the purposes of compliance checking under the Water Framework Directive (WFD). These cover the following reporting requirements:

- Article 3 (2004);
- Article 5 (2005);
- Article 8 (2007);
- Article 13 (2010).

Information has already been provided by the MS for the first three of these reporting requirements and initial compliance assessments completed. Following agreement of the Reporting sheets for the River Basin Management Plans (RBMP) (2010 reporting), the Reporting sheets for Articles 3 and 5 were reviewed and some changes agreed with the MS through Working Group D. During this review it was agreed to prepare an overall, consolidated document which would present, in a logical way, all the reporting requirements that had been agreed. This document fulfils that requirement.

1.2 Development of the Reporting Guidance

Reporting in the context of EU water legislation has been regulated and implemented in different ways over the past 30 years. For example for the remaining 'old' directives (Urban Waster Water Treatment Directive (UWWTD) – 91/271/EEC, Bathing Waters Directive (BWD) – 76/160/EEC, Nitrates Directive (NiD) – 91/676/EEC, Drinking Water Directive (DWD) – 98/83/EC) and the new Bathing Waters Directive (2006/7/EC, concerning management of bathing water quality and repealing Directive 76/160/EEC), reporting is based on several articles[1]. Some of the 'old' directives had clearly defined procedures for reporting adopted through the Committee procedures in the form of Commission Decisions (e.g. reporting on 'old' BWD is based on the provisions of Commission Decision 95/337/EC). However for the others, the reporting process had various backgrounds – sometimes through Committee procedures (e.g. reporting under Article 17 of UWWTD was set up via Commission Decision 83/481/EEC, while reporting under Article 15(4) was based on the Commission duty to issue the questionnaires (request of information) to the Member States with the duty to reply within six months.

For some other directives (stemming partially from the 1970s), streamlined monitoring was introduced with the Standardised Reporting Directive 91/692/EEC with a reporting cycle of three years. On the basis of this directive, the water questionnaire was introduced in 1992 and the latest version agreed by Committee in

[1] For UWWTD – articles 17, 16, 15(5); for 'old' BWD – article 13 and decision 95/337/EC (Annex VIII) amending decision 92/446/EEC; for 'new' BWD – article 13; for NiD (91/676/EEC) – article10; and for DWD (98/83/EC) – on article 13.

1995 (Commission Decision 95/337/EEC). The experiences from this reporting exercise are summarised as follows:

- Information was often not submitted or was incomplete;
- The format of the information provided varied (e.g. electronic vs paper copy) and often did not follow the format of the questionnaires in the 1995 Decision;
- It was not clear to MS what information had to be reported for the second reporting return, and what could be omitted and it was not clear to those carrying out the assessment what information had been submitted in previous returns;
- The quality of the information submitted by MS was very diverse and often difficult to read, validate and process;
- There were often differences between MS in the interpretation of the questions and information needs within the questionnaires. This led to information being incomparable between MS and difficulties in drawing comparisons on a year-on-year basis.

Also, for reporting for some 'old' water directives the experiences were mixed. Some of the reporting was organised without providing specifications and/or technical guidelines what to report and how. This led to a set of inconsistent, incomplete information with different levels of detail which were difficult to compare.

On the basis of all these experiences, there is a clear need to streamline the reporting exercise under the directives mentioned above along with the WFD in order to use more consistent approach, taking into account the electronic reporting foreseen under the Water Information System for Europe (WISE).

For the newer pieces of legislation, most of them have general provisions for reporting but include possibilities to specify the explicit requirements and needs in more detail. For example, Article 20 WFD stipulates in paragraph 2:

"*(2) For the purpose of transmission and processing of data, including statistical and cartographic data, technical formats for the purpose of paragraph 1 may be adopted in accordance with the procedures laid down in Article 21.*"

Once approved by the Regulatory Committee and adopted by the Commission, such formats would become legally binding. In other words, if a MS fails to submit even parts of the agreed information, it is not compliant with the Directive. Moreover, the procedures to develop such formats are time consuming and lack flexibility in case adaptations and improvements should be introduced on short notice. Furthermore, the agreement on the required specifications for reporting may be driven by the lowest common denominator and may not have been able to incorporate a feedback and testing process as applied now.

For these reasons, no such legally binding reporting formats have yet been developed. Even if they had been considered, the ambitious deadlines for implementation of the WFD would have made it difficult to publish legally binding reporting formats with sufficient lag time to allow MS to implement the system. Any delays would have triggered complex legal and formalistic discussions rather than focusing on the implementation of the Directive.

The past experience demonstrated that reporting without any detailed specifications and guidelines results in a diverse set of documents with different levels of details and with information which is poorly comparable. Furthermore, the development of the WISE requires some form of agreement on the contents and the technical specifications of data exchange. Therefore, and having the successful consensus-based cooperation under the Common Implementation Strategy (CIS) in mind, it was decided to prepare and agree guidance documents for the different reporting requirements using the format of Reporting sheets. These Reporting sheets have been prepared by a drafting group of the Working Group on Reporting (Working Group D), agreed by the Group and endorsed by the Water Directors on a consensus basis. These Reporting sheets therefore are informal arrangements between the MS and the Commission and thus are not legally binding. It is a voluntary commitment, agreed at high level, by the MS to submit this information to WISE. Current experiences show that this approach results in a higher success rate in reporting in comparison to the legally binding reporting requirements of the past.

Figure 1 below shows the Reporting sheets developed for surface water and the relationships between them. Similar sheets were developed for groundwater. Whilst the Reporting sheets were a useful tool for the development of the reporting requirements on an Article by Article basis, it is no longer necessary, or indeed helpful, to present the information requirements in this way. This consolidated guidance document contains all the information originally in the Reporting sheets but presented in a clearer, object-related way with the ultimate focus being on fully reported and comparable RBMP.

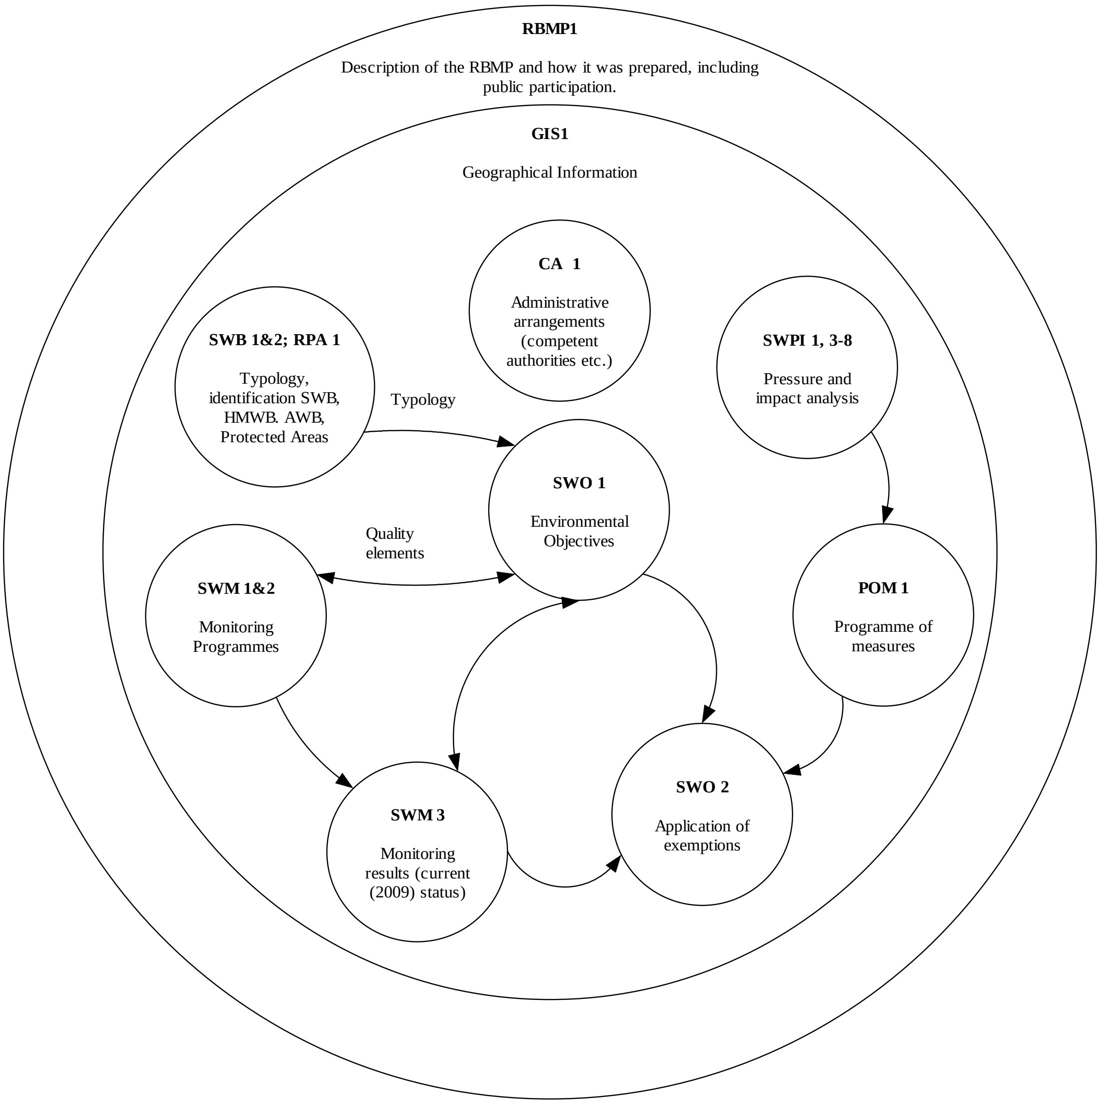

Figure 1 Relationships between Reporting sheets on surface waters

2 REPORTING REQUIREMENTS OF THE WATER FRAMEWORK DIRECTIVE

The reporting requirements of the WFD are specified in Articles 3 and 15. Article 3 requires MS to provide information to the European Commission on the identification of River Basin Districts and Competent Authorities, whilst Article 15 requires information to be provided to the Commission on:

- The analysis carried out according to Article 5;
- Monitoring programmes;
- River Basin Management Plans.

Article 18 of the Directive requires the Commission to publish reports on the implementation of the Directive and to submit them to the European Parliament and to the Council.

The first reports by MS were made in 2004 (for Article 3) and 2005 (for Article 5). The Commission has used the information provided to make reports to the European Parliament and Council as required under Article 18 of the Directive.

The first report on monitoring programmes was made by the MS in 2007 and the Commission will publish a report to the European Parliament and Council in early 2009. The first report by MS on the RBMPs will be made in 2010.

In addition to the specific requirements of the Directive, the Commission, as “Guardian of the Treaties”, also has a duty to ensure that the regulations and directives adopted by the Council and Parliament are being implemented in the MS. The Commission uses the information provided by the MS to carry out this compliance assessment and to ensure that the Directive is being applied consistently throughout the EU. The Commission has developed a concept for compliance checking for the WFD, and papers have been presented to the Member States specifying how the compliance check will be carried out. These have been completed for Articles 3, 5 and 8 and are currently being developed for Article 13. One of the key concepts used by the Commission is that of compliance indicators which are used for screening assessments to identify where a more detailed examination of compliance may be required. Compliance indicators may be simple (for example: have Competent Authorities been identified?– yes, no, to a certain extent, unclear – not sufficient information) or more complex and numeric indicators (for example: percentage of water bodies per water body category). The information requirements for these indicators have been identified as part of the reporting requirements. More detail on the Commission approach to compliance checking for the WFD can be found in the following documents:

- Questionnaire for the assessment of Compliance of WFD Article 3 Reports (discussed at the Working Group D meeting March 2006);
- Preliminary Screening For Compliance Checking Of Article 5 Reports (2005 Reporting) (discussed at the Working Group D meeting March 2006);
- “Use of information reported for Article 8 – concept paper on compliance checking” (presented at the Working Group D meeting March 2008);
- Concept paper on compliance checking on RBMP – currently being prepared.

	**Look Out!** Information that has already been reported for other purposes (e.g. UWWT Directive to the EEA under WISE-SoE reporting) does NOT have to be provided again.

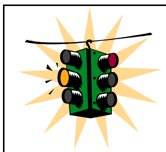
3 REPORTING REQUIREMENTS FOR RIVER BASIN MANAGEMENT PLANNING

3.1 Introduction

Article 13(1) of the WFD requires MS to ensure that a River Basin Management Plan (RBMP) is produced for each River Basin District (RBD) within their territory. Article 13(4) requires that the RBMP includes the information laid down in Annex VII of the Directive. Paragraph 8 of Annex VIIA requires MS to include a register of detailed programmes and management plans for the RBD in the RBMP.

Article 14 of the WFD requires MS to encourage the active involvement of all interested parties in the implementation of the Directive, and in particular in the production of the RBMP. For further information in relation to public participation in accordance with the WFD, refer to the Public Participation Guidance Document (WFD CIS Guidance Document 8)[2].

Article 3 of the WFD requires MS to ensure the appropriate administrative arrangements, including the identification of the appropriate Competent Authority, for the application of the rules of this Directive within each RBD lying within their territory. This will include Competent Authorities for the portion of any international RBD lying within its territory. The Directive requires Competent Authorities to be put be in place by 2003 and first reported in June 2004. Annex I of the WFD lays down the information that must be provided.



Look Out!

Member States first reported under Article 3 in 2004. In 2010, data should only be resubmitted if any was missing from the original submission or if any of the information has since changed.

3.2 How will the Commission use the information reported?

The Commission will use the information reported to ensure that the Member State has properly implemented the Water Framework Directive; ensuring that a register of more detailed programmes and management plans[3] is in place and that information has been provided to the public in accordance with the Directive. In particular, the information provided will be used to check the consistency of approach between Member States.

The following compliance indicators will be used:

- Have the Member States prepared a comprehensive River Basin Management Plan including all elements of and being consistent with the Directive and having been consulted with the public? (Possible answers: Yes / No / To a certain extent/ Unclear – not sufficient information).

---

[2] http://circa.europa.eu/Members/irc/env/wfd/library?l=/framework_directive/guidance_documents/guidancesnos8spublicspar/_EN_1.0_&a=d

[3] Dealing with particular sub-basins, sectors, issues or water types.

- A check list will be developed to ensure that every point in Annex VII and other relevant aspects are covered in some place of the RBMP. This check list will build on compliance indicators from other sheets.

Compliance of information provided by Member States on Competent Authorities will not be assessed in 2010. However, the provision of data will allow the Commission to ensure that all roles required by the WFD are being fulfilled within the RBD, making it unnecessary to seek further information from Member States at a later date. The data may be used for presentation to the European Parliament and will be provided to the public through WISE.

3.3 Information to be provided

The following information should be provided for each RBD (including national portions of international RBDs).

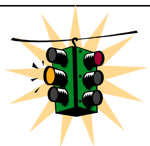
Data

For the RBMP the dates of publication of the:

- Timetable, work programme and consultation measures;
- Interim overview of significant water management issues;
- Draft copies of the RBMP;
- Final RBMP.

For each Competent Authority:

- The official name, acronym and Competent Authority Code[4];
- The full address and web-site.



Look Out!

Definition of a Competent Authority:

The various possible roles/responsibilities of a Competent Authority might be discharged at different levels in different MS. This could result in a large number of Competent Authorities in some MS. To circumvent any difficulties that this situation may cause, for reporting purposes a Competent Authority will be defined as having the following **core roles**:

A. Coordination, preparation and production of RBMPs;

B. Reporting (including of reporting on Article 5 requirements, monitoring requirements, establishment of programmes of measures, regulation and authorisation of surface water activities, regulation and authorisation of groundwater activities and public information and consultation).

[4] A Competent Authority may be associated with many RBDs, and may have different address and contact details for each association. A general/main address and specific addresses for RBDs should be provided if appropriate.

Summary text

Summary text should be provided covering the following items:

- A description of the (international) RBMP, including;
    - A table of contents of the plan;
    - Reference to any supporting documents that form part of the plan;
    - Reference to databases/repositories of information that support the plan;
    - A summary of the process and procedures used to develop the plan, and the main institutions involved in the planning process.
- The register of the programmes and management plans for the RBD, including sub-basins, Sub-units, sectors, issues or water types, and the information held within it (as specified in Article 13(5) and Paragraph 8 of Annex VIIA);
- **Only if it has not been possible** to produce an international RBMP for any RBD falling entirely within the Community, a justification for why this has not been possible;
- **Only if it has not been possible** to produce a single RBMP for any RBD that extends beyond the boundaries of the Community, a justification for why this has not been possible;
- **Only if any RBMP does not include the information detailed in Annex VII**, a justification for why this is the case;
- **Only if any RBMPs have not been published by 2009**, a justification for why publication is delayed;
- The public participation activities in place to encourage the active participation of the interested parties and consultation of the public in the development of the RBMP; including information on how the consultation on the RBMP was managed (including response periods); and including the arrangements in place to allow members of the public access to the background documents;
- A brief assessment of the experiences of the public participation activities carried out and what could be done in the RBMP to address these issues;
- The planned process of preparation of the first update of the RBMP;
- The legal status of each Competent Authority including:
    - The legislation establishing the Competent Authority;
    - The legislation laying down the duties of the Competent Authority in relation to the WFD;
    - The legislation laying down other duties of the Competent Authority relevant (but not directly related) to the WFD.
- The institutional relationships established in order to:
    - ensure co-ordination where the Competent Authority acts as a co-ordinating body for other Competent Authorities. This should include a list showing the co-ordinating body and the relationship between the co-ordinating body and the authorities whose activities it is co-ordinating;

    - ensure co-ordination where a RBD covers the territory of more than one MS or includes the territory of non-Member States.

- The core responsibilities of the relevant Competent Authority. If other relevant roles are fulfilled by organisations not defined as Competent Authorities for the purposes of reporting, a summary should be provided identifying these authorities and the roles that they perform.

References/Hyperlinks to more detailed supporting documents (e.g. methodology documents, documents provided as part of the public participation, statutes, founding treaty or equivalent legal documents) should be provided for each of the above-mentioned summaries, if available.

4 REPORTING REQUIREMENTS FOR GEOGRAPHICALLY REFERENCED INFORMATION

4.1 Introduction

Water Framework Directive

Articles 3 and 15 of the WFD require MS to provide information to the European Commission on the identification of RBDs and of the results of the analysis carried out under Article 5, including specific requirements to report geographic information. The first reports were made in 2004 (for Article 3) and 2005 (for Article 5).

In 2010 MS will be required to provide information on the RBMPs. According to Annex VII these should include information on the general characteristics of the RBDs. This section identifies the *geographic elements* of this information that should be provided to the Commission. The *data and textual aspects* of the information required are identified in other sections of this document.

Guidance on how this information should be provided can be found in WFD CIS Guidance Document No. 9[5] and Guidance Document No.22 - Updated Guidance on Implementing the Geographical Information System (GIS) Elements of the EU Water policy[6]. The Commission will use the information to prepare European wide maps for the assessment of compliance and to present information to the European Parliament, Council and general public. In some cases, reference data sets will be created to provide a common basis for assessments across the EU.

Annex V of the WFD specifies how Member States are to monitor and present "status" classification. For groundwater, the detailed provisions and criteria for the respective assessments of chemical and quantitative status are laid down in the Groundwater Directive 2006/118/EC.

	**Look Out!** Member States first reported under Article 5 in 2005 and under Article 8 in 2007. In 2010, data should only be resubmitted if any was missing from the original submission or if any of the information has since changed.

[5] Guidance Document No. 9 has been revised and replaced by Guidance Document No. 22 - Updated Guidance on Implementing the Geographical Information System (GIS) Elements of the EU Water policy. Future reporting of geographical information should be in accordance with the specifications agreed in the context of this process.

[6] Guidance Document No. 22 has been endorsed by the SCG and Water Directors and is available from:
http://circa.europa.eu/Public/irc/env/wfd/library?l=/framework_directive/guidance_documents&vm=detailed&sb=Title.
The appendices are available from:
http://eea.eionet.europa.eu/Public/irc/eionet-circle/eionet-telematics/library?l=/technical_developments/wise_technical_group/updated_2nd-edition/appendices_updated&vm=detailed&sb=Title
.

4.2 How will the Commission use the information reported?

The Commission will use the information to prepare European wide maps for the assessment of compliance and to present information to the Parliament, Council and general public. In some cases, reference data sets will be created to provide a common basis for assessments across the EU.

For further information on how the Commission will use the information reported on surface water bodies, see Chapter 5.

For further information on how the Commission will use the information reported on groundwater bodies, see Chapter 6.

For further information on how the Commission will use the information reported on pressures, impacts and Programmes of Measures, see Chapter 7.

4.3 Information to be provided

Data

	**Look Out!** The geographic information below should be harmonised to national and coastal boundaries. The technical specifications of such harmonisation are to be agreed in the context of the development of the updated GIS guidance.

For each **RBD** the data are required to enable the following maps to be produced:

- The RBDs;
- All river basins which have either been combined with larger river basins, or joined with neighbouring small basins to form individual RBDs as allowed under Article 3.1;
- Sub-units;
- The main rivers within the RBDs of a catchment area of, at least, 500 km²;
- The lakes which have been assigned to the RBDs;
- Transitional waters relating to the main rivers within the RBD;
- Coastal waters which have been assigned to the RBDs;
- Transboundary groundwaters which have been assigned to the RBDs;
- Other contextual data including:
    - River length;
    - Area of lakes, transitional and coastal waters.

For each **RBD/Sub-unit,** data will be required to enable the following maps of surface water status to be produced (reflecting the status as reflected in the RBMP). The maps shall present the following quality elements (QE):

- Map 1: Ecological status class of natural water bodies including data at a water body level, on which Biological QEs the assessment is based (default setting "unknown status" is applied if no class and BQE-specific data are provided)[7];

- Map 2: Ecological potential class for HMWB - MS should specify BQE concerned (default setting "unknown potential" is applied if no class and BQE-specific data are provided);
- Map 3: Status for protected areas – if not, specify reasons for failure **(if reported for other Directives (e.g. BWD, NiD, Habitats etc.) this information will not need to be reported again**. Reporting **will be required** for Article 7 protected areas as these are not defined under any other Directive);
- Map 4: Achievement/exceedance of EQS for **heavy metals[8]** out of list of Priority Substances;
- Map 5: Achievement/exceedance of EQS for **pesticides[9]** out of list of Priority Substances;
- Map 6: Achievement/exceedance of EQS for **industrial pollutants[10]** out of list of Priority Substances;
- Map 7: Achievement/exceedance of EQS for **other pollutants[11]** out of list of Priority Substances;
- Map 8: Achievement/exceedance of EQS for **other (national) pollutants**;
- Application of exemption for Water Bodies (by QE (to level 2 as defined in the 2007 monitoring Reporting sheets) and the target class)[12], which illustrates the envisaged/agreed objective for 2015.

Annex V of the WFD specifies how Member States are to monitor and present "status" classification. For surface water it has been agreed that the overall ecological status class of the waterbody will be reported using the defined colour codes. In addition, the following information should be provided[13]:

- An indication of which quality elements have been used in the classification;
- An indication of the status class indicated by the quality elements used;
- An indication of where information for a quality element is not available or not applicable;

---

[7] The WFD requires to determine the ecological status/potential class of every water body, but not to monitor all quality elements of all water bodies. Furthermore, some MS may not have appropriate monitoring for all BQE in place. The map should enable to create a disaggregated picture where only selected information is shown. It may be necessary to describe more detailed data and reporting needs to fulfil this aim.

[8] Cadmium, lead, mercury, nickel.

[9] Alachlor, atrazine, chlorpyriphos, chlorvenfinphos, diuron, endosulfan, isoproturon, HCH, pentachlorobenzene, simazine, trifluralin.

[10] Anthracene, Benzene, C_{10-13}-chloroalkanes, Naphthalene, Nonylphenol, octylphenol, chlorinated organics (incl. SCCP, TRI, PER, DCM, Chloroform, 1,2-Dichloroethane...), PentaBDE, DEHP.

[11] DDT, HCB, HCBd, TBT, PAHs (including Fluoranthene), PCP, TCB, drins.

[12] Default status “good status” unless water body is already at “high status” according to 2009 monitoring data and classification.

[13] Agreed at the SCG on 14-15 May 2008 (see document WGD/SCG14150508-13, "Reporting WFD ecological status of water bodies at European level", version 2).

- An indication of confidence in the ecological status class for the water body on a qualitative scale from 1 (Low confidence) to 3 (High confidence).

When monitored, monitoring data (disaggregated or aggregated) will be supplied for WISE-SoE reporting at the monitoring site level.

Data will be required to enable the following groundwater-related maps to be produced at **RBD** level (reflecting the status with data available in 2009). The maps shall present the following information:

- Map 1: Quantitative status – Identification of bodies that are at “good quantitative status” and those that are at “poor quantitative status”;
- Map 2: Achievement/exceedance of standard for **nitrates** (value in Annex 1 of GWD or set according to paragraph 3 of Annex 1 GWD, and according to status assessment procedure in Article 4 of GWD);
- Map 3: Achievement/exceedance of standard for **pesticides** (combined total and individual value in Annex 1 of GWD or set according to paragraph 3 of Annex 1 GWD, and according to status assessment procedure in Article 4 of GWD);
- Map 4: Achievement/exceedance of threshold values set by Member States for **other pollutants** (considering in this category the list of substances as contained in Part B of Annex II of GWD and more generally any other pollutants contributing to the characterisation of groundwater bodies as being 'at risk', and according to status assessment procedure in Article 4 of GWD);
- Map 5: Trends - Identification of: (a) groundwater bodies with environmentally significant and sustained upward trends in pollutant concentrations, and (b) groundwater bodies in which trends have been reversed[14];
- Application of exemption for WB (by QE (to level 2 as defined in the 2007 monitoring reporting sheets) and the target class)[15], which illustrates the envisaged/agreed objective for 2015.

For each **surface water body** the following data are required:

- Water body code;
- Water body name;
- Shapefile/GML file:
  - Rivers: for water bodies on rivers with catchments>500 km^2;
  - Lakes: for all lakes identified as water bodies by Member States;
  - Coastal and transitional waters: for all water bodies identified.
- Centroid (for all surface WBs) (technical specification for the calculation of the centroid to be developed in the context of the updated GIS guidance);
- Size (total length or area) at 1:250 000;

---

[14] For further information see Document No. 18 - Guidance on groundwater status and trend assessment.

[15] Default status “good status” unless water body is already at “high status” according to 2009 monitoring data and classification.

- Whether the water body (WB) is heavily modified (HMWB) or artificial (AWB);
- Type;
- Significant point source discharges to surface waters:
  - ID of significant point sources where data already available;
  - Latitude and longitude of each significant point source (if possible);
  - Type of point source (see SWPI3).
- Significant diffuse source pollution to surface waters:
  - WB Affected? (Y/N);
  - Type of source (see SWPI4).
- Significant water abstractions from surface waters:
  - WB Affected? (Y/N);
  - Latitude and longitude of each abstraction (if possible);
  - Type of abstraction (see SWPI5).
- Water flow regulations and morphological alterations:
  - WB Affected? (Y/N);
  - Type of Regulation/Alteration (see SWPI6).
- Significant saltwater or other intrusion:
  - WB Affected? (Y/N).
- Other pressures:
  - WB Affected? (Y/N);
  - Type of Pressure (to be specified see SWPI7).
- Impacts:
  - Type of impact identified (see SWPI8).
- Protected areas
  - Water body within or overlapping with a protected area (Y/N);
  - Type of protected area (**provide a Shapefile/GML file only where information is NOT reported under any other Directive. Where information has been provided under other Directives provide the unique identifier (code) of the appropriate protected area**):
    - WFD Article 7;
    - Sites for the protection of economically significant aquatic species;
    - Bathing Water Directive sites (Directives 76/160/EEC and 2006/7/EC);
    - Nitrate vulnerable zones (Directive 91/676/EEC);
    - Sensitive Areas (91/271/EEC);
    - Areas designated for the protection of habitats or species where the maintenance or improvement of the status of water is an important factor in their protection, including relevant Natura 2000 sites (Directive 92/43/EEC and 79/409/EEC);
    - Other protected areas defined under national legislation (specify – see also RPA1);
    - Other protected areas defined under regional/local legislation (specify – see also RPA1).

For each **groundwater body (GWB)** the following data are required:

- Water body code;
- Water body name;
- Shapefile/GML file:
    - Groundwaters: boundaries of groundwater bodies or groups of groundwater bodies larger than 100 km^2.[16]
- Centroid (for all groundwater bodies) (technical specification for the calculation of the centroid to be developed in the context of the updated GIS guidance);
- For groundwater bodies or groups of groundwater bodies, if available:
    - Layered (Y/N);
    - Average depth to groundwater body (m);
    - Average thickness of groundwater body (m);
    - Assignment to a depth range where the main part of the GWB is situated in (depth ranges: 0-20m, 20-50 m, 50-200 m, >200m);
    - Directly dependent aquatic ecosystems (Y/N);
    - Directly dependent terrestrial ecosystems (Y/N);
    - Geological formation – aquifer type (according to a predefined typology);
    - Type of vertical orientation of GWB (indicated by category and visualised by symbols);
    - Volume of aquifer (m^3) (if possible).
- Relevant point source discharges to groundwater:
    - ID of significant point sources where data already available;
    - Latitude and longitude of each relevant point source (if possible);
    - Type of point source (see GWPI3).
- Relevant diffuse source pollution to groundwater bodies:
    - WB Affected? (Y/N) ;
    - Type of source (see GWPI4).
- Relevant abstractions from groundwater:
    - WB Affected? (Y/N);
    - Latitude and longitude of each abstraction (if possible);
    - Type of abstraction (see GWPI5).
- Relevant artificial recharge of groundwater:
    - WB Affected? (Y/N);
    - Type of Regulation/Alteration (see GWPI6).
- Significant saltwater or other intrusion:
    - WB Affected? (Y/N).
- Other pressures:
    - WB Affected? (Y/N);
    - Type of Pressure (to be specified see GWPI8).

---

[16] When providing all GWB boundaries in one file please take care that the GWBs are not intersected. Alternatively provide separate files for each GWB horizon.

- Impacts:
    - Type of impact identified (see GWPI9).

- Protected areas:
    - Water body within or overlapping with a protected area (Y/N);
    - Type of protected area (**provide a Shapefile/GML file only where information is NOT reported under any other Directive. Where information has been provided under other Directives provide the unique identifier (code) of the appropriate protected area**):
        - WFD Article 7;
        - Nitrate vulnerable zones (Directive 91/676/EEC);
        - Areas designated for the protection of habitats or species where the maintenance or improvement of the status of water is an important factor in their protection, including relevant Natura 2000 sites (Directive 92/43/EEC and 79/409/EEC);
        - Other protected areas defined under national legislation (specify – see also RPA1);
        - Other protected areas defined under regional/local legislation (specify – see also RPA1).

For each **surface water monitoring site**, the following data are required:

- Site name;
- Is the site a surveillance monitoring or operational monitoring site, or both?;
- Unique site identifier;
- Link to the code/s of WB or WBs reported under Article 5 to which the site is associated (1 to 1-, 1 to many- or many to 1-relationship possible);
- X/Y co-ordinates (latitude/longitude) of the site;
- Identify if the site located in protected areas (Y/N). If so, the type of the protected areas (in accordance to Annex IV WFD) is required;
- Identify if the site is part of the intercalibration network (in accordance with Decision 2005/646/EC) or the national network of reference sites (i.e. determining reference conditions);
- Identify if the site is part of existing international monitoring networks (e.g. TNMN of the Danube river basin or WISE-SoE site);
- QE identifiers[17].

For each **groundwater monitoring site**, the following date are required:

- Unique site identifier;
- Identify the type of monitoring site:
  a) Is the site a well or a spring?;
  b) Is the site a quantitative or chemical monitoring site, or both?

[17] Development of an identifier system for QEs should be developed.

- Identify the use of monitoring site:
  Is the site used for monitoring, drinking water supply, industrial supply, irrigation or others?
- Unique code of GWB or group of GWBs to which the site is associated (1 to 1-, 1 to many- or many to 1-relationship possible);
- X/Y co-ordinates (latitude/longitude) of the site;
- Identify if the site is part of existing international monitoring networks (e.g. TNMN of the Danube river basin or WISE-SoE site);
- Information on sampling depth (site allows for sampling of upper, medium or deeper layer of the GW-body or for mixed samples);
- Parameter identifier.

5 REPORTING REQUIREMENTS FOR SURFACE WATER BODIES

5.1 Introduction

Identification and Characterisation of Water Bodies

Article 5 of the WFD requires Member States (MS) to identify surface water bodies that will be used for assessing progress with, and achievement of the WFDs environmental objectives. In addition, under certain conditions, Article 4(3) of the WFD permits MS to identify and designate artificial water bodies (AWB) and heavily modified water bodies (HMWB). HMWB and AWB are required to achieve Good Ecological Potential by 2015.

Identifying the size of water bodies was an important parameter that had implications on the design of the monitoring programmes and on the development of appropriate programmes of measures. A stepwise process for the identification of HMWB resulted in a provisional identification by 2004. Full identification should be completed by 2010 for publication in the RBMP.

Article 5 of the WFD also requires MS to analyse the characteristics of surface water bodies and provide a summary report on surface water characterisation including general information on their typology.

Article 6 of the WFD requires that a register of the water-related protected areas lying within each RBD be established. This will help to ensure that the management of the relevant water bodies also ensures the objectives of these protected areas are achieved. Annex IV of the WFD specifies what types of protected areas should be included in the register and specifies what the summary of the register, which should be part of the RBMP should include.

Classification and Monitoring of Water Bodies

Annex V of the WFD specifies how MS are to monitor and present "status" classification. The Commission needs to ensure that "good status/potential" has been defined according to the provisions of the Directive, and in a consistent and comparable way throughout the EU. The status requirements refer to all QEs in the Directive, chemical and biological. The normative provisions of Annex V provide a starting point. However, interpretation and application of these definitions may differ, which may lead to a wide range of variation between the MS. In this respect, it is important to compare the criteria and thresholds that MS have set. Whilst it is recognised that the intercalibration exercise has set out to ensure that the definition of high and good ecological status is consistent, the intercalibration exercise will not result in the findings of whether the Member States have followed the results of intercalibration or whether class boundaries have been established for all required water body types and quality elements. However, the intercalibration exercise has provided a useful template for the collection of such information which has been used in the development of this reporting guidance.

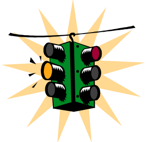
Article 8 of the WFD requires MS to ensure the establishment of programmes for the monitoring of water status in order to establish a coherent and comprehensive overview of water status within each RBD. Monitoring programmes should be in place by 2006 and reported in March 2007.

Investigative monitoring is reactive in nature and, as such, differs from the more routine surveillance and operational programmes. No detailed site specific information can be provided up front in relation to investigative monitoring. However, methodologies/strategies can be put in place detailing how each MS will investigate exceedances, reasons for likely failure to meet the environmental objectives and pollution incidents.

Strategies may include:

- Implementation of early warning systems (e.g. alert systems, public enquiries, pollution incident helplines etc);
- Procedures for dealing with individual exceedances (e.g. maximum allowable concentrations) and long-term exceedances (e.g. likelihood of non-compliance);
- Procedures for dealing with pollution incidents (e.g. incident notification, site visits, monitoring, reporting and action such as fines, clean-up etc).

In order to assess compliance with the requirements for *investigative monitoring*, MS are requested to provide an overview of the methodology/strategies that have been put in place at an RBD level to address the above issues.



Look Out!

Member States first reported under Article 5 in 2005 and under Article 8 in 2007. In 2010, data should only be resubmitted if any was missing from the original submission or if any of the information has since changed.

5.2 How will the Commission use the information reported?

The Commission will use this information to assess progress with, and achievement of, the WFD's environmental objectives. This information will be provided to the public through WISE.

The following compliance indicators, for the identification of surface water bodies will be used:

- Average size of river water bodies: as the total river water body length (km)/number of river water bodies;
- Average size of lake water bodies: total lake surface area (km^2)/number of lake water bodies (by Sub-unit);
- Average size of transitional water bodies: total area of transitional water bodies (km^2)/number of transitional water bodies (by Sub-unit);
- Average size of coastal water bodies: total surface area of coastal waters (km^2)/number of coastal water bodies/ (by Sub-unit);
- Minimum and maximum size (define dimensions) of water body in the Sub-unit per water category;

- Number and combined surface area (km^2) of lakes that are below the threshold (0.5 km^2). If no accurate figures are available then an estimate should be provided.

The following compliance indicators, for the identification of AWBs and HMWBs will be used for each water category (rivers, lakes, transitional waters, coastal waters):

- Number of artificial water bodies/Sub-unit – calculated by MSs;
- Number of heavily modified water bodies/Sub-unit;
- Percentage of water bodies per water body category.

With regard to the typology of surface waterbodies, the key issue for compliance will be identifying whether the level of typology is comparable. The information will be used to ensure that if System B has been followed, it provides at least the same level of differentiation as would be provided by System A and that type specific reference conditions can be adequately defined. It is also important for the Commission to check how the International River Basin District (IRBD) have co-ordinated their typology, and if not, the reasons why it was not coordinated, the steps that have been taken to address this shortcoming and by when co-ordination will be achieved.

For information relating to the typology of surface waters in accordance with the WFD, refer to the REFCOND, COAST and Waterbodies Guidance Documents (WFD CIS Guidance Document Nos 10, 5 and 2, respectively).

WFD Article 8 requires that monitoring programmes be established for each RBD and made operational by December 2006, and must be implemented in accordance with Annex V.

While Annex V sets out the minimum requirements for establishment of surface water surveillance, operational and investigative monitoring programmes, it is up to individual MS to develop the programmes, ensuring that the network of sites, parameters indicative of the QEs and monitoring frequencies are sufficient to provide a comprehensive and coherent overview of surface water status within each RBD.

A summary report of the monitoring programmes was reported to the Commission by March 2007. This summary should be sufficient to enable the Commission to carry out screening to ensure that the monitoring networks established for each purpose will be adequate to provide a comprehensive and coherent overview of surface water status for each RBD within each MS.

The Commission will check comparability of the monitoring programmes between Member States and consistency with the requirements of Annex V WFD and the outcome of the Article 5 analysis. Moreover, the Commission will use this information to inform the European Parliament and the public about the implementation progress in the Member States. Finally, some of the base data are necessary to establish a reference dataset with which monitoring results can be related and exchanged between the Member States and the European bodies more easily at a later stage.

WFD Annex V 1.3 requires that, under certain circumstances and to supplement surveillance and operational monitoring, MS may need to establish an investigative monitoring programme. The purpose of investigative monitoring is to determine:

- Reasons for exceedances, where these are unknown;

- Reasons for the likely failure to achieve the environmental objectives and where operational monitoring has not already been established; and,
- The magnitude and impacts of accidental pollution.

The outcomes of investigative monitoring will be used to inform the programme of measures.

Annex V 1.3.3 sets out the objectives and requirements for investigative monitoring. Additional monitoring requirements for protected areas and standards for monitoring are set out in Annex 1.3.5 and 1.3.6, respectively. No specific guidance is provided on selection of sites and monitoring frequencies. However, the number of sites and monitoring frequencies must be sufficient to determine the magnitude and impacts of accidental pollution and to achieve acceptable levels of confidence and precision.

For further information in relation to the establishment of monitoring programmes in accordance with the WFD, refer to the Monitoring Guidance Document (WFD CIS Guidance Document No. 7)[18].

Although compliance of information provided by Member States on the results of surface water monitoring programmes (status of surface waterbodies) will not be assessed in 2010, a key indicator will be percentage of moderate, poor or bad water bodies in the River Basin District or Sub-unit (i.e. those not of good ecological status and potential). Therefore, the main part of the reported information will be used for visualisation and for providing information to the public through WISE. Furthermore, the data and maps will provide a baseline or starting point for the implementation of the WFD (e.g. answering the question: how was the water quality before the programme of measures required by the WFD was implemented?). This means that the requested data and maps will be essential for trend analysis, for policy development and for the assessment of policy effectiveness. However, if Member States provide some of this information through the WISE-SoE reporting to the EEA, the Commission will use those data for its own purposes.

The following compliance indicator will be used:

- No compliance check will be carried out on 2009 monitoring results. However, for the purposes of illustrating the current status of water bodies to the public the indicator percentage of the water bodies being in different status classes specified for different quality elements (based on available maps) will be used.

Information provided by Member States on will be used to establish whether Member States have established a status classification scheme in accordance with the Directive, and to determine whether status classes are consistent with the Directive, comprehensive and comparable between Member States and River Basin Districts. The comparison of assessment criteria and thresholds will make the level and ambition of environmental protection more transparent and will allow to identification of differences in assessment methods, in terms of whether they are comprehensive and comparable.

[18]http://circa.europa.eu/Members/irc/env/wfd/library?l=/framework_directive/guidance_documents/guidancesnos7smonitoring/_EN_1.0_&a=d

The following compliance indicator will be used:

- Did Member States set a comprehensive set of criteria for assessing "good status/potential" (and other required boundaries) which is consistent with the Water Framework Directive and comparable throughout the EU? (Possible answers: Yes / No / To a certain extent / unclear – not sufficient information).

The Commission will use the information provided by Member States on protected areas to ensure that a register of protected areas has been established in the RBD.

The following compliance indicator will be used:

- Has information relating to protected areas been provided?

5.3 Information to be provided

Data

For each **RBD/Sub-unit** the following data are required:

- Total river water body length/total number of water bodies including artificial water bodies;
- Total lake water body surface area (km^2)/number of lake water bodies;
- Total area of transitional water bodies (km^2)/number of transitional water bodies;
- Total surface area of coastal waters (km^2)/number of coastal water bodies;
- Maximum and minimum size of water body (by water body category);
- Total number of HMWBs and AWBs.

The size of water body should be calculated at the scale of 1:250 000. If this is not possible then the scale at which the calculations have been made should be stated.

For each **category of water body** (rivers, lake, transitional and coastal waters) the following data are required:

- Number of types per water category (national or RBD);
- A list of types and a short description (<300 characters) of each type.

For each **surveillance and operational monitoring programme and for each surface water category** (rivers, lakes, coastal and transitional), the following data are required:

- Intended start date (if it differs from 22 December 2006);
- Total number of monitoring sites and frequency to be (or expected to be) monitored for each QE (see Table 1 below);
- List of Priority Substances and other substances discharged in significant quantities to be monitored.

Table 1 Information required for surveillance and operational monitoring programmes

Category	River		Lake		Coastal		Transitional	
	No. sites	Freq	No. sites	Freq	No. sites	Freq	No. sites	Freq
QE1 -Parameter 1 -Parameter 2 -Etc								
QE2 -Parameter 1 -Parameter 2 -Etc								
*QE (priority substances) -Parameter 1 (if applicable) -Parameter 2 (if applicable) -Etc								
*QE (other substances -Parameter 1 (if applicable) -Parameter 2 (if applicable) -Etc								

*Note: If individual substances are monitored at different frequencies, then the monitoring frequency for each substance/group of substances should be reported.

The following data on investigative monitoring should **only be provided as an illustration of how the system of investigative monitoring has been implemented – it can only be provided if an incident requiring investigative monitoring has occurred.**

- Type of investigative monitoring programme (e.g. incident response, unknown exceedances, likely failure of objectives);
- QEs and parameters monitored;
- Number of monitoring stations for each programme;
- Number of monitoring occasions (e.g. 1 off, monthly for 1 year etc).

No specific monitoring results per monitoring station in water bodies will be required at this stage. For the purpose of plausibility and consistency checking with the assessment of status, other data submitted to WISE (e.g. WISE-SoE reporting) may be used. If the Commission requires additional monitoring data for an in-depth analysis, a specific data request will be issued.

For each **surface water type and relevant QE,** the status/potential class boundaries should be reported (see Table 2):

Table 2 Reporting of Classification boundaries

Water category	QE or parameter code (Reported under Article 8)	National method in use (hyperlink) (Reported under Article 8)	National type (name or code) (Reported under Article 5)	Short description of national type (Reported under Article 5)	Reporting units	Reference conditions (if applicable)	High-Good boundary	Good-Moderate boundary	Moderate – Poor boundary	Poor – Bad boundary	Does this boundary reflect the result of the intercalibration exercise? (For biological quality elements only) (this column may be removed depending on results of discussions ongoing in intercalibration process) Yes/No/Other (specify)	Can the Member State implement this quality element at this stage?
Rivers	Dissolved oxygen	In situ measurement	Type R1; type R2 etc.	Small, high altitude, low alkaline	5-percentile mg O_2/L	9	7,5	6				
	Soluble reactive phosphorus	CEN 11564			μg/L	25	30	50				
	…											
	Macro-invertebrates	GREB			EQR	1	0,86	0,65			Yes	
	Phytobenthos	MMPB			EQR	1	0,75	0,55			No	

Water category	QE or parameter code (Reported under Article 8)	National method in use (hyperlink) (Reported under Article 8)	National type (name or code) (Reported under Article 5)	Short description of national type (Reported under Article 5)	Reporting units	Reference conditions (if applicable)	High-Good boundary	Good-Moderate boundary	Moderate – Poor boundary	Poor – Bad boundary	Does this boundary reflect the result of the intercalibration exercise? (For biological quality elements only) (this column may be removed depending on results of discussions ongoing in intercalibration process) Yes/No/Other (specify)	Can the Member State implement this quality element at this stage?
	…											
	Priority substances (specify)(1) – CAS number	….			…..	NA	NA	[means EQS]	NA	NA	NA	
	Other pollutants– CAS number					NA	NA	[means EQS]	NA	NA	NA	
	Supporting parameters (hydromorphology and physico-chem			…								

Water category	QE or parameter code (Reported under Article 8)	National method in use (hyperlink) (Reported under Article 8)	National type (name or code) (Reported under Article 5)	Short description of national type (Reported under Article 5)	Reporting units	Reference conditions (if applicable)	High-Good boundary	Good-Moderate boundary	Moderate – Poor boundary	Poor – Bad boundary	Does this boundary reflect the result of the intercalibration exercise? (For biological quality elements only) (this column may be removed depending on results of discussions ongoing in intercalibration process) Yes/No/Other (specify)	Can the Member State implement this quality element at this stage?
Lakes, transitional, coastal and territorial waters												

Summary text

Summary text should be provided for each RBD covering the following items:

- The methodology/criteria used to:
  - delineate each category of surface water bodies such as size, river confluence, etc;
  - identify HMWB and AWB;
  - identify and characterise small water bodies less than the threshold;
  - determine the QEs and the class boundaries for natural waters;
  - determine the QEs and the class boundaries for artificial and heavily modified water bodies;
  - combine QEs to define the final status class;
  - assess the "no deterioration" objective (Art. 4.1.a). The information should demonstrate on how the assessment is carried out (including: baseline, trend analysis etc.).
- **If System B has been used** for the characterisation of water bodies, a list of those factors (obligatory and optional) listed in Annex II 1.2 of the WFD that have been used for the definition of typology of water bodies should be provided;
- The coordination for international RBDs to:
  - designate water bodies;
  - characterise water bodies;

  If no co-ordination has been achieved, give reasons why not and details of what has been put in place to overcome this situation.
- A list of any legislation identifying additional national, regional or local water related protected areas other than those identified in EU legislation.

Summary text for each monitoring programme and for each surface water category should be provided covering the following items:

- The methodology/criteria used to:
  - select sites;
  - select monitoring frequencies for each QE.
- The sampling and analysis methodology to be used for each QE and details of any relevant national or international standards (e.g. CEN/ISO);
- The extent of where any monitoring deviates from what is outlined in the monitoring programme overview above (e.g. frequency, QEs) and number or percentage of sites that is affected (in particular for surveillance monitoring and where possible/applicable also for operational monitoring);
- Information on the levels of confidence and precision expected to be achieved from the results of monitoring;
- Any additional monitoring requirements for waters used for the abstraction of drinking water in relation to Article 7[19];

[19] Monitoring requirements for protected areas (other than for the abstraction of drinking water) identified in Annex IV will be incorporated into WISE and are not required to be reported here.

- If the monitoring programmes will start later than 22 December 2006, a justification of why the monitoring programme/s are delayed;
- If the monitoring programme includes the identification of sub-sites[20], a summary of the extent and how the concept of sub-sites has been applied;
- The investigative monitoring strategy, including an example of where the strategy has been implemented, if available;
- Whether a paper-based report, e.g. for national consultation, international co-ordination, public information or other purposes, to describe the establishment of the monitoring programmes in accordance to Article 8 WFD (e.g. in PDF- or DOC-format) was produced. If yes, the report should be provided or uploaded.

References/Hyperlinks to more detailed supporting documents (e.g. methodology documents, documents provided as part of the public participation, statutes, founding treaty or equivalent legal documents) should be provided for each of the above-mentioned summaries, if available.

5.4 Reporting on specific initiatives and management objectives

If Member States choose to set operational management objectives they will be asked to report those in a generic form. In order to communicate such information to the public it would be beneficial to provide detailed, geographically referenced information on specific management measures taken and the management objectives put in place. At the highest level this could be provided for each RBD or Sub-unit. The information that would need to be provided to enable data to be displayed visually would be:

- The RBD (code);
- The Sub-unit (code);
- For nutrient load (if objectives set) the current nutrient load, the target nutrient load for the Sub-unit (for 2015) and the load reduction required for the impacted groups of water bodies;
- For connectivity (if objectives set), current status of connectivity of the Sub-unit (yes, no, partial). This question should be answered for 2009, 2015, 2021, 2027 and the target date by which the Sub-unit will be connected to the river network;
- MS may report information on other management objectives that they have set for other parameters;
- A textual summary of what measures are being put in place to achieve this (e.g. dam removal and target dates).

If this is not possible, summary text with hyperlinks to more detailed information may be provided. The summary should include the targets that have been set, the deadlines

[20] It may be necessary to monitor parameters at a number of sub-sites within a single monitoring site (E.g. to determine profiles of stratification in lakes/reservoirs, transitional and coastal waters or in large rivers (e.g. temperature, oxygen, nutrient or phytoplankton conditions) or to monitor chemical and biological QEs at different points in one site).

by which they should be achieved, the measures in place to achieve the targets and the resulting improvements in water quality that would result. Given the generalised nature of this information it should be reported at a RBD level.

On the basis of this information, data should be provided to allow maps to be produced along the lines of the examples presented by Germany (see presentation at http://circa.europa.eu/Members/irc/env/wfd/library?l=/working_groups/new_wg_reporting/meetings/meeting_1718_october/reporting_janningppt/_EN_1.0_&a=d#261,1,Reporting 2010).

6 REPORTING REQUIREMENTS FOR GROUNDWATER BODIES

6.1 Introduction

Identification and Characterisation of Water Bodies

Article 5 and Annex II of the WFD requires MS to identify the location and boundaries of groundwater bodies. The Commission will use the information provided on the level of subdivision of groundwater to ensure that this is adequate to describe the status of groundwater bodies.

Article 6 of the WFD requires that a register of the water-related protected areas lying within each RBD be established. This will help to ensure that the management of the relevant water bodies also ensures the objectives of these protected areas are achieved. Annex IV of the WFD specifies what types of protected areas should be included in the register and specifies what the summary of the register, which should be part of the RBMP, should include.

Classification and Monitoring of Water Bodies

Annex V of the Water Framework Directive specifies how Member States are to monitor groundwater, present chemical and quantitative status classification results and identify groundwater bodies with significant and sustained upward trends[21] in pollutant concentrations. The detailed provisions and criteria for status and trend assessments are laid down in the Groundwater Directive.

In addition to the WFD reporting requirements, the Groundwater Directive introduces several additional reporting requirements to ensure that groundwater body status and trends have been defined according to the provisions of the Directive, and in a consistent and comparable way across the EU.

The reporting requirements include threshold values (groundwater quality standards set by Member States). These have to be reported along with a summary of the methodology used for identifying the pollutants (or their indicators) and deriving the threshold value(s). The criteria for establishing threshold values are included in Article 3 and Annex I and II of the GWD (reporting obligations in GWD Article 3.5 and Annex II Part C). This is linked to the pressure and impact analysis required by Article 5 of the WFD and Article 17 of the WFD relating to strategies to prevent and control pollution of groundwater. According to Article 3.1(b) of the GWD, threshold values have to be established for pollutants, groups of pollutants and indicators of pollution – the relevant parameters – which have been identified as contributing to the characterisation of groundwater bodies as being at risk of not meeting the WFD Article 4 objectives, taking into account at least the list of the GWD Part B Annex II).

Article 8 of the WFD requires MS to ensure the establishment of groundwater programmes for the monitoring of water status (quantitative and chemical), including the assessment of the available groundwater resource, in order to establish a coherent

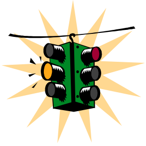
---

[21] In this reporting sheet the term 'significant and sustained upward trends' refers to the definition in Article 2.3 of GWD.

and comprehensive overview of water status within each RBD. Monitoring programmes should be in place by 2006 and reported in March 2007.

The GWD requires that the results of both chemical and quantitative status assessment and the methodology used to classify groundwater bodies are reported. The requirements are laid down in WFD Annex V, GWD Article 4, and Annex III (reporting requirements in GWD Article 4.4 and Annex III point 5).

In addition, the GWD requires that the results of trend assessment and the method used for trend assessment, including the way in which results from monitoring at individual points has been used, must be reported. The starting point for trend reversal and the reasons for selecting the starting point must also be reported. Requirements for the identification of upward trends and the definition of starting points for trend reversal are laid down in GWD Article 5 and Annex IV (reporting requirements in GWD Article 5.4, 5.5 and Annex IV, Part A point 3).



Look Out!

Member States first reported under Article 5 in 2005 and under Article 8 in 2007. In 2010, data should only be resubmitted if any was missing from the original submission or if any of the information has since changed.

6.2 How will the Commission use the information reported?

The Commission will use the information provided on the level of subdivision of groundwater to ensure that this is adequate to describe the status of GWB. The following compliance indicators will be used:

- Number of groundwater bodies per RBD/Sub-unit;
- Average size of groundwater body per RBD/Sub-unit.

WFD Article 8 requires that groundwater monitoring programmes be established for each RBD and made operational by December 2006, and must be implemented in accordance with Annex V.

WFD Annex V (2) requires that MS must establish a groundwater monitoring programmes (quantitative and chemical status). The groundwater network must be designed in order to provide a reliable assessment of the status of all GWBs or groups of GWBs, including the assessment of the available groundwater resource.

For further information in relation to the establishment of monitoring programmes in accordance with the WFD, refer to the Monitoring Guidance Document (WFD CIS Guidance Document No. 7).

A summary report of the monitoring programmes was reported to the Commission by March 2007. This summary should be sufficient to enable the Commission to carry out screening to ensure that the monitoring networks established for each purpose will be adequate to provide a comprehensive and coherent overview of groundwater status for each RBD within each MS.

The Commission will check comparability of the monitoring programmes between Member States and consistency with the requirements of Annex V WFD and the outcome of the Article 5 analysis. Moreover, the Commission will use this information to inform the European Parliament and the public about the implementation progress in the Member States. Finally, some of the base data sets (such as geographic information) are necessary to establish a reference dataset with which monitoring results can be related and exchanged between the Member States and the European bodies more easily at a later stage.

Information provided by Member States under the Groundwater Directive will be used to ascertain whether they have established and applied methodologies, in accordance with the WFD and GWD, for: deriving threshold values; assessing status (chemical and quantitative) and; identifying environmentally significant pollutant trends (and starting points for trend reversal).

The Commission will determine whether the methods applied are comparable between Member States and River Basin Districts. The comparison of assessment criteria and thresholds will make the level and ambition of environmental protection more transparent and will allow any differences to be identified. Information on threshold values and the substances for which such values have been established will be summarised and analysed.

Although compliance will not be assessed in 2010, a key indicator will be number of poor status groundwater bodies per River Basin District (i.e. those not of good status). This information will be provided to the public through WISE. Appropriate explanation will accompany the information on status noting that an overall result of poor status could reflect problems that are very different in severity and character (i.e. the problems can exist throughout the whole groundwater body or only in part of the body and the gap between the WFD objectives and the actual state of the groundwater can be large or small).

The following compliance indicators will be used:

- It will be analysed whether threshold values have been established in accordance with the Groundwater Directive. Did Member States set a comprehensive set of criteria for assessing "good status" which is consistent with the WFD and comparable throughout the EU? (Possible answers: Yes / No / To a certain extent / unclear – not sufficient information);
- No compliance check will be carried out on status and trends results. However, for the purposes of illustrating the current status of water bodies to the public the indicator percentage of the groundwater bodies being of good and poor chemical and quantitative status (based on available maps) will be used.

The Commission will use the information provided by Member States on protected areas to ensure that a register of protected areas has been established in the RBD.

The following compliance indicator will be used:

- Has information relating to protected areas been provided?

6.3 Information to be provided

Data

For each **RBD** the following data are required:

- Total number of groundwater bodies;
- Average area (m^2) of the groundwater bodies;
- Number of groundwater bodies for which there are directly dependent surface water or terrestrial ecosystems.

For each **surveillance and operational monitoring programme**, the following data are required:

- Intended start date (if it differs from 22 December 2006);
- Total number of monitoring sites to be (or expected to be) monitored;
- Total number of protected areas used for drinking water abstraction (from groundwater) for which there are groundwater monitoring sites associated;
- List of parameters (mainly level and pollutants) expected to be monitored.

For sites that are located in drinking water abstraction areas, the following data are required:

- Any additional monitoring requirements in relation to drinking water abstraction areas, over and above those already provided;
- Detailed site-specific information on monitoring frequencies is only required where monitoring deviates from the general programme outlined above.

No specific monitoring results per monitoring station in water bodies will be required at this stage. For the purpose of plausibility and consistency checking with the assessment of status, other data submitted to WISE (e.g. WISE-SoE reporting) may be used. If the Commission requires additional monitoring data for an in-depth analysis, a specific data request will be issued.

The following information on the **classification used for groundwater bodies** should be reported for each RBD:

- The Threshold Values (TV) established in accordance to Article 3 of the GWD and the level at which TV are established (Member State level / international RBD / national part of RBD / GWB level)[22];
- The Threshold Values established for nitrates and pesticides, only if more stringent than the groundwater quality standards identified in Annex 1 of GWD;
- The starting point for trend reversal, and reasons for their definition where they are different from 75% of the applicable TV.

Table 3 summarises the information requested.

[22] All TVs that are relevant for the RBD should be reported, including those developed at MS or GWB level.

Table 3 Information required on Groundwater Classification

Pollutants / Indicators	Threshold Value (or range)[2, 4]	Level on which the TV is established (Member State / international RBD / national part of RBD / GWB)	Starting point for trend reversal (in % of TV)[3, 4]
Nitrates			
Active substance in pesticides			
Pesticides total			
Parameter 1[1]			
Parameter 2[1]			
…[1]			
Parameter n[1]			

[1]) Considering at least the list of substances as contained in Part B of Annex II of GWD and extended by further relevant parameters/indicators as appropriate.
[2]) For nitrates and pesticides, only if different from those in Annex I to GWD.
[3]) Only if different from 75%.
[4]) Insert the range of TVs respectively the range of starting points if different TVs or starting points are applied at GWB-level within the RBD.

The following should be reported on **groundwater chemical status**, background levels and trends for each **groundwater body or group of groundwater bodies**:

- The result of the chemical status assessment (good/poor);
- If the GWB is identified as poor status;
  - The relevant pollutants / indicators for the GWB as referred to in Annex II Part A of GWD including the observed concentration values; and
  - The reason(s) for failing to achieve good chemical status, including the threshold values or quality standards that have been exceeded:
    - Multi-selection of reasons:

      a) Saline or other intrusions;
      b) Exceedance of one or more quality standard or threshold value;
      c) Failure to meet environmental objectives in associated surface water bodies or significant diminution of the ecological or chemical status of such bodies;
      d) Significant damage to terrestrial ecosystems which depend directly on the groundwater body;
      e) Deterioration in quality of waters for human consumption;
      f) Significant impairment of human uses;
      g) Significant environmental risk from pollutants across the groundwater body.
- The background level for those substances that occur naturally in the groundwater body and for which threshold values have been established;

- Information on significant and sustained upward trends including the pollutants for which trend assessment has been required.

The following should be reported on **quantitative status for each groundwater body or group of groundwater bodies**:

- The results of quantitative status assessment (good/poor);
- If the GWB is identified as poor status;
    - The reason(s) for failing good quantitative status:
        - Multi-selection of reasons:

        a) Exceedance of available groundwater resource by long-term annual average rate of abstraction that may result in a decrease of groundwater levels;
        b) Failure to achieve environmental objectives (Article 4 WFD) for associated surface waters;
        c) Significant diminution of the status of surface waters;
        d) Significant damage to terrestrial ecosystems directly depending on groundwater;
        e) Saline or other intrusion.

Summary text

Summary text should be provided for each RBD covering the following items:

- The methodology/criteria used to delineate GWBs;
- A list of any legislation identifying additional national, regional or local water related protected areas other than those identified in EU legislation;
- The establishment of groundwater threshold values (GWD Annex II Part C) covering the following items:
    - The way the procedure set out in Annex II Part A of the Groundwater Directive has been followed to derive threshold values;
    - The relationship between threshold values and background levels for naturally occurring substances;
    - The relationship between threshold values and environmental quality objectives and other standards for water protection that exist at national, Community or international level.
- The assessment of groundwater chemical and quantitative status describing the following methodologies:
    - The assessment of groundwater chemical status to cover an explanation of how exceedances of groundwater quality standards or threshold values at individual monitoring points have been taken into account in the final assessment, including the indication of what option from GWD Article 4.2 has been used (GWD Article 4.4);
    - The assessment of groundwater quantitative status.
- The assessment of trends and trend reversal (GWD Article 5.4) describing:
    - The way in which the trend assessment at individual monitoring points within a body or a group of bodies of groundwater, has contributed to identifying that those bodies are subject to a significant and sustained upward trend;

  - The way in which the trend assessment at individual monitoring points within a body or a group of bodies of groundwater has contributed to identifying that those bodies are subject to a reversal of that significant and sustained upward trend;
  - The reasons to establish starting points for trend reversal where they are different from 75% of the parametric value of the threshold value or groundwater quality standards (see GWD Article 5.4 and Annex IV, Part B, point 1).

- The results of any existing assessments of the impacts of relevant (expanding) plumes (GWD Article 5.5) in particular, verification by additional trend assessments that existing plumes from contaminated sites do not expand, do not deteriorate the chemical status of groundwater bodies and do not present a risk for human health and the environment;

- For transboundary groundwaters, a summary of the steps put in place to co-ordinate the objectives (establishment of threshold values, status and trend assessment).

Summary text for **quantitative and chemical monitoring programmes** should be provided separately covering the following items:

- The methodology/criteria used to;
  - select sites;
  - select monitoring frequencies.

- The sampling and analysis methodology to be used and details of any relevant national or international standards (e.g. CEN/ISO);

- The extent of where any monitoring deviates from what is outlined in the monitoring programme overview above (e.g. frequency, QEs) and number or percentage of sites that is affected (in particular for surveillance monitoring and where possible/applicable also for operational monitoring);

- If the monitoring programmes will start later than 22 December 2006, a justification of why the monitoring programme/s are delayed;

- If the monitoring programme includes the identification of sub-sites[23], a summary of the extent and how the concept of sub-sites has been applied.

References/Hyperlinks to more detailed supporting documents (e.g. methodology documents, documents provided as part of the public participation, statutes, founding treaty or equivalent legal documents) should be provided for each of the above-mentioned summaries, if available.

[23] It may be necessary to monitor parameters at a number of sub-sites within a single monitoring site (E.g. to determine profiles of stratification in lakes/reservoirs, transitional and coastal waters or in large rivers (e.g. temperature, oxygen, nutrient or phytoplankton conditions) or to monitor chemical and biological QEs at different points in one site).

7 REPORTING REQUIREMENTS FOR PRESSURES, IMPACTS AND PROGRAMMES OF MEASURES

7.1 Introduction

Article 5 of the WFD requires MS to identify the key pressures present in the RBD likely to cause water bodies to be of less than good status. It also requires MS to assess the impacts on water bodies to support the determination of status.

Article 11 of the WFD requires MS to ensure the establishment of a programme of measures for each RBD, or part of international RBDs within its territory to achieve the objectives laid down in Article 4 of the Directive. The programme of measures should take account of the analyses carried out according to Article 5 and the subsequent monitoring results collected with the network established under Article 8.

For each RBD, the programme of measures must include “basic” and, where required, “supplementary measures”. Basic measures are listed in Article 11(3) of the Directive. The basic measures are divided into those measures which are regulated in other EU directives (Article 11 (3)(a)) (including those listed in Annex VI, part A) and those measures additionally introduced by the WFD (Article 11 (3), sub-paragraphs (b) to (l)).

A tentative list of supplementary measures (Article 11 (4)) are listed in Annex VI, part B.

Article 4(4-9) of the WFD allows MS to extend the deadlines for the achievement of good status/potential or to set other objectives under certain specified circumstances. Additional information can be found in the CIS Paper on "Environmental Objectives" agreed in 2005[24].

Article 4(4-9) goes on to require MS to provide information regarding such extensions or other objectives and the reasons for it in the River Basin Management Plan.

	**Look Out!** Member States first reported under Article 5 in 2005 and under Article 8 in 2007. In 2010, data should only be resubmitted if any was missing from the original submission or if any of the information has since changed.

7.2 How will the Commission use the information reported?

The purpose of the collection of the information is to identify the main pressures within the RBD. The summary information will be used to compile maps at a European level of relevant pressures and to ensure that relevant pressures have been identified at RBD level. Statistics and information will be provided to the European Parliament at EU wide level. Information will be provided to the public through WISE.

[24] http://forum.europa.eu.int/Public/irc/env/wfd/library?l=/framework_directive/thematic_documents/environmental_objectives/environmental_20605pdf/_EN_1.0_&a=d

The following compliance indicators relating to surface waters will be used:

- Number of water bodies failing to reach good status/potential as a result of each pressure;
- Number of water bodies or river length etc/Sub-unit "not in good status/potential" as a result of point sources (either as a result of point sources only or in combination with other pressures);
- Whether information has been provided on the substances discharged from point sources and the load of those substances;
- Number of water bodies/Sub-unit "not in good status/potential" as a result of diffuse sources (either as a result of diffuse pollution only or in combination with other pressures);
- Whether information has been provided on the substances discharged from diffuse sources and the load of those substances;
- Whether information has been provided on the number of abstraction points and the volumes abstracted;
- Number of water bodies/Sub-unit "not in good status/potential" as a result of water abstractions (wholly or partially);
- Whether information has been provided on the water flow regulations and morphological alterations;
- Number of water bodies/Sub-unit "not in good status/potential" as a result of water flow regulations and morphological alterations, either as a result of water flow regulations and morphological alterations only or in combination with other pressures;
- For each pressure type (point sources, diffuse sources, water abstractions, and water flow regulations and morphological alterations) is “significance” defined in a way that is comparable with the approach used in other RBDs/Member States;
- Number of water bodies/Sub-unit "not in good status/potential" as a result of unknown pressures;
- Whether information has been provided on the actions to be taken to identify the unknown pressures;
- Whether information on the impacts on surface water bodies has been provided;
- Whether information on the impacts on uncertainties and data gaps have been provided;
- Whether sufficient steps have been taken since 2005 to address the uncertainties and data gaps;
- Whether future plans have been put in place to address any continuing uncertainties and data gaps;

The following compliance indicators relating to groundwaters will be used:

- Number of groundwater bodies failing to reach good status as a result of each pressure or combination of pressures (depending on the information provided);
- Number of GWBs/RBD "not in good status" as a result of point sources (either as a result of point sources only or in combination with other pressures);
- Whether information has been provided on the substances discharged from point sources and the load of those substances;
- Whether information has been provided on the substances discharged from diffuse sources and the loads of those substances;
- Number of GWB/RBD "not in good status" as a result of water abstractions only or in combination with other pressures;
- Whether information has been provided on the number of abstraction points and the volumes abstracted;
- Number of water bodies/RBD "not in good status" as a result of artificial recharge only or in combination with other pressures;
- Whether information has been provided on the number of artificial recharges and the volumes concerned;
- Number of GWBs/RBD "not in good status" as a result of saltwater intrusion (either as a result of saltwater intrusion only or in combination with other pressures);
- Whether information has been provided on the number of groundwater bodies affected by saltwater intrusion;
- Number of groundwater bodies/RBD "not in good status" as a result of pressures not covered by other reporting sheets or unknown pressures;
- Whether information has been provided on the actions to be taken to identify the pressures;
- Whether information on the further characterisation/assessment of human impacts on GWBs has been provided;
- What level of further characterisation of groundwater has been carried out and what plans are in place to complete the work in preparation for the publication of the draft River Basin Management Plans in 2010;
- Whether information on the impacts on uncertainties and data gaps has been provided;
- Whether sufficient steps have been taken since 2005 to address the uncertainties and data gaps;
- Whether plans have been put in place to address any continuing uncertainties and data gaps.

Information provided by Member States on the summary of steps and measures taken to meet the requirements of Article 11 will be used by the Commission to ensure that the provisions of Article 11 have been properly and consistently applied according to the Directive, and to provide information to the Parliament and public on the relevant measures. A screening assessment will be made on the basis of the compliance indicator which builds on an approach based on pressures.

The following compliance indicators will be used:

- For every significant pressure that has been identified, the Commission will check that Member States have ensured that measures are in place to address that pressure or that exemptions are applied and justified. An aggregated compliance indicator will be developed. (Possible answers: Yes / No / To a certain extent/unclear – not sufficient information);
- A check list will be developed to ensure that every point in Article 11 and any other relevant aspects is covered in some place of the Programme of Measures and to ensure that every pressure identified has been adequately addressed.

The Commission will use information provided by Member States on the classification of status to give summary statistics to the European Parliament and the public and assess whether the level of exemptions is comparable and justified. The comparative screening assessment will be based on the compliance indicators (see below). Taking account also the summary text provided, the screening assessment will be used to determine whether more detailed analysis is required.

The Commission will use the geographic information provided to produce a map for the Parliament and the Public to show the distribution of water bodies across the EU where Article 4(4-7) has been used and also to create a map showing the status of water bodies. This information will be made available through WISE.

The following compliance indicator will be used to prioritise those River Basin Districts where the use of Article 4 (4-7) requires further investigation:

- Percentage of surface water bodies where each exemption per Article 4 (4, 5, 6 and 7) has been used/River Basin District (per (national part of international) River Basin District or Sub-unit), as a proportion of all SWBs and the SWBs not achieving good status as reported in the River Basin Management Plan.
- Percentage of groundwater bodies where each exemption per Article 4 (4, 5, 6 and 7) has been used/River Basin District (per (national part of international) River Basin District or Sub-unit), as a proportion of all GWBs and the GWBs not achieving good status as reported in the River Basin Management.

7.3 Information to be provided

A list of pressures is given below. This is indicative and it is not expected that all these pressures will be significant for all RBDs:

- Point sources including:
  (to surface water)
  - UWWT plants;
  - Storm overflows;
  - IPPC plants (EPRTR);
  - Other industrial plants outside the IPPC Directive not covered in EPRTR;
  - Additional point sources (e.g. small agglomerations) that may cause a significant impact in the status of water body or water bodies.

  (to groundwater)
  - Leakages from contaminated sites;

  - Leakages from waste disposal sites (landfill and agricultural waste disposal);
  - Leakages associated with oil industry infrastructure;
  - Mine water discharges;
  - Discharges to ground such as disposal of contaminated water to soakaways;
  - Other relevant point sources.

- Diffuse sources including:
  (to surface water)
  - Via storm overflows (if data not available to allow this to be treated as a point source) or the built environment (urban run-off);
  - Due to agricultural activities (via leaching, erosion, spills, direct drainage discharges,);
  - Due to transport and infrastructure without connection to canalisation/sewers (ships, trains, automobiles and airplanes and their respective infrastructures outside the urban area);
  - Abandoned industrial sites;
  - Releases from facilities for the storage and/or treatment of domestic effluent in areas without sewerage networks (e.g. leaks from septic tanks etc.);
  - Other diffuse sources not listed above.

  (to groundwater)
  - Due to agricultural activities (e.g. fertilizer and pesticide use, live stock etc.);
  - Due to non-sewered population;
  - Urban land use.

- Water Abstractions including
  (from surface water)
  - Abstractions for irrigation in agriculture;
  - Abstractions for public water supply;
  - Abstractions by manufacturing industry;
  - Abstractions for the production of electricity (cooling);
  - Abstractions by fish farms;
  - Abstractions by hydro-energy (not for cooling);
  - Abstractions by quarries/open cast coal sites;
  - Abstractions for navigation (e.g. supplying canals);
  - Abstraction for water transfer;
  - Other major abstractions.

  (from groundwater)
  - Abstractions for agriculture;
  - Abstractions for public water supply;
  - Abstractions by industry;
    - IPPC industries;
    - Non-IPPC industries;
  - Abstractions by quarries/open cast coal sites;
  - Other major abstractions.

- Water flow regulations and morphological alterations of surface water including:

  - Water Flow Regulations;
  - Groundwater re-charge;
  - Hydroelectric dams;
  - Water supply reservoirs;
  - Flood defence dams, dykes and channels;
  - Diversions;
  - Locks;
  - Weirs.

- River management including:
  - Physical alteration of channel;
  - Engineering activities;
  - Agricultural enhancement;
  - Fisheries enhancement;
  - Land infrastructure (road/bridge construction);
  - Dredging.

- Transitional and coastal water management including:
  - Estuarine/coastal dredging;
  - Marine constructions, shipyards and harbours;
  - Land reclamation and polders;
  - Coastal sand suppletion (safety);
  - Tidal barrages including those for flood defence and power generation.

- Other morphological alterations or surface waters including:
  - Barriers;
  - Land sealing in riparian area/zones and flood plains.

- Artificial recharge of groundwater including:
  - Discharges to groundwater for artificial recharge purposes;
  - Returns of groundwater to GWB from which it was abstracted (e.g. for sand and gravel washing);
  - Mine water rebound;
  - Other major recharges.

- Saltwater intrusion of groundwater including:
  - Saltwater intrusion;
  - Other intrusion.

- Other pressures not covered by the list above.

Data

- The number of water bodies in each Sub-unit or RBD failing to reach good status as a result of each pressure type (point sources, diffuse sources, water abstractions etc.) for each water body category (rivers, lakes, transitional waters, coastal waters, groundwaters). This will result in some water bodies being counted more than once;

- Number of significant point sources in the Sub-unit (UWWT plants, storm overflows, IPPC Plants (EPRTR), other industrial plants outside the IPPC Directive not covered in EPRTR);

- Number of other significant point sources that are relevant in the Sub-unit (e.g. small agglomerations);
- Number of relevant point sources in the RBD causing groundwater bodies to be "not in good status";
- Loads (monitored, calculated or estimated) of pollutants (COD, nutrients, priority substances, other pollutants, saline discharges)25 discharged to surface waters (total for Sub-unit) (if not provided to the EEA under WISE-SoE Reporting);
- Number of significant abstractions and volumes abstracted/year or in different seasons by category of abstraction (see list in the introduction to this section) and per Sub-unit;
- Number of relevant abstractions in a RBD and volumes abstracted (annual average) by category of abstraction (if not provided to the EEA under WISE-SoE Reporting);
- Water balance (as defined in the guidance on the assessment of groundwater status) (or groundwater exploitation index);
- Number of relevant recharges and volumes recharged by category of recharge (see list in the introduction to this sheet) and per RBD.

Provide data on basic measures (Article 11(3)(a) and (b-l)), supplementary measures (Article 11(4)) and additional measures (Article 11 (5)) according to the templates provided in Tables 3 - 5.

Table 4 Basic Measures required by Article 11(3)(a) and listed in Annex VI Part A

Directive listed in Annex VI Part A	**Measures implemented in Member State (self assessment) – tick if yes**	**Additional comments or if no, additional explanations (<2000 characters)**
Bathing Water Directive (76/160/EEC and 2006/7/EC)		
Birds Directive (79/409/EEC)		
Drinking Water Directive (80/778/EEC) as amended by Directive (98/83/EC)		
Major Accidents (Seveso) Directive (96/82/EC)		
Environmental Impact Assessment Directive (85/337/EEC)		
Sewage Sludge Directive (86/278/EEC)		
Urban Waste-water Treatment Directive (91/271/EEC)		
Plant Protection Products Directive (91/414/EEC)		

[25] Specification of detailed pollutant lists and units when preparing the schemas.

Directive listed in Annex VI Part A	Measures implemented in Member State (self assessment) – tick if yes	Additional comments or if no, additional explanations (<2000 characters)
Nitrates Directive (91/676/EEC)		
Habitats Directive (92/43/EEC)		
Integrated Pollution Prevention Control Directive (96/61/EC)		

Table 5 Other basic measures as required by Article 11(3)(b-l)

Measure (Article 11(3))	Implemented in Member State (self assessment) – tick if yes	Reference to legislation or other document (hyperlink or document)	Description of measure (<500 characters)	Additional comments or if no, additional explanations (<2000 characters)
Measures for the recovery of cost of water services (Article 9)				
Measures to promote efficient and sustainable water use				
Measures for the protection of water abstracted for drinking water (Article 7) including those to reduce the level of purification required for the production of drinking water (note: these basic measures may not apply to the whole territory)				
Controls over the abstraction of fresh surface water and groundwater and impoundment of fresh surface waters including a register or registers of water abstractions and a requirement for prior authorisation of abstraction and impoundment				

Measure (Article 11(3))	**Implemented in Member State (self assessment) – tick if yes**	**Reference to legislation or other document (hyperlink or document)**	**Description of measure (<500 characters)**	**Additional comments or if no, additional explanations (<2000 characters)**
Controls, including a requirement for prior authorisation of artificial recharge or augmentation of groundwater bodies.				
Requirement for prior regulation of point source discharges liable to cause pollution				
Measures to prevent or control the input of pollutants from diffuse sources liable to cause pollution.				
Measures to control any other significant adverse impact on the status of water, and in particular hydromporphological impacts.				
Prohibition of direct discharge of pollutants into groundwater				
Measures to eliminate pollution of surface waters by priority substances and to reduce pollution from other substances that would otherwise prevent the achievement of the objectives laid down in Article 4				
Any measures required to prevent significant losses of pollutants from technical installations and to prevent and/or reduce the impact of accidental pollution incidents				

Table 6a Need for Supplementary/Additional Measures (Article 11(4) and 11(5))

Estimated % of SW bodies (as a proportion of river length/surface area) within the basin that may fail to reach GES/GEP (by 2015)	What is the nature of the pressure that will prevent the water bodies from reaching good status or potential by 2015 (chemical pollution, hydromorphology etc.)	Will the basic measures identified above be sufficient to address this (Y/N)	Comments

Estimated % of GW bodies within the basin that may fail to reach good status (by 2015)	What is the nature of the pressure that will prevent the water bodies from reaching good status or potential by 2015 (chemical pollution, hydromorphology etc.)	Will the basic measures identified above be sufficient to address this (Y/N)	Comments

Table 6b Significant Pressures and Measures Checklist – incl. Supplementary Measures (only to be completed if table 5.a indicates that supplementary measures are required. INFORMATION SHOULD ONLY BE PROVIDED FOR THOSE PRESSURES THAT ARE RELEVANT – IT IS NOT NECESSARY TO PROVIDE INFORMATION FOR THOSE PRESSURES THAT ARE NOT RELEVANT OR WHERE BASIC MEASURES ARE SUFFICIENT) Information can be provided at different levels if required.

Significant Pressure	**Where relevant give details of supplementary measures (Art 11(4)) put in place (including hyperlink)**		**Where relevant give details of additional measures (Art 11(5)) put in place (including hyperlink)**		**Geographic coverage of measure (RBD, part-RBD, Water Body, National etc.)**	**Comments**

Point sources:						
To surface water						
UWWT plants						
Storm overflows						
IPPC plants (EPRTR)						
Other industrial plants outside the IPPC Directive not covered in EPRTR						
Additional point sources (e.g. small agglomerations) that may cause a significant impact in the status of a water body or water bodies						
To groundwater						
Leakages from contaminated sites						
Leakages from waste disposal sites (landfill and agricultural waste disposal)						

[26] Pick list to include: revision of permits; establishment of stricter environmental standards.

Significant Pressure	**Where relevant give details of supplementary measures (Art 11(4)) put in place (including hyperlink)**		**Where relevant give details of additional measures (Art 11(5)) put in place (including hyperlink)**		**Geographic coverage of measure (RBD, part-RBD, Water Body, National etc.)**	**Comments**
	Type of measure (from pick list of Annex VI Part B)	Details including hyperlink	Type of measure (from pick list[26])	Details including hyperlink		
Leakages associated with oil industry infrastructure						
Mine water discharges						
Discharges to ground such as disposal of contaminated water to soakaways						
Other relevant point sources						
Diffuse sources:						
To surface water						
Via storm overflows (if data not available to allow this to be treated as a point source) or the built environment (urban run-off)						
Due to agricultural activities (via leaching, erosion, spills, direct drainage discharges)						
Due to transport and infrastructure without connection to canalisation/sewers (ships, trains, automobiles and airplanes and their respective infrastructures outside the urban area)						
Abandoned industrial sites;						

Significant Pressure	Where relevant give details of supplementary measures (Art 11(4)) put in place (including hyperlink)		Where relevant give details of additional measures (Art 11(5)) put in place (including hyperlink)		Geographic coverage of measure (RBD, part-RBD, Water Body, National etc.)	Comments
	Type of measure (from pick list of Annex VI Part B)	Details including hyperlink	Type of measure (from pick list[26])	Details including hyperlink		
Releases from facilities for the storage and/or treatment of domestic effluent in areas without sewer networks (e.g. leaks from septic tanks etc.)						
Other diffuse sources not listed above						
To groundwater						
Due to agricultural activities (e.g. fertilizer and pesticide use, livestock etc.)						
Due to non-sewered population						
Urban land use						
Water Abstractions:						
From surface water						
Abstractions for irrigation in agriculture						
Abstractions for public water supply						
Abstractions by manufacturing industry						
Abstractions for the production of electricity (cooling)						
Abstractions by fish farms						
Abstractions by hydro-energy (not for cooling)						
Abstractions by quarries/open cast coal sites						

Significant Pressure	**Where relevant give details of supplementary measures (Art 11(4)) put in place (including hyperlink)**		**Where relevant give details of additional measures (Art 11(5)) put in place (including hyperlink)**		**Geographic coverage of measure (RBD, part-RBD, Water Body, National etc.)**	**Comments**
	Type of measure (from pick list of Annex VI Part B)	Details including hyperlink	Type of measure (from pick list[26])	Details including hyperlink		
Abstractions for navigation (e.g. supplying canals)						
Abstraction for water transfer						
Other major abstractions						
From groundwater						
Abstractions for agriculture						
Abstractions for public water supply						
Abstractions by industry: IPPC activities						
Abstractions by industry: Non-IPPC activities						
Abstractions by quarries/open cast coal sites						
Other major abstractions						
Water flow regulations and morphological alterations of surface water						
Water Flow Regulations						
Groundwater re-charge						
Hydroelectric dams						
Water supply reservoirs						
Flood defence dams, dykes and channels						
Diversions						

Significant Pressure	**Where relevant give details of supplementary measures (Art 11(4)) put in place (including hyperlink)**		**Where relevant give details of additional measures (Art 11(5)) put in place (including hyperlink)**		**Geographic coverage of measure (RBD, part-RBD, Water Body, National etc.)**	**Comments**
	Type of measure (from pick list of Annex VI Part B)	Details including hyperlink	Type of measure (from pick list[26])	Details including hyperlink		
Locks						
Weirs						
River management including:						
Physical alteration of channel						
Engineering activities						
Agricultural enhancement						
Fisheries enhancement						
Land infrastructure (road/bridge construction)						
Dredging						
Transitional and coastal water management including:						
Estuarine/coastal dredging						
Marine constructions, shipyards and harbours						
Land reclamation and polders						
Coastal sand suppletion (safety)						
Tidal barrages including those for flood defence and power generation						
Other morphological alterations including:						
Barriers.						
Land sealing in riparian area/zones and flood plains						

Significant Pressure	**Where relevant give details of supplementary measures (Art 11(4)) put in place (including hyperlink)**		**Where relevant give details of additional measures (Art 11(5)) put in place (including hyperlink)**		**Geographic coverage of measure (RBD, part-RBD, Water Body, National etc.)**	**Comments**
	Type of measure (from pick list of Annex VI Part B)	Details including hyperlink	Type of measure (from pick list[26])	Details including hyperlink		
Artificial recharge of groundwater						
Discharges to groundwater for artificial recharge purposes						
Returns of groundwater to GWB from which it was abstracted (e.g. for sand and gravel washing)						
Mine water rebound						
Other major recharges						
Saltwater intrusion of groundwater						
Saltwater intrusion						
Other intrusion						
Other pressures not covered by the list above						

Data on the costs of measures should be provided as detailed in Table 7.

Table 7 Costs of measure (per MS or RBD as available)

Type of measure	**Total cost of measures (€)**	**Comments**
Basic measures (Article 11(3)(a) (Table 1)		
Basic measures (Article 11(3)(b-l) (Table 2)		
Supplementary and additional measures (Article 11(4-5) (Table 3b)		

Note: The figures should be based on readily available administrative budgetary allocations (not private) or alternatively official or informal estimations. The method for estimation is left to the MS. If possible, it should refer to the total costs of the programme of measures during **one** entire RBMP. If not, annual or otherwise aggregated figures can be provided. A pick list should allow classifying the costs (e.g. pick list on methods for calculation, reference years, etc.). Where available, reference to relevant documents should be provided. If it is not possible to provide the costs disaggregated by the type of measure, a total cost should be provided:

- The percentage of water bodies per Sub-unit where each exemption under Article 4(4-7) applies and the main justifications for each exemption and the quality elements concerned;
- Statistics on the water bodies where an exemption applies under Article 4(4-7) and the justification for the exemption (Table 8).

Table 8 Data to be provided on exemptions

Exemption	%age of the total river length/surface area of water bodies in Sub-unit to which exemption applies %age of the total number of GWBs in Sub-unit to which exemption applies	Justification (from a pick list to be defined – multiple selections to be allowed – examples given below)	%age of exempt (by river length/surface area) WBs where this justification applies (total may be above 100%) %age of exempt GWBs where this justification applies (total may be above 100%)	Further comments or explanation
Article 4(4)		1) Technical feasibility 2) disproportionate cost 3) natural conditions	1) x% 2) y% 3) z%	
Article 4(5)		1) Technical feasibility 2) disproportionate cost	1) x% 2) y%	
Article 4(6)		1) Natural causes (a-floods, b-droughts) 2) *Force majeure* 3) Accidents	1) x% 2) y% 3) z%	
Article 4(7)		1) New modifications to physical characteristics of surface water 2) New sustainable human development activities	1) x% 2) y%	

Summary Text

Summary text should be provided for each RBD covering the following items:

- For surface water the methodology and criteria provided in 2005 for identifying the following should be updated:
  - Significant point sources;
  - Significant diffuse sources. Loads (calculated or estimated) of pollutants (nutrients, priority substances, other pollutants, temperature, saline discharges)[27] discharged (total for Sub-unit) if available (**if not provided to the EEA under WISE-SOE reporting**);
  - Significant abstractions;
  - Significant morphological alterations;
  - Other significant pressures.

- For **groundwater** the methodology and criteria provided in 2005 for identifying the following should be updated:
  - Relevant point sources including a list of pollutants discharged to the GWBs from the relevant point sources where thresholds have been established and, where available, an indication of the loads of those pollutants discharged. Loads, if available, (monitored, calculated or estimated) of pollutants (NO3, As, Cd, Pb, Hg, NH4, Cl-, SO4, Trichloroethylene, Tetrachloroethylene) discharged (total for RBD) if not already provided to the EEA under WISE-SoE reporting;
  - Relevant diffuse sources including a list of pollutants discharged to the GWBs in the RBD from the relevant diffuse sources where thresholds have been established and an indication of the loads of those pollutants discharged where available;
  - Relevant abstractions;
  - Relevant artificial recharge;
  - Relevant saltwater intrusions;
  - Other relevant pressures.

- The plan of actions to be put in place to identify any unknown pressures to surface waters or groundwaters;

- The main environmental impacts on **surface waters** occurring in the RBD as a result of significant pressure. This should include the following if appropriate:
  - Nutrient enrichment (at risk of becoming eutrophic) (unless information already provided under UWWTD);
  - Organic enrichment;
  - Contamination by priority substances or other specific pollutants;
  - Contaminated sediments;
  - Acidification;
  - Saline intrusion;
  - Elevated temperatures;
  - Altered habitats as a result of hydromorphological alterations.

[27] Specification of detailed pollutant lists and units when preparing the schemas.

- The methodology and criteria used for identifying significant impacts on **surface waters** should be provided. This should include a description of the following where appropriate:
    - Numerical models;
    - Quantification tools;
    - State assessment tools;
    - Data sources (e.g. whether existing data were used or whether data was collected specifically for the purpose);
    - Expert judgment;
    - Legal status of the assessment criteria;
    - Role of supporting quality elements in the assessment of significance of impacts.
- The main impacts on groundwaters occurring in the RBD as a result of relevant pressures should be provided. This should include the following if appropriate:
    - Anthropogenic alterations of the level of groundwater leading to significant diminution of the ecological and qualitative status of associated surface water bodies;
    - Chemical composition of groundwater leading to significant diminution of the ecological and qualitative status of associated surface water bodies;
    - Anthropogenic alterations of the level of groundwater leading to significant damage to terrestrial ecosystems which depend directly on the GWB;
    - Chemical composition of groundwater leading to significant damage to terrestrial ecosystems which depend directly on the GWB;
    - Altered habitat in dependent surface water or terrestrial ecosystems;
    - Substitution of populations.
- The methodology and characteristics assessed in the further characterisation of GWBs;
- The description of progress to resolve uncertainties and data gaps since 2005;
- A list of uncertainties and data gaps;
- A list of planned actions to address uncertainties and data gaps.

References/Hyperlinks to more detailed supporting documents (e.g. methodology documents, documents provided as part of the public participation, statutes, founding treaty or equivalent legal documents) should be provided for each of the above-mentioned summaries, if available.

8 REPORTING REQUIREMENTS FOR ECONOMIC DATA[28]

8.1 Introduction

Economic Analysis of Water Use

Article 5 of the Water Framework Directive (WFD) requires Member States to undertake an economic analysis of water uses according to the specifications of Annex III. Article 13 and Annex VII requires Member States to send summary reports of the analyses required under Article 5 and Annex II as part of the first river basin management plan.

Annex III of the WFD Directive stipulates that the economic analysis of water uses should contain enough information in sufficient detail (taking account of the costs associated with collection of relevant data) in order to:

- Make the relevant calculations necessary for taking into account the principle of recovery of the costs of water services under Article 9, taking into account long term forecasts of supply and demand for water in the river basin district and where necessary:
  - estimates of the volume, prices and costs associated with water services; and
  - estimates of the relevant investment including forecasts of such investments.
- Make judgements about the most cost-effective combination of measures with respect to water uses to be included in the programme of measures under Article 11 based on estimates of the potential costs of such measures.

The Commission has found that at the time the Article 5 reports were submitted in 2005 the information reported was often not sufficient, taking account of the costs associated with collection of the relevant data, to fulfil these requirements. Several years later additional data may have been collected in order to update the economic analysis and to close the gaps of 2005.

Summary of Steps and Measures Taken to Recover the Costs of Water Services (Article 9)

Article 9 of the Water Framework Directive (WFD) requires that Member States take account of the principle of recovery of the costs of water services, including environmental and resource costs, having regard to the Annex III economic analysis and in accordance with the polluter pays principle.

According to Article 9.1 Member States shall ensure by 2010:

[28] Disclaimer: WFD reporting on economics expressed in this chapter (previously consulted and agreed as Reporting sheets ECO1 and ECO2) represents an informal arrangement between the Member States and the Commission. The information reported is without prejudice to any related infringement procedures.

- That water pricing policies provide adequate incentives for users to use water resource efficiently, and thereby contribute to the environmental objectives of this Directive;
- An adequate contribution of the different water uses, disaggregated into at least industry, households and agriculture, to the recovery of the costs of water services.

Member States have the possibility to account for social, environmental and economic effects in defining pricing policy.

Under Article 9.2 Member States shall report in the river basin management plans on the planned steps towards implementing paragraph 1 that will contribute to achieving the environmental objectives of this Directive and on the contributions made by the various water uses to the recovery of the costs of water services.

According to Article 9.4 Member States can indicate that they will not apply the provisions of Article 9.1, 2nd indent and the relevant parts of Article 9.2 for specific water use activities, if this does not compromise the purposes and achievements of the objectives of the WFD. This paragraph refers to "established practices" meaning at the time of adoption of the WFD in the year 2000. The Member States should report the reasons for doing so in the river basin management plans.

8.2 How will the Commission use the information reported?

The Commission will use this information to ensure that the Member States have carried out an economic analysis consistent with the requirements of Article 5 and Annex III and also that the provisions of Article 9 WFD have been properly and consistently applied according to the Directive. The information will also be used to provide statistics and information on a EU wide level to the European Parliament and the general public. A screening assessment will be made on the basis of the compliance indicators which builds on an approach based on the three main elements of Article 9: i) incentive pricing; ii) adequate cost-recovery; and iii) polluter pays principle.

In addition information on gaps will be collected in order to take further action and to plan future activates in order to support Member States in the further use of Article 9.

The following compliance indicators will be used:

- Have Member States prepared a comprehensive economic analyses including all elements of and being consistent with the Directive? (Possible answers: Yes/No/To a certain extent/Unclear – not sufficient information);
- Where necessary, have estimates of the volume, prices and costs associated with water services been provided;
- Where necessary, have estimates of the relevant investment including forecasts of such investments been provided;
- How has long term forecasts of water supply and water demand been taken into account in the principle of the recovery of the costs of water services;
- Have approaches been identified showing that the economic analysis was used to assist in judging cost effectiveness;

- What progress that has been made since 2005 to address the uncertainties and data gaps in the economic analysis;
- Have Member States have ensured that the measures to implement Article 9 address all three main elements of Art 9: i) incentive pricing; ii) adequate contribution to cost-recovery including environment and resource costs, iii) polluter pays principle. (Possible answers: Yes/No/To a certain extent/Unclear – not sufficient information);
- How has the definition of water services and uses been implemented in practice;
- How water pricing policies provide adequate incentives for users to use water resources efficiently;
- Which approach was taken to ensure that water uses are providing an adequate contribution to the recovery of the costs of water services;
- Whether future plans have been put in place to address any continuing uncertainties and data gaps on the recovery of the costs of water services.

8.3 Information to be provided

Data

Member States should provide the information set out below, where it was included in the economic analysis, for each River Basin:

- Volumes abstracted/discharged per water service;
- Estimated investments for water services[29] in Euro per year (2009 to 2015) or as available for the period;
- Costs of water services (Euro per m3 or other relevant unit), with an indication if environmental and resource costs are included or not and the share they have in the overall costs;
- Level of cost recovery in % per water service;
- Water prices per water service in Euro per m3 or other relevant unit;
- Information relating to measures to comply with Article 9 will be reported as described in Chapter 7, Table 5: Measures for the recovery of cost of water services.

Summary text

In order to better understand the data above, summary text should be provided (max 5000 characters) covering the following items:

- Where relevant, provide a summary of the cases and reasons why estimates on volume, prices and costs of water services and estimates of relevant

[29] Where this information is not collected separately, the aggregated data should be reported and clearly marked as such.

investments including forecasts of such investment were not included in the economic analysis;

- Summary of the methodology (eg aggregation) and assumptions used to estimate the costs of investments for the period 2009 to 2015[30];
- Summary of the methodology (eg aggregation) and assumptions used to estimate the volume, costs and prices associated with water services[31];
- Summary of the methodology used for calculating the cost recovery rate for water services;
- Summary of how the issue of cross-subsidies is handled in cost recovery calculations;
- Approach to estimate the costs of future investments[32], as well as how the baseline scenario has been considered/developed;
- For international RBDs, has there been any coordination of economic analysis? If yes, provide reference. If no, please provide additional explanations;
- For international RBDs, has the judgement of cost effectiveness of measures been coordinated? If yes, provide reference. If no, please provide additional explanations;
- Summary of how the economic analysis has been considered when making judgement about cost effectiveness of measures;
- How has the definition of water services and uses been applied in practice;
- Summary on the planned steps towards implementing Article 9.1 that will contribute to achieving the environmental objectives of this Directive (Article 9.2);
- Summary of how environmental and resource costs were considered and estimated;
- Where applicable, report the reasons for not fully applying paragraph 1, second sentence, to be reported in the River Basin Management Plans (Article 9.4). (This exemption possibility is only possible to apply for "a given water-use activity", so Member States must specify which water uses are considered. It also needs to be transparently explained by Member States that applying the specific exemption does not compromise the purposes and the achievement of the objectives of the Directive);
- How has the Member State ensured that “water-pricing policies provide adequate incentives for users to use water resources efficiently, thereby contributing to the environmental objectives of the Directive” (Article 9.1);

[30] In cases where estimates of the relevant investments including forecasts of such investments were not included in the economic analysis, this item does not apply.

[31] In cases where estimates on volume, prices and costs associated with water services were not included the economic analysis, this item does not apply.

[32] See footnote 30.

- How has the Member State ensured an adequate contribution of the different water uses to the recovery of the costs of water services taking account of the polluter pays principle;
- Any problems encountered in data collection or methodology used;
- Gaps in information identified that could not be closed since 2005 and planned additional data collection to fill gaps for the second implementation cycle.

Other information

- Hyperlinks to more detailed supporting documents including references to legal documents or methodology documents should be provided.

9 HOW TO REPORT

9.1 What is WISE?

The Water Information System for Europe – WISE – is comprised of data and information collected at EU level by various institutions or bodies which has previously either not been available or been stored in a number of different places. There are four EU partners developing WISE: DGs Environment, JRC and Eurostat, and EEA.

The WISE project started in 2002 and in 2003 a report on "Reporting for Water – Concept Document: towards a shared Water Information System for Europe (WISE)" defined the overall concepts of WISE which was endorsed by the Water Directors under the Italian Presidency in November 2003.[33]. The paper identified the following core objective:

"…the European Commission (DG ENV, Eurostat and JRC) and the EEA are committed to continue the development of a ***new, comprehensive and shared European data and information management system for water****, including river basins, following a participatory approach towards the Member States, in order to have it operational as soon as possible and to implement it, including all the various elements set out in this document,* ***by 2010****.*

Member States have agreed to provide data under the WFD to WISE. Rules and Procedures to do this have been agreed[34].

9.2 Reporting into WISE

The EEA has a central role in the management of WISE due to its role as EU data centre for water. The reporting services (Reportnet) of the EEA will be used and further developed towards the needs of WISE. The EEA is acting as a WISE operator (with the assistance of DGs Environment, JRC and Eurostat) and is responsible for the provision and operation of the WISE infrastructure at EU level.

The right to upload information and data for official compliance reporting needs to be thoroughly regulated and implemented. There will be a limited number of officially nominated individuals with the rights to submit, update and validate data on behalf of a Member State. The European Commission (DG Environment, unit D.2) will forward the list of the authorised WISE data providers to the EEA which is the responsible body for managing the access rights through Reportnet[35]. The EEA – through the WISE helpdesk - will contact the authorised WISE data providers to provide a

FOREWORD

The EU Member States, Norway and the European Commission in 2000 have jointly developed a common strategy for implementing Directive 2000/60/EC establishing a framework for Community action in the field of water policy (the Water Framework Directive). The main aim of this strategy is to allow a coherent and harmonious implementation of this Directive. Focus is on methodological questions related to a common understanding of the technical and scientific implications of the Directive.

One of the main objectives of the strategy is the development of non-legally binding and practical Guidance Documents on various technical issues of the EU water policy. These guidance Documents are targeted to those experts who are directly or indirectly implementing the WFD in the river basins. The structure, presentation and terminology are therefore adapted to the needs of these experts and formal, legalistic language is avoided wherever possible.

In the context of the above mentioned strategy, a working group dedicated to the development of technical specifications for implementing a Geographical Information System (GIS) for the reporting needs of the Water Framework Directive was established in 2001 under the coordination of the Joint Research Centre. The working group, with the support of most Member States, the Commission, Eurostat and the EEA produced Guidance Document no 9 Implementing the Geographical Information System Elements (GIS) of the Water Framework Directive, which was published in 2003.[1]

Since then, significant changes have been made to the way in which data and geographic information are gathered, reported and shared at the European level and these made it necessary for the Guidance Document to be updated and extended to the needs for EU water legislation and electronic reporting within Water Information System for Europe (WISE). A Drafting Group under the auspices of the WISE Technical Group carried out this task starting in 2007, including a number of consultations with the experts from the Member States through GIS workshops (held in January and November 2008) and via working group on reporting (WG D under CIS) and Strategic Coordination Group. In 2008, an updated WISE GIS Guidance Document was presented to the Water Directors for their approval and endorsement.

We, the Water Directors of the European Union and Norway, have examined and endorsed this updated guidance during our informal meeting under the French Presidency in Paris (24-25 November 2008). We would like to thank the Drafting Group for producing the update and we strongly believe that this and other Guidance Documents developed under the Common Implementation Strategy play a key role in the process of implementing the Water Framework Directive.

We also commit ourselves to assess and decide upon the necessity for reviewing this Guidance Document in the future based on experiences gained during continued implementation of the Water Framework Directive and other water policies of the European Union.

LIST OF TABLES

LIST OF FIGURES

1 Introduction

The EU Member States, Norway and the European Commission have jointly developed and followed a common strategy for supporting the implementation of Directive 2000/60/EC establishing a framework for Community action in the field of water policy (the Water Framework Directive – WFD). The main aim of the strategy is to allow a coherent and harmonious implementation of the Directive based on common understandings of the technical and scientific implications of the Directive.

One of the important tools to bring about the common understanding is the development of practical Guidance Documents on various technical issues. In this context, the development of technical specifications for implementing a Geographical Information System (GIS) for the reporting needs of the WFD was begun in 2001 by a working group of representatives of most Member States and the European Institutions under the coordination of the Joint Research Centre. At their meeting under the Danish Presidency (21-22 November 2002) the Water Directors of the EU endorsed the GIS Guidance (Guidance Document No 9)[2] which was published the following year.

After the GIS Guidance was published in 2003, a number of reporting exercises under the WFD and other water directives took place and significant improvements were made to the way in which data and geographic information were to be gathered, reported and shared at the European level.

In 2003, a report on "Reporting for water – Concept document: towards a shared Water Information System for Europe (WISE)" defined the overall concept of WISE which was endorsed by the Water Directors under the Italian Presidency in November 2003[3]. The WFD introduced a new approach to information and data collection and reporting, providing a more streamlined reporting process and a clearer distinction between the needs of different actors and different levels. WISE was to be the system that provided the streamlining and clarity. WISE had to be flexible, easy to be updated, manageable in terms of human resources and descriptive, in that textual information, data, documents, metadata, figures, graphs, maps etc, had all to be incorporated.

In July 2004, DG Environment submitted a proposal for a directive aimed at the introduction of a European spatial data infrastructure (INSPIRE) to encourage harmonisation of geographic data and information exchange leading to streamlined reporting and the common use of geographic information for different environmental policy areas. The directive 2007/2/EC establishing an Infrastructure for Spatial Information in the European Community (INSPIRE) entered into force on 15 May 2007[4].

In October 2005, the Environmental Policy Review Group published a vision on reporting and monitoring around the concept of a Shared Environmental Information System (SEIS)[5].

[5] http://ec.europa.eu/environment/seis/index.htm

In order to improve access to environmental information and the availability of reports, the European Commission (DG Environment, Joint Research Centre and Eurostat) and the European Environment Agency (so called Group of Four, Go4) on 24 November 2006 endorsed the WISE Implementation Plan for 2006-2010[6]. On 22 March 2007, the official launch of the public WISE map viewer as "a gateway to water" at the European level took place[7]. WISE serves as a pilot for implementing the INSPIRE directive and the SEIS initiative, and currently is still at its formative phase, developing an electronic data and information system on water that will serve as an exemplar for other environmental sectors.

Following the Common Implementation Strategy for the WFD, streamlining the reporting process for all EU water sector directives (Urban Waste Water Treatment, Nitrates, Bathing Waters and Drinking Water Directives[8]) intensively started in 2007. Other newly adopted (such as the Groundwater Directive[9] and Marine Strategy Directive[10]) and upcoming directives (such as the Directive on Environmental Quality Standards in the field of water policy[11]) will follow the process of the Common Implementation Strategy as regards reporting information on water at the EU level during 2008-2015.

These major steps in the evolution of a system to improve the flow of information, to avoid duplication and to reduce the burden on Member States are described in more detail in Chapter 1.2.

1.1 Purpose of the Guidance

This document aims at guiding experts and stakeholders in the implementation of the Water Framework Directive (WFD) (2000/60/EC) and focuses on the GIS elements which will contribute to the development and understanding of all EU water related GIS reporting requirements under all water directives, as described above, including the River Basin Management Plans as required under Article 13 of the WFD by March 2010 and the revision of reporting arrangements for other water policy areas.

The original GIS Guidance (see above) required updating because of the many changes brought about by the development of the WISE, the practical experience gained from the first 4-5 years of the implementation of the WFD, the technical evolution and the need to adapt to new requirements of SEIS and INSPIRE.

The WISE Steering Group requested members of the WISE Technical Group to do the update during 2007-2008. The WISE GIS community were consulted on the drafts and their comments taken into account. The Guidance is intended not only for those who are responsible for reporting the national information but for those who use and develop it at national and European levels.

The purpose of updating the Guidance is to support the development of WISE by providing guidelines and technical specifications, IT tools, services and digital

[6] http://ec.europa.eu/environment/water/water-framework/transp_rep/pdf/wise_ip_2006_2010.pdf

[8] http://ec.europa.eu/environment/water/index_en.htm
[9] http://ec.europa.eu/environment/water/water-framework/groundwater/policy/current_framework/index_en.htm
[10] http://ec.europa.eu/environment/water/marine/index_en.htm
[11] http://ec.europa.eu/environment/water/water-dangersub/surface_water.htm

resources to be used by the data providers and WISE developers to ensure satisfaction and availability of water information at the European level for the users.

The revised Guidance is divided into two parts. The first is a set of textual documents describing the general concepts of the GIS requirements in WISE for the WFD and other EU water policy legislation, the types of WISE GIS datasets and the ways in which they are visualised and the principles of compatibility and interoperability. The second part is a set of documents which give more specific, technical details for data specifications, metadata, reference datasets, updating, coding, data exchange and harmonisation. In addition there are a number of Appendices to support and explain the Guidance and a link is provided to digital resources such as XML schemas[12]. The Appendices are living documents in the sense that when new GI layers have been specified, the details will be added to the web-based versions.

1.2 Development of WISE via implementing WFD and other EU-wide reporting on water

The following Chapters describe how WISE has grown in size and technical complexity as the reporting obligations under WISE evolve in accordance with the timetable in the directive and the schedule unfolds for incorporating reporting under other EU water directives. In addition the geographical scope and data content of WISE has increased as the EEA SoE reporting agreements with its member countries becomes fully incorporated.

1.2.1 Developing reporting obligations under WFD

The Water Directors of the European Community and Norway, at an informal meeting in Paris 23-24 October 2000, identified the following elements (*inter alia*) of a Common Implementation Strategy for the WFD[13]:

- The necessity to share information between Member States and the Commission;
- The need to ensure coherence between the implementation of the WFD and other sectoral and structural policies;
- The need to ensure coherence between the implementation of the WFD and other water directives and process and product oriented directives;
- The need to integrate activities on different horizontal issues for the effective development of River Basin Management Plan;
- The need to establish working groups and develop informal guiding and supporting documents on key aspects of the WFD.

During 2003, a Reporting for Water Concept Paper was produced and endorsed by the Water Directors in November 2003. This laid down the various purposes of reporting, i.e. to satisfy the various mandatory and voluntary information needs of the European Commission (in particular DG Environment, DG Eurostat, DG Joint Research Centre, the European Environment Agency and the Commissions and Conventions covering

[12] http://water.eionet.europa.eu/schemas/dir200060ec
[13] http://ec.europa.eu/environment/water/water-framework/objectives/implementation_en.htm

large international rivers and European marine waters). It also described a common vision for information and data sharing and gave the principles for a shared Community data and information management system (the precursor to WISE). The paper identified the need for coherence between the reporting mechanisms and proposed the WFD as a platform for streamlining.

Since 2003, Working Group D (Reporting) has shaped the agenda for reporting under the WISE and has developed the reporting requirements, in the form of Reporting Sheets, for Articles 3 (2004), 5 (2005), 8 (2007) and 13 (2010) of the WFD. The Reporting Sheets, which may be considered as the conceptual models for specific reporting needs, are developed, debated and agreed within the Working Group and the Strategic Coordination Group before formal endorsement by the Water Directors.

Information has already been provided by the Member States for the first three of these reporting requirements and initial compliance assessments have been made for the first two. The reporting exercise for Article 8 (Monitoring Programmes) was the first fully electronic reporting exercise for the WFD and was a great success in terms of streamlining and facilitating reporting. The initial compliance assessment also indicated that good progress had been made and a more detailed assessment is currently underway.

Following agreement on the Reporting Sheets for the River Basin Management Plans, (Article 13), the Reporting Sheets for Articles 3 and 5 were fully reviewed and revised. It is the Commission’s intention to provide a consolidated Reporting Guidance document containing all the Reporting Sheets for the WFD and this is scheduled for approval by the Water directors in November 2008.

The relationship between the Reporting Sheets for WFD Articles 3, 5 and 13 is shown in Figure 1.2.1a (The Reporting Sheets for Article 8 may be considered to be a separate, but interlinked, series).

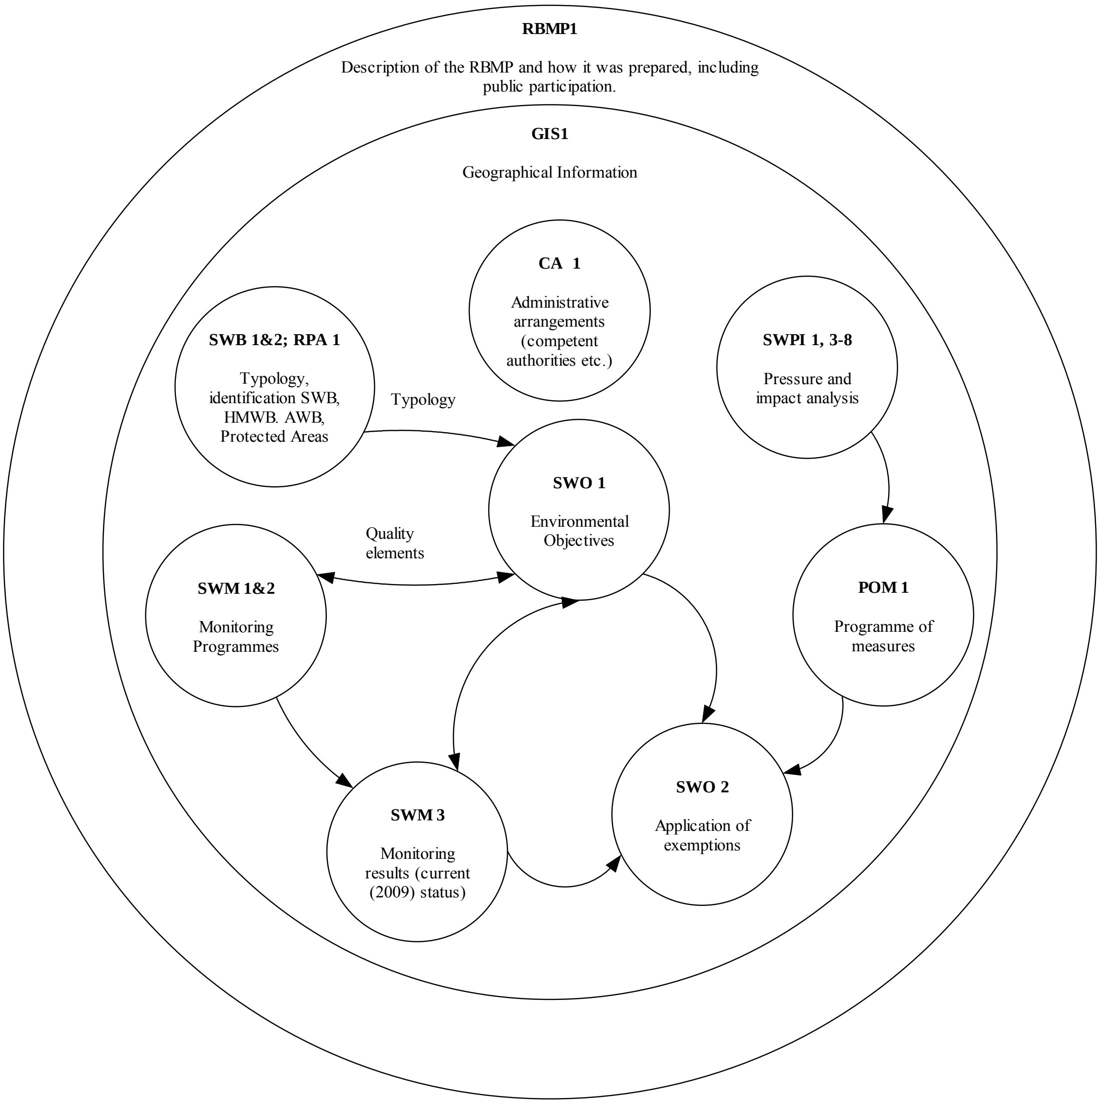

***Figure 1.2.1a Relationship between the WFD Reporting Sheets** (for surface waters only, relationship with groundwaters is virtually the same)*

Following the review, a new, generic Reporting Sheet (GIS 1) was developed to cover all the geographical information requirements for Articles 3, 5, 8 and 13.

Reporting Sheets are converted to logical models and reporting tools in the form of XML schemas which are handled by the Reportnet input tools of the WISE. The new Reporting Guidance will be tested in 2009 in good time for operational use in 2010. The WISE data flows are shown schematically in Figure 1.2.1b. A review period may follow the production of reference datasets.

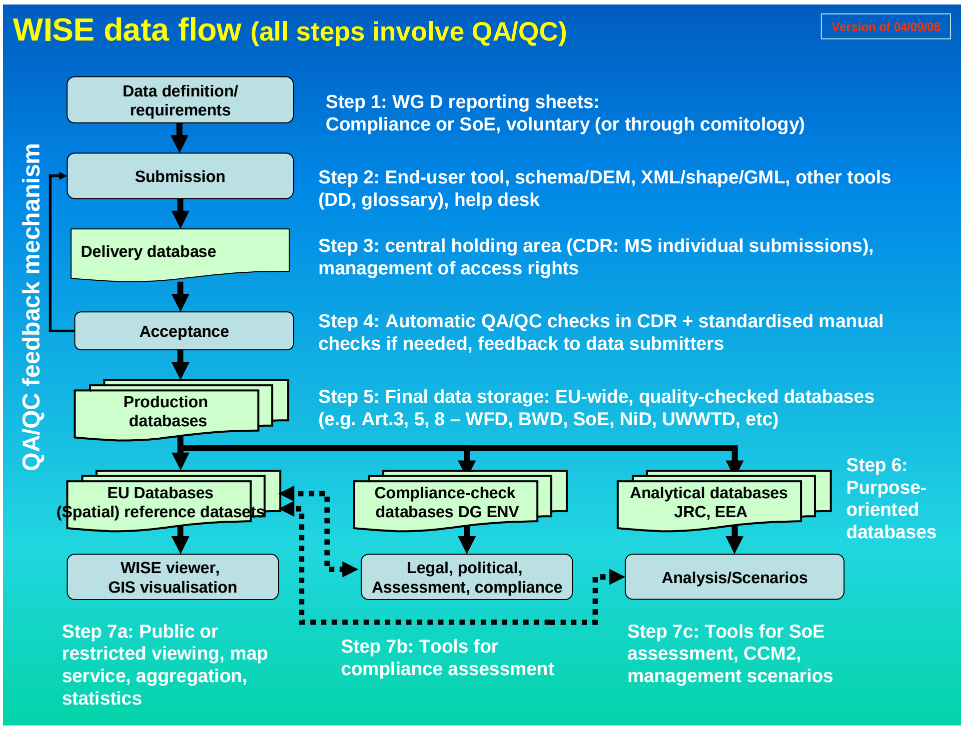

Figure 1.2.1b WISE Data flows

1.2.2 WISE – a system constantly expanding

In 2008, a communication from the Commission to the Council, European Parliament and others (COM(2008) 46 final) laid down the needs for, principles of, costs and benefits of and actions put in place for the Shared Environmental Information System (SEIS). Some of the key principles are:

- Information should be managed as close as possible to its source;
- Information should be collected once and shared with others for many purposes;
- Information should be readily available to public authorities and enable them easily to fulfil their legal reporting obligations;
- Information should be readily accessible to end-users ….. to enable them to assess in a timely fashion the state of the environment and the effectiveness of their policies and to design new policy;
- Information should also be accessible to enable end-users …… to make comparisons at the appropriate geographical scale.

At a horizontal level the INSPIRE Directive (2007/2/EC) establishing an infrastructure for spatial information in Europe entered into force in May 2007.[14] It contains provisions aiming to improve the accessibility and interoperability of spatial data. INSPIRE is based on similar principles to SEIS. Its successful implementation will go a long way towards overcoming existing inefficiencies relating to the usability and use of spatial data stored by public authorities. It is important to recognise,

[14] http://inspire.jrc.ec.europa.eu/

however, that INSPIRE will not directly address data of a non-spatial or non-numerical nature or documents, it will not by itself constitute an integrated e-reporting system related to EU environmental legislation, and will not lead directly to an improvement in the quality and comparability of data. The updated Guidance recognises that the GIS component of WISE will be a building block of the European Spatial Data Infrastructure and will be compliant with the requirements of INSPIRE.

The Global Monitoring for Environmental Security (GMES)[15] initiative aims to provide operational information services based on Earth monitoring data obtained from satellites and *in-situ* observations on water, air and land.

An integrated platform that can link all these initiatives into a shared and common system is required and SEIS aims to provide that function. With the help of Member States this new system will modernise the production, exchange and use of environmental data and information based on the latest information technology.

WISE is seen as the water pillar of SEIS. Although originally designed as a reporting tool in the context of the WFD, WISE is now being extended to integrate reporting data flows from a number of existing and upcoming water-related directives as well as water relevant statistical data. Furthermore, WISE not only relates to the reporting flow but also covers the aspect of information visualisation and dissemination through the WISE map viewer. The overall scale of WISE is shown in the following figure (Figure 1.2.2).

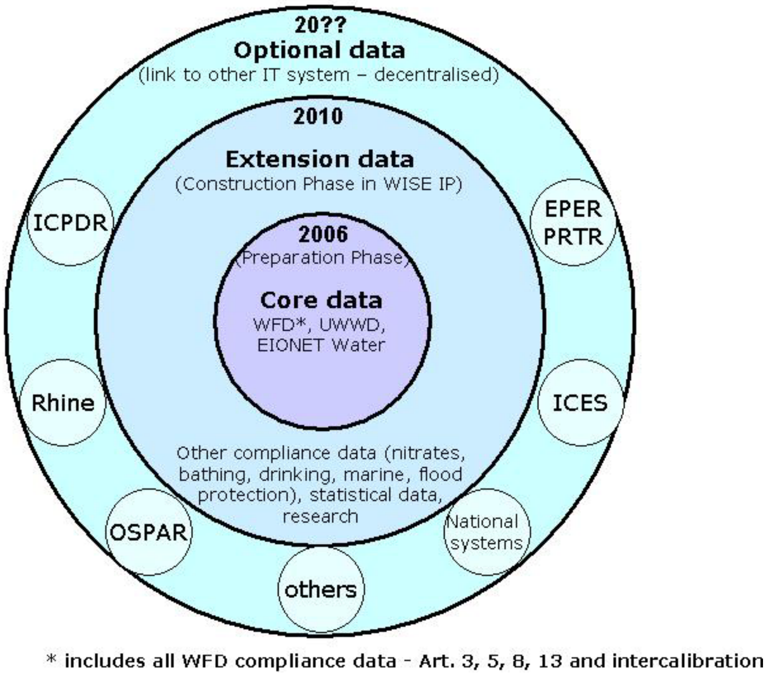

Figure 1.2.2 Planned expansion of WISE

The annual EC Bathing Water Report for the 2007 bathing season (based on Member State submissions under the Bathing Waters Directive) was made available in WISE

---

[15] http://www.gmes.info/

map viewer in June 2008[16]. A further extension of the functionality was realised in July 2008, when EEA and Microsoft launched a new environmental information portal 'Eye on Earth', displaying the latest information on the water quality in bathing sites across Europe. Through its first application, 'Water Watch', the new portal allows users to rate beaches and to share their comments with others[17].

For the Nitrates Directive, the reporting process through WISE takes place in 2008 and by 2010 should be streamlined with the State of the Environment Reporting (for the EEA via the Eionet). The Reporting Sheets for the Drinking Water Directive were agreed in 2007 and the IT formats are currently being implemented into WISE with the objective reporting through WISE and visualisation of information in 2009.

The Urban Waste Water Treatment Directive (UWWTD) was reported in 2007 and improvements are underway in time for the next reporting cycle in 2009 to use Reportnet as a single entry point of information for WISE. Visualisation of reported data under UWWTD in WISE is already also available through WISE viewer.

Streamlining of reporting on the UWWTD and the requirements for the joint Eurostat/OECD Joint Questionnaire on Inland Waters (JQ-IW) is also being discussed in 2007 by the institutions (Eurostat and DG Environment) and Member States (national contact points on water statistics) and took part in 2008 by aggregating reported data for UWWTD (during the last reporting exercise) to the Member State level and pre-filling this JQ-IW. This process will be further developed in the frame of WISE by making the process more automatic.

The EEA's water data gathering system (Eionet-Water) from its Member Countries (considerably larger than the EU27) has been integrated with WISE and is now called WISE State of the Environment reporting (WISE-SoE). It is based on the Eionet and also has a planned expansion to meet the reporting ambitions of the EEA which is increasingly based on indicators.

In terms of new water policy, the reporting requirements of the Floods Directive have been described in a Floods Reporting Concept Paper and draft Reporting sheets have been produced to meet the needs of the Groundwater Directive. The concept of development WISE –marine part is also under way, and will find its place and the solution in a frame of WISE and other activities related to the marine issues within upcoming few years, with the first deadline on data reporting under the marine strategy directive being in 2010.

The Implementation Plan of WISE[18] describes this progressive expansion and the system design has to be flexible to accommodate the step by step changes.

The WISE is hosted, managed and maintained by the EEA in its capacity as the Water Data Centre based on an agreement between EEA, DG Environment, Eurostat and the Joint Research Centre. Ultimately WISE will be a distributed system and proposals have been made for the design and implementation of the distributed architecture of WISE that take account of INSPIRE guidelines and that the architecture has to be feasible with open source software. The proposed architecture makes a number of

[16] http://ec.europa.eu/environment/water/water-bathing/report_2008.html and http://www.eea.europa.eu/themes/water/status-and-monitoring/state-of-bathing-water
[17] http://www.eea.europa.eu/highlights/heading-for-your-favourite-beach-is-the-bathing-water-clean
[18] http://ec.europa.eu/environment/water/water-framework/transp_rep/pdf/wise_ip_2006_2010.pdf

assumptions: that data from the Member States should be available by both "push" and "pull"; more than one version or format of schemas can be handled; the system is backward-compatible; and countries can use the "old-style" of reporting if they wish. The definition of the service layers is relatively easy but the challenge will be in bringing together different services from all EU Member States and EEA Member Countries. Over the next 2-3 years, a number of Member States/Countries will cooperate with the EEA in exploring the technical options of how to bring that about.

1.2.3 Lessons learned from the first 4 years of WFD implementation

A number of lessons have been learned and these can be divided into five different areas as follows:

(i) The *usage of the WISE portal for reporting data* falls into two phases. In a first phase, the WISE reporting prototype at the JRC was used to store reported data on WFD Articles 3 and 5. While the data reported was stored and a certain level of quality assurance was performed, no European datasets were built at that stage. In a second phase, the reporting of data in accordance with WFD Article 8 and the hand-over of all reported data to the EEA which assumed the responsibility for managing the data marked a major change in procedures. A full quality assurance process was established for Article 8 and the first European datasets were established. Also, the production of GIS reference datasets from the Article 3 submissions on River Basin Districts has begun and, following consultation with Member States, the objective is to have an EU-wide harmonised reference dataset. The reporting as such was moved to the Reportnet system in order to have a common approach across environmental directives, and to use Reportnet as a common data entry point for reporting on water. In a later stage, most probably by 2015, when the reporting formats and data specifications will be in place and fully operational, WISE could be described as a shared and distributed system completely implementing initiative of SEIS.

(ii) In assessing the experiences with *agreed vs voluntary contributions of information* from Member States, the picture is fragmented. Reporting can be regarded as an evolutionary process where experiences have to be collected on both sides: those that do the reporting and those that receive the reports. The history of the Article 3 reporting shows that quality has been improved with the resubmission of data in a second phase. Article 5 data quality, where no resubmission has yet been initialised, suffers from various, non-matching interpretations of the reporting requirements by Member States resulting in heterogeneous data quality and quantity. Also to be taken into account is the improvement of technology e.g. the maturing of GIS systems during the past years which has improved the ability of the Member States to deliver better quality data, as well as making more clear guidelines to harmonise on the technical formats and requirements to report information (in the sense of tabular/point data as well as geographical information) in a uniform way.

(iii) The process of *validating and harmonising data from Member States* has begun with the on-going production of GIS reference datasets. This is a huge task and the available resources on the EU side and on Member States side are not always sufficient enough to lead to a timely production of quality data products. The experiences from the initial years of the WFD reporting are very useful to guide the process on the upcoming Article 13 reporting, which is of key importance in terms of implementing the WFD with a sound data and information base. This process is also serving as a guiding line on reporting and data visualisation process for other EU water directives.

(iv) The *experiences of handling resubmissions of data*, derived from the Article 3 resubmissions, show that this is an important way of improving data availability and data quality. Therefore the opportunity of improving Article 3 and in particular Article 5 data in conjunction with the Article 13 reporting will be strongly recommended. The Article 3, 5 and 13 Reporting Sheets are being amalgamated into a single consolidated Guidance and the associated XML schemas are being streamlined to avoid duplication and reduce the reporting burden on Member States. Also, Article 8 data, which is seen to be especially dynamic (changeable), will be subject to periodical updates. This is an area in which new technologies and distributed system architectures will be initially explored and applied.

(v) The *experience of provision of updated information* is derived from the fact that the Article 3, 5 and 8 data were submitted over a span of years and designed to be interlinked for the purpose of reducing duplication of reporting. The experience has shown that information inevitably changes over even a short time period and the management of versioned submissions is crucial for the correct processing and interpretation of data.

1.3 Terminology and abbreviations

Ambiguity in terms may easily evolve in a period where several related processes are taking place simultaneously in the domain of spatial data infrastructures. It has not been the intention with this document to come up with new definitions of concepts, rather we have strived for alignment with the terminology applied by INSPIRE working groups in order to improve transparency. A part of the INSPIRE terminology has been developed through the elaboration of documents from the INSPIRE Drafting team "Data Definition". The terminology may however continue to evolve until the INSPIRE process deliver a final glossary to be available from http://www.ec-gis.org/inspire/.

A wider glossary of terms can be found in Appendix 14.

1.3.1 Terminology

In order to avoid ambiguity in terms, it is important to note that the following terminology will be used throughout this document:

Code:

A rule for converting a piece of information (for example the confluence of rivers) into another form or representation, not necessarily of the same sort.

> **A**: a representation of information in a shorter alphanumerical form**.**
>
> EXAMPLE: the two letter ISO 3166 Country code (e.g. DE for Germany); acronyms and abbreviations; ASCII code.
>
> **B:** identifiers with a certain logic for which more than just the simple identification relationship can be derived.
>
> EXAMPLE: Hydrological feature code - A Pfaffstetter code describes the relative position of a river in a river network (see Chapter 5.4).

Feature:

Abstraction of real world phenomena [ISO 19101]. In this document synonymous with spatial object. Unfortunately "spatial object" is also used in the ISO 19100 series of International Standards, however with a different meaning: a spatial object in the ISO 19100 series is a spatial geometry or topology.

Feature type:

Classification of **features**.

> EXAMPLE Cadastral parcel, road segment or river basin are all examples of potential feature types.
>
> NOTE In the conceptual schema language UML a spatial object type will be described by a class with stereotype <<FeatureType>>.

GIS layer:

Identifiable collection of spatial data produced according to a data product specification, used synonymously with the "spatial data set".

Identifier:

Linguistically independent sequence of characters capable of uniquely and permanently identifying that with which it is associated (ISO 19135).

Map:

A graphical representation of a section of the Earth's surface. The Water Framework Directive refers to a number of maps, each one with a specific thematic content – a spatial data set (e.g. a map of the River Basin Districts). A map can be made up of one or many GIS layers. Using GIS software, maps can be presented in digital form from which an analogue map can be plotted.

Object:

in this document used as a generic term for abstractions, often represented as either tables or features.

River basin:

The area of land from which all surface run-off flows through a sequence of streams, rivers and, possibly, lakes into the sea at a single river mouth, estuary or delta. (Definition from WFD). A river basin may include sub-basins.

River basin district:

The area of land and sea, made up of one or more neighbouring river basins together with their associated groundwaters and coastal waters, which is identified under Article 3(1) as the main unit for management of river basins. (Definition from WFD).

River sub-basin:

The area of land from which all surface run-off flows through a series of streams, rivers and, possibly, lakes to a particular point in a water course (normally a lake or a river confluence). (Definition from WFD).

Table:

Most software systems require the organisation of datasets in one or more tables. In order to make information comparable between organisations, the structure of these tables must be similar. (Definition fromWFD GIS Guidance).

WISE Reference GIS dataset:

Dataset which provides a comparable basis for visualisation or assessment of geo-referenced data across Europe (for more details see Chapter 3.1).

CONCEPTUAL CHAPTERS

2 GIS in WISE: developing a common understanding

2.1 Scope of GIS Guidance and purpose of GIS in WISE

This Chapter introduces the general basis for the detailed specifications which are described in the following Chapters. It reflects the common understanding of the Working Group experts (and others) on the purpose and the structure of the GIS elements to be developed as a basis for the reporting obligations under the water policy domain. A common understanding is an essential pre-requisite for a consistent approach to the reporting of spatial information and it had to be achieved on issues such as the contents of the various maps, the scale and positional accuracy of the data, and the reference system and projections to use. Given the fact that the various GIS layers at national or River Basin District level will be part of a European picture, it was necessary to consider issues such as the harmonisation at boundaries and the use of common identifiers. Recommendations are given on the standards to be implemented for data exchange and data access and on the content and structure of the metadata to accompany each layer.

Technical possibilities nowadays allow the required GIS layers to be provided in two different ways. One option is to transfer them into a centralised system, where they will be stored, quality checked and analysed. The other option is to leave them at their place of origin (i.e. to store the data sets locally in each River Basin District or at national level) and to guarantee broad access to these data through common standards and protocols. While the first option is easier to implement and has been pursued as a short-term objective, the second option will reduce the burden of transferring data and the longer-term objective is for the set-up of a decentralised or distributed system and work is currently in progress on that.

In a more general context, it should also be noted that information, consultation and participation are requirements of the Directive, since they will ensure a more efficient and effective implementation. The *Guidance on Public Participation*[19] provides more detail about these forms of participation. In particular WFD Article 14 promotes the active participation of all interested parties in the development of River Basin Management Plans and requires Member States to inform and consult the public. The latter can most efficiently be done through maps, GIS technology and web mapping.

2.1.1 GIS guidance – a necessity for streamlining reporting

Building on the common understanding, further consistency is achieved through the processes of the Common Implementation Strategy where the conceptual aspects of reporting are described in the WFD Reporting Concept report which was developed and agreed by Working Group D (Reporting) and the Strategic Coordination Group (SCG) and endorsed by the Water Directors on behalf of the EU Member States. Detailed specifications were then drafted in the form of Reporting Sheets by a Drafting Group of Working Group D and subsequently discussed and agreed by the main Working Group and the SCG with final endorsement by the Water Directors. The Reporting Sheets were converted into XML Schemas (or other Reportnet tools) which were used by the Member States for their formal reporting to WISE.

[19] http://circa.europa.eu/Public/irc/env/wfd/library?l=/framework_directive/guidance_documents/guidancesnos8spublicspar/_EN_1.0_&a=d

For the reasons explained in Chapter 1.2.1 it has become necessary to re-assess Reporting Sheets for reporting the information required under WFD Articles 3 and 5 that were developed over a number of years, in accordance with the reporting deadlines, and to streamline and update them while the reporting for Article 13 (River Basin Management Plans) is under consideration. The task is to produce a streamlined, consolidated Reporting Guidance to Member States (and other WISE users) and gain the endorsement of the Water Directors by the end of 2008. Contemporaneous with this, the XML schemas for Article 13 reporting will be streamlined to allow Article 3 and 5 information to be resubmitted if it is out of date (in accordance with Article 3.9 and Article 5.2) while recognising that if RBMP information has been reported under other directives (see Chapter 1.2.2), it need not be reported again. The aim is to eliminate duplication and achieve the objective of "report once, use many times".

2.1.2 The role of GIS in WISE

Even though only Annex I (Competent Authorities) and Annex II (Surface Waters) of the WFD explicitly state that the respective maps should as far as possible be available for introduction into a GIS, it is obvious that the best way to provide most of the requested information will be in the form of GIS layers. This is due to the fact that most of the data is to be presented in its spatial context and that questions like 'where are the critical areas?', 'how much area is involved?', or 'which points are in a designated area?' can easily be answered when the data are kept in their spatial context and when the background database has the appropriate design.

The provision of (or access to) the requested GIS layers will not only facilitate reporting by the Member States themselves; it will also facilitate the further compilation and analysis of the information as a basis for the Commission's own reporting obligations under the WFD in accordance with the requirements of Article 18. Such development is also in line with current efforts under the INSPIRE (Infrastructure for Spatial Information in Europe) initiative of the Commission and the Member States, aiming at the development of a harmonised European spatial data infrastructure (see Chapter 1.2.2). Many parties are involved in the implementation of the WFD, ranging from local water authorities to the European Commission. Regarding this wide range of parties, having different practices for water management, different reporting obligations and different levels of technical abilities, this Guidance Document strives to keep specifications as simple as possible, based upon standards where feasible, and according to best current technical options.

The agreed Reporting sheets for WFD (Articles 3, 5, 8 and 15) require that Member States report a considerable amount of information in the form of spatial data. This is especially so for the reporting of the River Basin Management Plans where the results of the surface water monitoring programmes have to be reported to enable the following maps to be produced:

- Map 1: Ecological status class of natural water bodies;
- Map 2: Ecological potential class for Heavily Modified Water Bodies;
- Map 3: Status for Protected Areas;

- Maps 4-8: Achievement or exceedance of Environmental Quality Standards for heavy metals; pesticides; industrial pollutants; other pollutants (all from the list of Priority Substances) and, other (national) pollutants.

For groundwater bodies, (or group of Groundwater Bodies), Member States are required to provide the information necessary to produce the following maps:

- Map 1: Achievement/exceedance of good quantitative status;
- Map 2: Achievement/exceedance of good chemical status for nitrates;
- Map 3: Achievement/exceedance of good chemical status for pesticides;
- Map 4: Achievement/exceedance of good chemical status based on national thresholds for other pollutants;
- Map 5: Identification of Groundwater bodies where a significant and sustained upward trend (notifying the relevant substances) has been identified.

The implementation of the WFD therefore requires the handling of spatial data both for the preparation of the River Basin Management Plans and for the reporting to the Commission. In the first case GIS techniques will be essential for the derivation of various information layers (e.g. on the characteristics of river basins and water bodies, on the chemical and ecological status of water bodies and potentials of various management measures), while in the second case GIS will be the tool for the preparation and delivery of the GIS layers required for the reporting.

2.1.3 Member State GIS submissions and WISE Reference GIS datasets

There are two main types of spatial datasets involved in WISE:

- Spatial data submitted by MS according to Directives:
  - Named by the Directive e.g. “WFD River Basin Districts”.
- WISE Reference GIS datasets:
  - Aggregated from MS submissions;
  - Prenfix “WISE” e.g. “WISE River Basin Districts”.

The basic concepts for the GIS layers are as follows:

- All the GIS layers described in this guidance are vector data (point, line or polygon datasets);
- The WISE GIS reference layers are made available through WISE;
- All GIS layers will have associated attribute information which can be accessed as required or used to derive maps;
- In certain circumstances WISE layers are to be made available for download;
- It is the responsibility of the Member States to collect and compile GIS layers conforming to requested precision, quality and content for use within WISE under an agreed format (developed/clarified through recommended guidance for each layer), including metadata and data IT formats to ensure that an EU-wide harmonised layer will be available in WISE;

- It is the responsibility of the EEA and/or third parties to compile and maintain Reference, Background and External GIS layers within WISE;
- It is recognised that for data collection an input scale of 1:250,000 or better should be a common goal;
- All data will be harmonised to enable analysis and subsequent dissemination at the European level using WISE Water Reference and Background / External datasets (which should be provided by the Member States under agreed technical/IT formats).
- It should be noted that a map derived from GIS layers relating to datasets in WISE (e.g. a map of ecological potential) is not a GIS layer in itself as it is based on the attribution of one or more other layers, and is transient over time as that attribution changes or the rules for creating the map change.

2.2 GIS data requested from Member States under WISE

The reporting of spatial information under the water-related directives function as a reference frame for other documentation of the implementation of the directives. The form of reporting has, as a consequence of the Common Implementation Strategy, shifted from specific map products into spatial data that may be further processed in a GIS environment. The table below (Table 2.2) provides an overview of the data layers that have currently been defined and requested for the water-related directives and voluntary agreements.

Table 2.2 is provided as an overview; details can be found in subsequent Chapters, in particular Chapter 5.2 and Appendices 05 and 06.

Table 2.2 Overview of GIS data requested from Member States

Policy area	Feature group	Data layers
WFD	Management units	River Basin Districts
		Sub-units
		Competent Authorities
		Water bodies categorised by: Lake, River, Transitional, Coastal, and Groundwater
		Drinking water protected areas
		Economically significant aquatic species protected areas
		Recreational waters protected areas

		Nutrient-sensitive protected areas
		Habitats protected areas
		Birds protected areas

		WISE-SoE Water quantity stations
		WISE-SoE Transitional, Coastal and Marine water stations
		WISE-SoE Transitional, Coastal and Marine water flux stations
		WISE-SoE Groundwater sampling sites
	Influencing features	WISE-SoE Groundwater saltwater intrusion

UWWTD	Management units	Receiving areas
		Sensitive area – River, Lake Transitional water,, Coastline, Coast area, Catchment
		Less sensitive area – Transitional water; Coastline
	Influencing features	Agglomeration
		Urban waste water treatment plants
		Discharge points

Bathing Water Directive	Management units	Bathing Water
	Measurement features	Sampling points inland and coastal
Drinking Water Directive	Management units	Water Supply Zones
Nitrates Directive	Management units	Nitrate Vulnerable Zones
	Measurement features	Monitoring zones on surface water
E-PRTR	Management units	Location of sites

3 Definition of derived products (maps)

3.1 Types of WISE GIS datasets

There are various types of dataset in WISE:

- **Member State submitted GIS datasets:** these may be relatively dynamic, such as the point locations of monitoring stations. Others may be relatively stable over time, such as UWWT agglomerations, UWWT plants and discharge points from UWWT plants. Datasets may be points as described above or polygons, such as Protected Areas and Nitrate Vulnerable Zones. These datasets may be considered candidate WISE Reference GIS datasets to be further developed in the future;
- **WISE Reference GIS datasets:** these are relatively stable over time. There are currently five WISE Reference GIS datasets. The WISE Reference GIS datasets are created using detailed digital spatial data provided by Member States and other sources, generalised for the purposes of visualisation and assessment of geo-referenced data across Europe. Thematic data can be attached or linked to WISE Reference GIS datasets;
- **Background GIS datasets:** refer to datasets such as administrative borders of the Member States, coastline, main cities/towns and roads. They provide the background and context for mapping the WISE Reference GIS datasets;
- **External GIS datasets:** these can be used to support further analysis and the visualisation of the WISE Reference GIS datasets, such as CCM2, Corine Land Cover and EEA European River Catchments.

All WISE Reference GIS datasets will fulfil standard quality criteria and will be made available to all WISE stakeholders and, wherever possible, made publicly available through official outlets e.g. through the EEA or GISCO.

All WISE Reference GIS datasets will be managed and maintained within WISE by the EEA. Background and External GIS datasets will be maintained by their data owners. Other GIS datasets will be managed and maintained by the EEA water data centre as they become integrated with WISE Reference GIS datasets.

The WISE Reference GIS datasets and the Member State submitted GIS datasets can be categorised into two different application types:

- Hydrological infrastructure layers describe the features of the physical hydrological system, e.g. rivers, lakes and river basins. The hydrological infrastructure layers can respond to questions such as “which areas contribute to flow of water at this point?”
- Water management layers describe the hydrological features from a management perspective that allow the aggregation of features across river basin boundaries, e.g. River Basin Districts and water bodies. The water management layers can respond to questions such as “who is responsible for the water quality in this area?” or “which water features are affected by similar pressures, have a similar status and may be managed in a similar fashion?”

More detailed information on all datasets in WISE can be found in Appendix 05.

3.1.1 WISE Reference GIS datasets

The current WISE Reference GIS datasets are:

- Large Rivers and Large Lakes;
- Main Rivers and Main Lakes;
- Water Bodies;
- River Basin Districts;
- Sub-units.

The River Basin Districts and Sub-units WISE Reference GIS datasets will support the visualisation and analysis of the Large Rivers and Large Lakes, Main Rivers and Main Lakes, and Water Bodies WISE Reference GIS datasets. The Main Rivers and Main Lakes WISE Reference GIS dataset will be the primary reference dataset used to present information at the European scale.

Additional information concerning each WISE Reference GIS dataset is provided in the following Table 3.1.1.

Table 3.1.1 Description of WISE GIS Reference datasets

WISE Reference GIS dataset	Description
1. Large Rivers and Large Lakes	Large Rivers is dataset with two feature types: a) Rivers with a catchment area > 50,000 km^2 and b) rivers and main tributaries that have a catchment area between 5,000 km^2 and 50.000 km^2 Large Lakes are lakes that have a surface area > 500 km^2. Large Rivers and Large Lakes are based on GISCO data at a scale of 1:10,000,000, supplemented by WFD Article 3 submissions. The data set is intended for visualisation only.
2. Main Rivers and Main Lakes	Main Rivers are rivers that have a catchment area ≥ 500 km^2. Main Lakes are lakes that have a surface area ≥ 10 km^2. Main Rivers and Main Lakes are based on WFD Article 3, Article 5 submissions and when needed ERM (EuroRegionalMap) or CCM2 v2.1 have been used to complement the layer.
3. Water Bodies	Water Bodies are based on WFD Article 5 submissions of Surface Water Bodies and Groundwater Bodies. River water bodies have a catchment area > 10 km^2, lake water bodies have a surface area > 0.5 km^2, all transitional and coastal water bodies are included.
4. River Basin Districts	River Basin Districts are based on WFD Article 3 submissions.
5. Sub-units	Sub-units are based on the submission of Sub-units by Member States at the request of the European Commission. Sub-units are defined by the national Competent Authorities of the River Basin Districts for management purposes where the River Basin Districts are very large. Sizes can vary between 5,000 and 50,000 km^2.
6. WISE-SoE stations	WISE-SoE stations are based on Eionet-Water and WFD Article 8 stations. The WISE-SoE stations have a history of more than 10

	years being annually reported and used for EEA SoE assessments.

Details regarding the production of WISE Reference GIS datasets can be found in Chapter 6.2.

3.1.2 Purpose of the WISE Reference GIS datasets

WISE Reference GIS datasets provide the basis against which comparable statistics and indicators are calculated. WISE Reference GIS datasets are based on nationally reported data from the Member States for use at different scales. Features at European, national and regional levels are linked through vertical integration using coding.

The WISE Reference GIS datasets have three main purposes:

- ***Visualisation:*** through the WISE Viewer it is possible to display features reported by Member States, the results of any analysis of the data, or a combination of any information available.
- ***Analysis:*** the data reported by Member States and contained in WISE can be used for analysis and assessment (compliance checking, policy effectiveness, modelling of scenarios for policy development, etc). Indicators can be determined at various levels. They should be produced using methodologies that are robust and transparent in agreement with the Member States.

  The visualisation and analysis of indicators at different scales can be achieved by linking the WISE Reference GIS datasets, either by code or spatially (see Figure 3.1.2a below). At the most detailed level, actual values may be visualised and analysed using the geometry defined for the feature against which the values were reported. Alternatively, reported values may be aggregated to a different spatial unit. For example, heavily modified river water bodies could be visualised and analysed at the individual water body level. Alternatively, a percentage of heavily modified river water bodies within a River Basin District or Sub-unit could be calculated by aggregating values within the spatial unit, or the heavily modified river water bodies could be related to their associated Main River stretch.

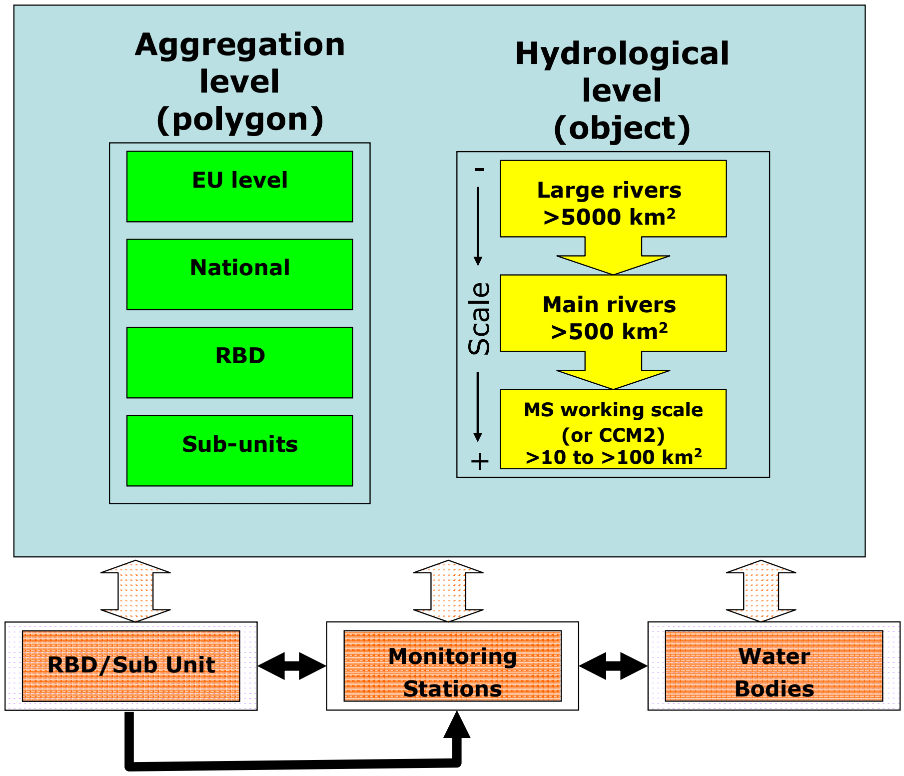

Figure 3.1.2a Visualisation of WISE Reference GIS datasets at different scales

- ***Reporting:*** future reporting exercises should be linked with the WISE Reference GIS datasets. Integrity and consistency of codes should be maintained. For example, whenever a Member State reports a river monitoring station, it should be located on and linked by code with its associated river water body (for more detailed information see Chapter 5.4).

3.2 Policy implementation visualisation

The implementation of European legislation is often divided into phases where Member States gradually implement the approaches and obligations specified in the directives. The phases cover a time span of several years. The European Commission, as a guardian of the EU legislation, is obliged to monitor the progress of implementation of the EU water legislation and to inform the European Parliament and the European Council, national governmental institutions, all interested groups and stakeholders as well as European citizens on the progress made by the Member States. The EC also informs the European Water Directors as part of the Common Implementation Strategy. The monitoring of progress, and the review and compliance checking of information related to it, has several key objectives:

- To have a general overview at the EU level on the status of the implementation of the EU water legislation;
- To identify early and resolve general problems related to the Member States' ability to implement the directive in question;

- To stress the importance of all Member States fulfilling the requirements of the European environmental legislation;
- To assess policy effectiveness.

The focus of the information on the progress of water policy implementation in the EU will, by its nature, be an overview based on simple high level indicators and map representations of key aspects of implementing water directives at the EU level, for example:

- Transposition of directives into national legislation;
- Implementation of key features of a particular legislation (e.g. establishment of River Basin Districts and identification of Competent Authorities, designation of water bodies, designation of sensitive areas and Nitrate Vulnerable Zones, establishment of a Register of Protected areas, etc);
- Establishment of monitoring programmes;
- Establishment of programmes of measure;
- Reporting to the Commission.

It should be underlined that for some water directives the requirements to show the status or progress of the implementation of a directive are rather straight forward, simply presenting and visualising the raw data reported by Member States.

Some of these data, e.g. bathing water quality monitoring sites and the status of bathing water quality, can be directly (after certain QA/QC procedures), be presented at the EU level on interactive maps using the WISE map viewer. For example, Figures 3.2.1a and 3.2.1b represent the status of implementation of the bathing water directive showing bathing water quality of inland and coastal waters at the EU as well as the MS level.

For other reported information, some aggregation, selection or clustering of reported data should be done and compliance or performance indicators derived. Visualisation of the status and performance of the implementation of a directive can be achieved using the WISE map viewer or they may be static presentations available for download (e.g. from the EEA's Atlas). Examples of such maps of indicators are:

- Overview map of WFD River Basin Districts (see Figure 3.2.1c and 3.2.1d);
- Density of monitoring stations (e.g. number of stations per 1000 km^2) visualised by Member State or River Basin District (see Figure 3.2.1e);
- Density of surveillance monitoring as reported by Member States under WFD Article 8 (see Figure 3.2.1f);
- Percentage of heavily modified water bodies visualised by River Basin District (see Figure 3.2.1g).

Development of each selected indicator and/or map will need to be clearly defined in terms of:

- The context of the directive;
- Data sources, particularly where data from different directives and/or sources are combined within an indicator;

- Derivation, presentation and visualisation.

Textual explanations of the rationale, limitations and assumptions made in the processing of the original data reported by Member State to develop indicators and present and visualise this derived information in maps will be elaborated to ensure valid interpretation.

3.2.1 Compliance assessments visualisation

In addition to the information directly requested by the EC and reported by Member States, and its visualisation using the WISE map viewer, a legal compliance assessment of the data reported against the directive requirements will be made.

The purpose of the compliance assessment is to evaluate in quantitative and qualitative terms whether a Member State has fulfilled its obligation of implementing the European legislation in accordance with the specifications and the sentiments of the legislation in question. Therefore, compliance assessment is performed by using certain methodologies and rules. The outcome or results of the compliance checking can also be visualised and presented on maps, such as displaying the status of how a Member State is implementing a certain directive.

The visualisation of the results of compliance checking can be done in two ways: by directly presenting the results of the compliance check on maps, or by developing certain indicators derived or based on the results of the compliance check.

In some cases, the outputs (maps) of the results of compliance assessments can be considered information elements in the assessment process and can provide a useful means of visually communicating the outcome of the assessments. The maps of indicators presenting results of compliance checking are used to inform EU services, European politicians, national governments of Member States and the public about the level of compliance of implementation of the water related policies.

The focus on visualising information reported on the status of implementation and compliance of directives will be as European overviews and individual country representations (using maps) with the use of derived and detailed indicators of key aspects and issues associated with implementing water directives. Examples of such compliance indicators are:

- Numbers of identified and designated water bodies in relation to the size of Member States and River Basin Districts;
- Identification of significant pressures, numbers/areas/proportion of affected waters and water bodies at risk;
- Numbers and types of monitoring sites in relation to the size of Member States and River Basin Districts;
- Numbers and types of parameters and quality elements used in monitoring;
- Frequency of monitoring;
- Level of urban waste water treatment against required designated sensitive areas and requirements for treatment based on the sensitivity of these areas;
- Bathing water quality status per bathing water against water quality requirements/thresholds for certain parameters.

It should be noted that in the compliance assessment process the EC is not limited to the information directly reported by the Member States but may apply information as deemed relevant.

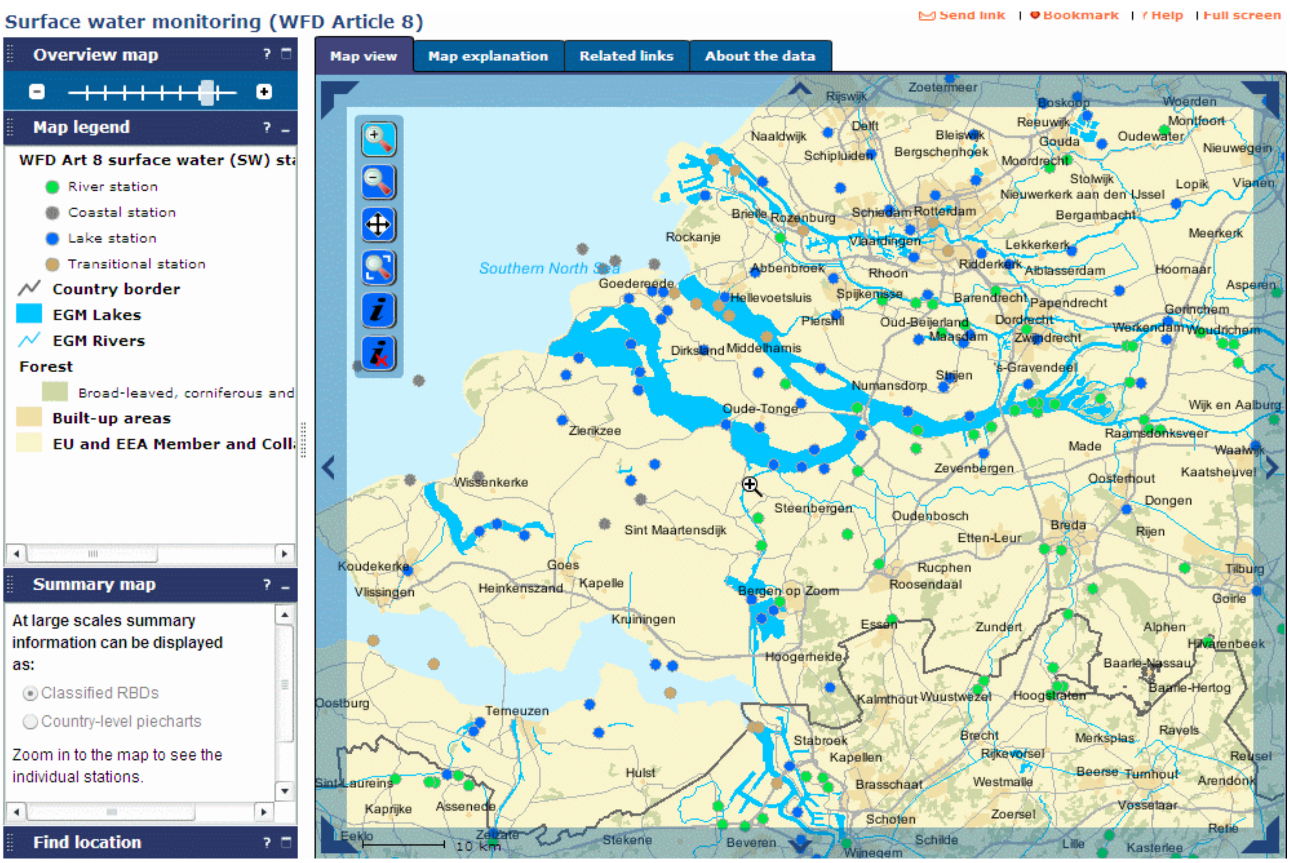
3.3 Overview of WISE map viewer application

3.3.1 Purpose and concept of the WISE map viewer

The WISE system building started in summer 2006 after a user requirement study was undertaken and an architecture document was consequently developed. From the user requirement study and from the political commitment to make data and information from the Water Framework Directive available to the general public, the development of a map viewer became a key priority.

The WISE map viewer allows the user to explore and query data presented on maps, an example of which is shown below in Figure 3.3.1.

The WISE map viewer is hosted by the European Environment Agency (EEA), in its role as water data centre. It has been developed by the EEA in consultation with the European Commission and other institutions, in accordance with specified user requirements. The WISE map viewer and a list of the interactive thematic maps that are currently available can be found at the following location: http://www.eea.europa.eu/themes/water/mapviewers/.



Source: http://www.eea.europa.eu/themes/water/mapviewers/art8-sw

Figure 3.3.1 WISE map viewer

The concept of the WISE map viewer is to package pre-defined maps and queries within a web-based interactive interface. The default view of each map is at European level, typically showing data aggregated to either Member State or River Basin

District. The pre-defined maps and queries present the information submitted by Member States as a single merged dataset at European level.

As the user zooms in the classified features (e.g. monitoring stations) are shown and the user can click on them to retrieve further information. Information is output either through a map pop-up or a table in a separate tab. Context for the map is provided in a ‘Map explanation’ tab, giving a short textual explanation of the definition and background to the map, and a ‘Related links’ tab. It is possible to search different features on the map through a search box on different layers.

Additionally, experts in each theme (e.g. relating to the Water Framework, Urban Wastewater Treatment or Bathing Water Directives, WISE-SoE, etc) have specified how data can be aggregated to either the Member State or River Basin District levels, adding value to this comparable European view. These experts are also responsible for ensuring the data displayed in the WISE map viewer has been through a quality checking procedure.

3.3.2 Technical Architecture of the WISE map viewer

After a review of the available technology options and bridging between security requirements, usability concerns and performance aspects, the WISE map viewer has been developed by the EEA for the integration and display of water related European datasets.

The WISE map viewer interface is intended to provide a rich application experience for the user when exploring the maps and data. The WISE map viewer is also designed to present the information in a readily accessible manner, hence the building of separate viewers around each map. The technology is also utilised across other of the EEA’s map-based interfaces.

The data behind the client interface is currently stored in a database spatially enabled with ESRI ArcSDE technology and delivered via an ESRI ArcIMS web map service to bring the selected data to the client.

The detailed internal functionality of the WISE map viewer falls outside of the scope of this document but the viewer should be seen as a black box which controls the interaction with the user and the response and request cycle to the data services.

3.3.3 Specification of a map and its cartography

Maps displayed in the viewer have been subject to consultation, their presentation format agreed and they conform to the needs of the user. They are first prototyped by the thematic experts in a standalone ArcMap document with the available data and the user interaction described with use cases. The technical specification for each map is then documented and the WISE map viewer application is developed and tested according to the specification. The following is a list of the typical information to be included in the technical specification:

- Data preparation – aggregation and other pre-processing tasks for data display;
- Define the display – background layers, reference and other GIS datasets to be used;
- Display scale specifications – what should be shown at different zoom levels;

- Data attribute explanation;
- Visualisation of map and legend at different scales – RBG values for legend and text for legend. Value thresholds for WISE data;
- Map interaction description – pre-conditions, triggers, post-conditions e.g. output to pop-up, table or graph;
- Map explanation text and related links.

Classification of points and colouring are important elements in helping the user quickly understand what they are looking at. Within WISE, many of the datasets have precedents set on their display. Data relating to the Bathing Water, Urban Wastewater Treatment and Water Framework Directives are displayed according to the classification and colouring specified in their respective directive text. The background to the WISE maps is a set of layers developed at the EEA from various sources, optimised for web display.

3.3.4 Alternative and future map viewing options

With the development of WISE into a distributed system using service oriented architecture (SOA) principles, more ways of serving maps and visualising data will become available. The next steps of serving maps to other machines are explained further in Chapter 5.7.

The EEA will further develop map viewing options, in particular user-friendly ways to serve a wider group of users which are not specialised in GIS and who may not be familiar with the currently used viewing tools. Within the WISE website, the theme of bathing water serves as an example for more flexible ways of presenting data: see http://www.eea.europa.eu/themes/water/status-and-monitoring/bathing-water-data-viewer for more information. This includes the display in Google Earth™ or Microsoft Virtual Earth™ as well as the possibility to download data in KML format. This flexible line, supporting multiple tools will be supported in the future and will be based on open standards wherever possible.

3.4 State of the Environment visualisation

At the core of any water related State of Environment (SoE) assessment is the need to quantify and identify the current state of, and impacts on, the water environment - how these are changing in time and whether the measures taken at different levels are effective.

Such an assessment should:

- Provide the basis for identification and assessment of environmental problems and the dominant threats at regional and European levels;
- Provide information necessary to enable actions/policies to be taken to improve the environmental state of the water bodies and to ensure sustainable development;
- Be based at the most relevant time and spatial scales to meet the two objectives stated above.

The European information needed in relation to water quantity can generally be described as:

- How much is there (runoff, availability, etc)?
- What is the state of the water quality (nutrients, hazardous substances) and ecological quality?
- Is the situation getting better or worse?
- What are the pressures on the environment (abstraction and water use by sectors)?
- Are there targets in place, such as are water-pricing policies used to provide adequate incentives for users to use water resources efficiently?

The EEA bases its water quality data on a representative sub-sample of national monitoring results, which EEA member countries report voluntarily each year to the EEA. The EEA has mainly collected annual values (e.g. average, median, minimum and maximum).

In the context of the implementation of the Water Framework Directive (WFD), the EEA's Eionet-Water annual data flow for waters is in the process of being transferred into the WISE-SoE (State of the Environment) voluntary data flow. The transition from Eionet-Water to WISE-SoE reporting has already been done for water quality related determinands for rivers, lakes and groundwater. In developing this transition, there was a clear principle that there should be no double reporting. The aim is a delivery of one dataset that might be useful for both WFD compliance by the European Commission services and EEA SoE assessments.

Data from WISE-SoE reporting are stored in Waterbase (a series of SoE databases within WISE) found at: http://dataservice.eea.europa.eu/dataservice/available2.asp?type=findkeyword&theme=waterbase.

At the end of 2007, Waterbase contained water quality information on:

- More than 6000 river stations in 35 countries;
- More than 2200 lake stations;
- Quality data from around 1100 groundwater bodies.

In the future the monitoring stations reported to the EEA will be similar to, or a subset of, the monitoring stations reported by countries under Article 8 of the WFD.

The data stored in Waterbase are visualised and communicated to the public using the WISE map viewer at http://www.eea.europa.eu/themes/water/mapviewers/ (see Chapter 3.3 for more information) and in the future will be supplemented by tabular data extraction templates. The freshwater water quality Waterbase databases consist of three main tables. For rivers, for example, the number of records stored in the database are:

- Waterbase-Rivers: **Stations** (6369 records);
- Waterbase-Rivers: **Pressures** (2876 records);
- Waterbase-Rivers: **Quality** (637344 records).

In addition, there is a fourth table containing **hazardous substances** (>300,000 records, not publicly available).

In 2008, the EEA and its European Topic Centre on Water began test data collections of data on water availability and water abstraction, and emissions to water. During 2009, these data collections will be established as annual WISE-SoE water quantity and emissions reporting. Work is also underway to develop data flows on biological and hydromorphological indicators.

In addition, the EEA bases its SoE reporting and indicators on data collected through the reporting of the Urban Wastewater Treatment, Nitrates, and Bathing Water Directives, as well as Eurostat's collection of data via the OECD/Eurostat questionnaire on environmental data on water availability, water abstraction, water use and wastewater treatment.

The data stored in the different databases form the basis of the EEA's water indicators. The EEA has the following core set of indicators relating to water:

- Use of freshwater resources (CSI 018);
- Oxygen consuming substances in rivers (CSI 019);
- Nutrients in freshwater (CSI 020);
- Nutrients in transitional, coastal and marine waters (CSI 021);
- Bathing water quality (CSI 022);
- Chlorophyll in transitional, coastal and marine waters (CSI 023);
- Urban waste water treatment (CSI 024).

In the near future the data behind the EEA indicators will be available via WISE.

3.4.1 Visualisation of State of the Environment (SoE) data in WISE

Data stored in Waterbase (on water quality) and collected via Member States reporting (Bathing Water, Urban Wastewater Treatment and Nitrates Directives) are visualised in the WISE map viewer.

During the visualisation process, different formats are used depending on the scale of the map:

- Often, for the scale 1:5,000,000 and less detailed (European overview), data are aggregated by country or national River Basin District (RBD) level;
    - For countries: pie charts of percentage of the variable (e.g. BOD, Bathing water quality or wastewater treatment type) classification by country is displayed;
    - The national RBDs are coloured according to the average of all the stations located within the RBD, falling within defined classes.
- For the scale more detailed than 1:5,000,000, individual station points are visible instead of a classified cartogram, and these are coloured according to the variable classification. Symbol size depends on the map scale (the more detailed the map, the bigger the symbol).

An updated list of SoE maps available via the WISE map viewer can be found at the following location: http://www.eea.europa.eu/themes/water/mapviewers.

In the future, additional maps will be added, which may include:

- Maps on diffuse nutrient pollution;
- Maps illustrating groundwater water quality;
- Water availability per River Basin District;
- Water abstraction by main sectors per River Basin District;
- Water exploitation index (available water resource divided by water abstraction) per River Basin District.

4 Principles of WISE compatibility and interoperability

4.1 What is WISE compatible?

As described in Chapter 1.2 WISE may, depending on the context, be seen as an initiative, a concept, a process, an information system, a set of rules or tools for reporting, a dataset or component or something else.

If WISE is referred to as an information system, it includes all possible WISE nodes, data and viewer providers as well as the common WISE public web site and their interactions. It is not a central "mega-database" but rather a decentralised system at EU level which will have capabilities to interoperate with existing national systems.

It is intended that WISE will cover all water-related information arising from EU water policy (e.g. Water Framework, Urban Waste Water Treatment, Nitrates, Bathing Waters, Drinking Water and Floods Directives) as well as the upcoming Marine Strategy Directive. In addition, WISE will include other water-related datasets such as Eionet-Water (now known as WISE-SoE) developed by EEA and those arising from relevant water research projects.

Because of the extent of themes and the number of stakeholders involved in developing WISE, guiding principles are required to be followed during development and implementation. The guiding principles for WISE compatibility are elaborated in the following text.

4.1.1 Standards applicable to WISE

WISE is a system merging spatial and non-spatial data from various physical locations. In this respect, an important aspect is the hosting of geo-referenced data, making WISE a building block for INSPIRE. WISE will build on the service-oriented architecture, applying the appropriate standards and specifications from the Open Geospatial Consortium (OGC), the International Standards Organisation (ISO) and the European Committee for Standardisation (CEN). The application of standards does on one hand ensure that the process takes on board experiences gained from other information management communities, and on the other hand that specifications are written so that they may be implemented by different developers and data managers independently of a specific technical solution or software.

- The OGC has developed a family of technical documents - OpenGIS® Specifications[20]. These specifications cover a wide range of aspects from the specification of how to encode spatial data for exchange to specification for various web-services needed for discovering, accessing and visualising spatial data. The OpenGIS® specifications build on other standards such as the family of XML standards. The application of the OpenGIS® standards is described in detail in Chapters 5.6 and 5.7;
- ISO has developed the ISO 19100 family of standards for geographic information (e.g. ISO 19115/119 covers metadata and services) and the specific adaptation of this is described in further detail in Chapter 5.5. CEN

[20] The OGC specifications and best practices may be found at http://www.opengeospatial.org/standards

have adopted a number of standards. An overview of the appropriate standards and status can be found in Appendix 04;

- INSPIRE – The ongoing INSPIRE process will lead to a binding set of implementation rules as well as a set of guiding documents specifying good practice. This document, "The WISE GIS guidance", follows the INSPIRE recommendations to the level available, and may thus be described as INSPIRE compliant given the constraint that reporting requirements have already been specified for a number of water-related directives. An overview of the INSPIRE technical architecture is shown in Figure 4.1.1.

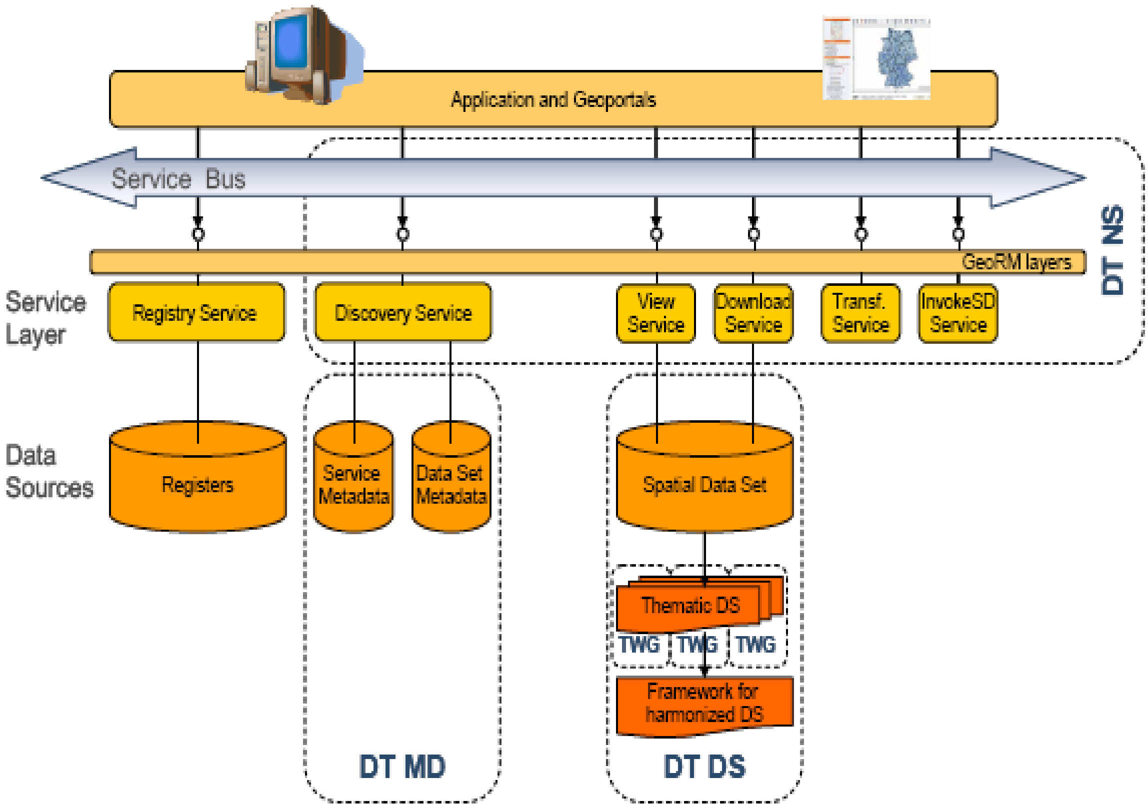


Figure 4.1.1 INSPIRE Technical Architecture overview

4.1.2 WISE compatibility

During the first 7 years of WFD implementation, a set of processes agreed by all stakeholders has been developed. WISE compatibility can be considered true when information regarding the environment is defined, gathered, exploited and disseminated as requested by the Commission. The processes follow a set of guiding principles for streamlining of reporting and the shared information system.

Streamlining reporting:

- Key principle: "Report once use many times[21] – harmonise reporting tools". This key principle overarches many of the efforts in streamlining the reporting processes between stakeholders at all levels;
- WISE will integrate State of the Environment (SoE) and compliance reporting data flows and, where appropriate, others. The principle here is a natural outcome of the key principle, as it will reduce the burden of reporting for mandatory and voluntary data flows;
- Follow the Subsidiarity Principle;
- Data should be maintained at the most appropriate level and shared between all other levels;
- To be WISE compatible means applying the collaborative processes developed as part of the WFD Common Implementation Strategy. Part of the process is to identify the most appropriate type and level of information either to be available or to be reported at the European level. Other parts of the collaborative process ensure both the sharing of good practise and common ownership of the policy implementation (see Chapter 1.2);
- Use of MS data for visualisation and analytical purposes according to the “WISE reporting arrangements”. The unrestricted use of MS data is a paramount requirement for the multiple uses of the data. MS data may be aggregated and compiled into seamless European wide layers (see Chapter 6);
- Reporting based on public schemas and multi-approach tools. The reporting is based on XML schemas which are independent of vendor specific software. MS are, to a variable degree, capable of preparing XML documents from their information systems. Tools have thus been developed to organise, validate and reformat data according to the reporting schemas. The reporting schemas themselves fit into the service-oriented architecture;
- Data processing follows an open and agreed process. The procedures for accepting, validating and exploiting the data reported by MS to WISE follow a standard procedure as illustrated in Figure 4.1.2a.

It is important to note that recommendations and specifications in this guidance build on the existing processes (reporting methods, schemas, Reporting Sheets etc). The future developments may require changes of a technical nature (reformatting of specifications etc), but the actual content will continue and be stable over time.

[21] Data should be collected once, maintained at most appropriate level and shared between all levels.

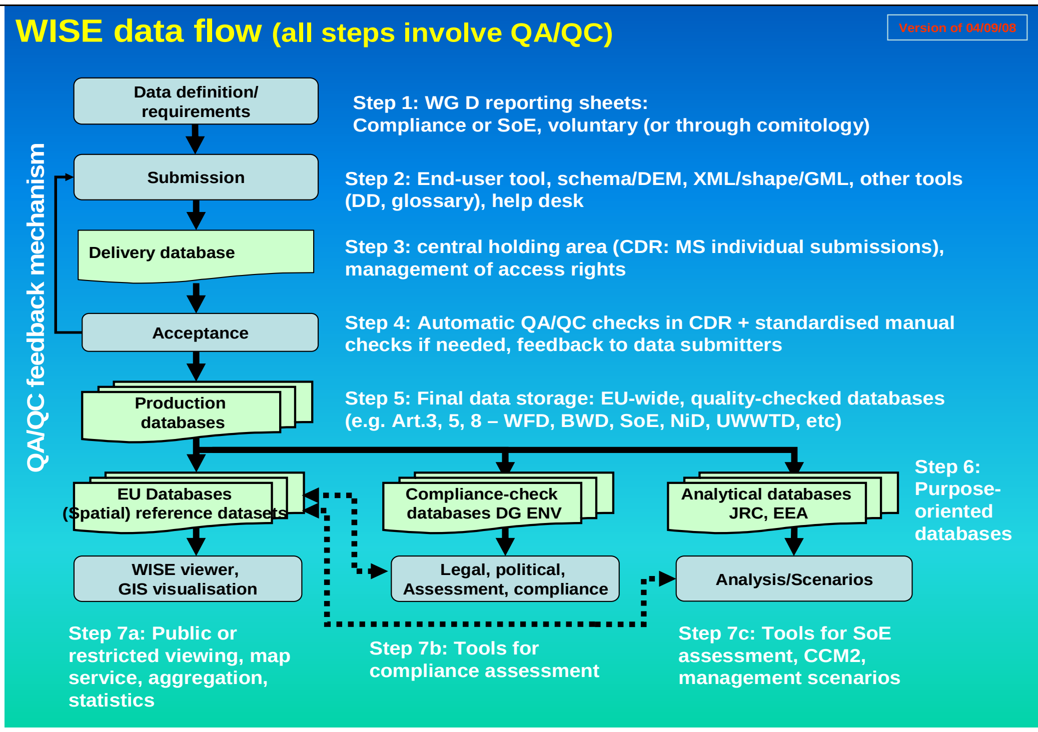

Figure 4.1.2a WISE data processing flow

Shared Information System:

- WISE is built as distributed data nodes (see Figure 4.1.2b). Data should be stored at different nodes and information should be shared between all participating nodes. It is not the intention that a data node will contain the full dataset. The distributed nodes are an application of the Subsidiarity Principle;
- Vertical integration between local, national and European levels. Vertical integration is supported by specifying spatial objects which, through stable identifiers, can serve as links to more detailed information at national / local level. These stable identifiers ease reporting provided that the spatial data is stable over time. However, an effort to maintain vertical integration is required to keep temporal track of the spatial changes;
- Interoperable system;
- For the sake of information sharing and exchange, all participating nodes must be interoperable. Data should be exchangeable and services should be able to access and process data from different nodes;
- Transparent system (open);
- It should be easy to discover data and services. Users should be able to determine fitness for purpose of data and the conditions of usage should be clearly described.

Ultimately, WISE should centralise only those data which are needed as a reference against which reporting is made. The major part of information and data will be decentralised which means that linkages between national water information systems and WISE will need to be established.

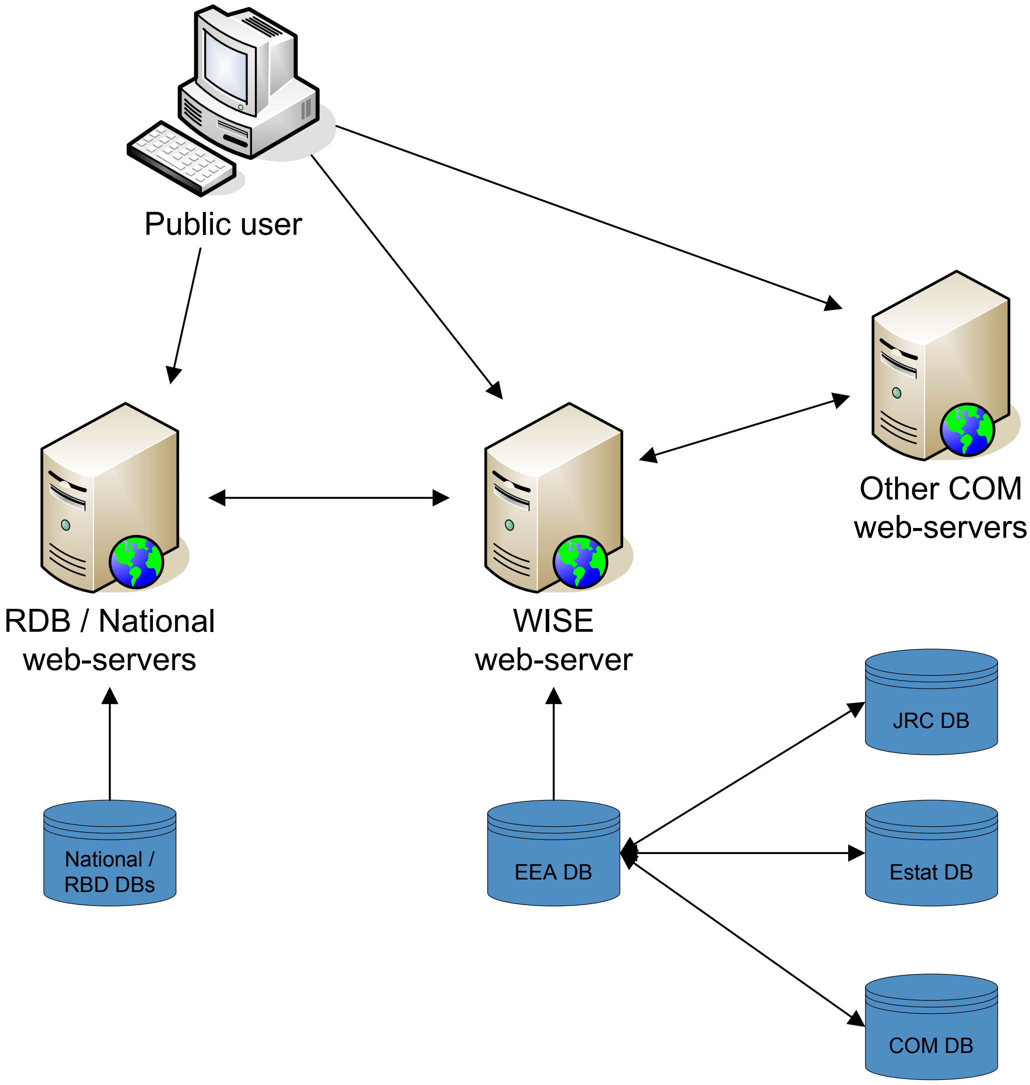

Figure 4.1.2b WISE network of databases and web-servers

4.1.3 WISE interoperability

Interoperability "is the capability to communicate, execute programs, or transfer data among various functional units in a manner that requires the user to have little or no knowledge of the unique characteristics of those units" (CEN Technical Report 15449[22]).

Interoperability between systems and components has other aspects:

- Network-protocol interoperability allows communication between components;

[22] CEN/TR 15449 "Geographic information – Standards, specifications, technical reports and guidelines, required to implement Spatial Data Infrastructure" CEN/TC 287.

- Standard interface specifications can enable clients to perform procedures on a remote system;
- Data transfer interoperability allows access to data, sharing of geographic databases and other services independent of the proprietary format;
- Semantic interoperability concerns the ability of an application to interpret data consistent for common representation or processing.

WISE interoperability will, in the short term, focus on the level of “data transfer interoperability” which will be based on a agreed set of public and open specifications for web services. The web services will be responding to requests that are encoded using WISE semantics and will return a WISE related dataset.

The long term recommendation for WISE interoperability aims at semantic interoperability. This level of interoperability is however not sufficiently mature neither at the technical level (tools for semantic processing) nor at the level of adequate thesauri and ontologies or the adaptation in Member States. The semantic interoperability will open for a use of the wider set of voluntary data services related to the water domain based on local requirements and priorities and disseminated by national and regional institutions. The services are already in place in several Member States but are not currently well adapted for international use.

WISE as a shared and interoperable system is reinforced by a number of decisions:

- WISE is based on open and service-oriented architecture;
- WISE web map nodes will serve the community with small scale data, whereas national and regional data nodes are expected to provide data services at a larger scale;
- Users can build own services to connect their data to WISE or access WISE data.

The service-oriented architecture implies that all the harmonisation described is performed at the “service layer” level. Any of the data sources will have full freedom to model and organise their data in their databases according to their own needs as long as the provided services correspond to the WISE data models and common agreed service specification. See Figure 4.1.2b for the INSPIRE service-oriented architecture model.

The European WISE portal serves the user community with pan-European spatial views at smaller scales. When zoom levels go beyond 1:250,000 the data sources should be from national web servers. The distributed responsibility for providing information at different scales and the freedom for users to build own services and connect their data to WISE or access WISE data require the WISE system to contain the necessary registries for:

- Data models and specifications and service specifications;
- Other WISE nodes.

Another WISE related requirement is the interest and willingness from Member States to deliver data and services prepared for pan-European viewing.

In the WISE implementation of the service-oriented architecture, the responsibility will be shared between MS and the European Institutions (DG ENV, ESTAT, JRC and EEA) in the following way:

- EEA / DG ENV have already implemented View services at the WISE portal. It is the responsibility of the EEA to develop the necessary Registry services to support the MS with data and service specifications and to develop Discovery services allowing the WISE nodes to register their data and services and allow users to discover these.
- MS can implement View services and Download services and, in the future, will be able to register the associated metadata for data and services at the WISE Discovery service.

Chapters 5.6 and 5.7 describe further details of data exchange, interoperability and web services.

4.2 Update of existing datasets

4.2.1 Introduction

The term "update" implicitly assumes that data is reported to replace earlier reported data. The following WISE reporting arrangements have been agreed:

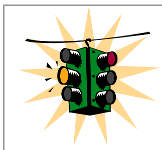
> "*Member States will be allowed to update their information and data **at any time**. Whilst the updating of information in between the reporting deadlines is voluntary, it will be beneficial always to ensure that the latest, correct information is available in WISE since that will be the one used for compliance checking and publication (adding a reference year to the data)"*. (WISE reporting arrangements[23]).

Updates can be limited to a single data object or as large as the full dataset. Under WISE two sorts of updating data are considered:

- **Data resubmission** is the update of a complete dataset. The resubmission is necessary when:
- Data is missing;
- Data is not provided according to the agreed structure, format or detail;
- Mismatch between reported data (e.g. water bodies provided for Article 5 WFD and included in the monitoring dataset reported under Article 8 WFD);
  - Resubmissions are always initiated by the European Commission (DG Environment).
- **Data update** is the submission of modified data compared to a previous submission. Updates can be either descriptive updates, geometry updates or both. A Member State can update its data at any time which helps:

[23] Guidance on practical arrangement for electronic reporting to the Water Information System for Europe (WISE); "WISE REPORTING ARRANGEMENTS "; Final Document (01/03/2007) http://circa.europa.eu/Public/irc/env/wfd/library?l=/framework_directive/w-wise_background/arrangements_1307doc/_EN_1.0_&a=d

- Member States to avoid intensive update exercises at specific reporting deadlines because all updates are frequently submitted to WISE;
- EC/EEA to update its reference datasets more frequently;
- EC/EEA to provide the most up to date statistics.



Look out!

Data reporting is the submission of data according to deadlines defined by different reporting exercises (i.e. defined by directives as well as voluntary-based reporting such as WISE-SoE and on water statistics by Eurostat/OECD Joint Questionnaire, etc)

According to this, update of WISE geographical and descriptive data at reporting deadlines (legal or voluntary reporting) can be considered as special cases of the arrangement “at any time”.

After the first reporting date EC assumes it has the MS latest data available through regular update procedures by the next reporting date.

The procedures of the update process play an important role in the success of a reporting system. Therefore special attention has to be paid to set up a well-balanced system which includes all necessary rules to guarantee the correct use of updated data and to be able to follow developments in time. The paragraphs below will explain these procedures in more detail.

4.2.2 Technical data update flow

Due to the wide variety of data that is reported under WISE not all data can be treated the same regarding the technical update procedures. In Figure 4.2.2a, four different types of update are presented. The types are based on their update frequency and the number of objects that are reported (see also Chapter 5.7). Typical usages of each type are:

- Type I: This type could be the update of an attribute for a single object. For example when the name of a specific water body has changed;
- Type II: This type could be the update of a River Basin District. A single object is reported and it is most likely that a Member State is updating its River Basin Districts infrequently;
- Type III: This is a less common type but could be used for example to exchange aggregated datasets;
- Type IV: Some Member States may revise the complete dataset of their major rivers (new surveys). In this case the Member State reports a complete dataset on a certain topic.

	High frequency	Low frequency
Object based	Type I	Type II
Dataset based	Type III	Type IV

Figure 4.2.2a Technical update types

To organise the update procedures, all WISE data will be classified according to the technical update type, the data objects size and the need to update the data for dissemination. In the future WISE will have two methods of update flows:

- Flow 1 will use INSPIRE-like services to communicate between MS and the EC. This flow typically handles updates of descriptive data and point geometries. Flow 1 can process single data objects or lists of complete datasets;
- Flow 2 will be the reporting through Reportnet. This will allow MS to continue to use existing systems. Furthermore this flow will handle all line and polygon geometries. Flow 2 will always handle complete datasets.

Flow 1 is a new method of reporting which will require some additional explanation, as all data submitted to WISE has to undergo several processes and QA/QC procedures. In flow 1 WISE aims at near real time updates of data to be able to incorporate changes pushed by national systems and to ensure that the latest correct information is available in WISE.

Figure 4.2.2b illustrates the data flow and the QA/QC procedures after data (re)submission or update:

- On MS data submission to WISE (1) an immediate message that data are in WISE will be processed and generated (2a).
- Automatic quality checks are performed and MS will be informed when the data could not be processed correctly (2b – feedback to MS). Aspects such as formal quality, data consistency and data content checks will be taken into consideration (see also Chapter 6.1).
- The data processing will not continue until MS deliver data of sufficient quality.
- After this QA/QC feedback mechanism the data will be incorporated into WISE (3), data currently used in WISE will be updated and data will be available for several purposes and processes as mentioned above

(update/preparation of WISE reference GIS datasets (4a), compliance checks (4b), analysis, and visualisation).

- These processes will have additional QA/QC procedures and a report will go back to MS if data do not fulfil the requirements.

Data related to reporting periods (e.g. legal and voluntary reporting) or update cycles (e.g. WISE reference GIS datasets) will be tagged with the respective update or reporting period and its reference date.

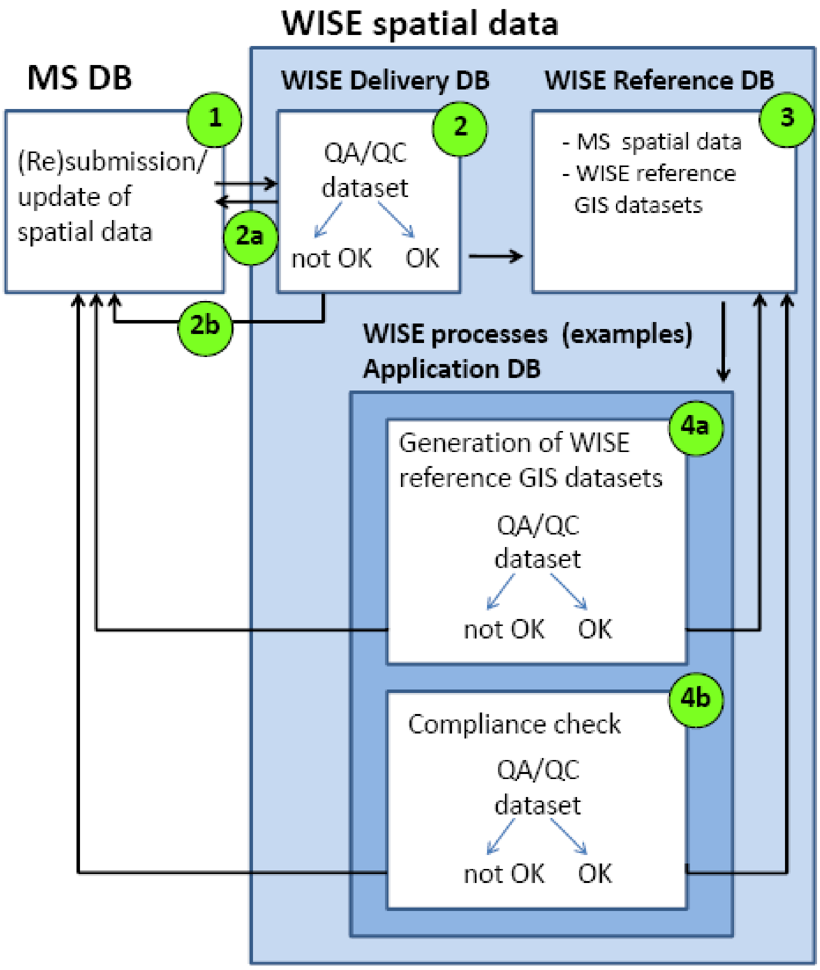


Figure 4.2.2b Submission/update of MS data: general data flow and QA/QC procedures

4.2.3 WISE update arrangements

4.2.3.1 Legal and voluntary reporting

Each water-related directive will have its own reporting deadlines. In accordance with these reporting deadlines, periods for resubmission and final deadlines will be defined. The data available at this deadline will be used for compliance checking. It will be referred to as the final dataset for the defined reporting period and tagged accordingly. Data submitted after this deadline will not be integrated into the compliance check process until the next reporting period. However, they will be available in the WISE Reference Database and can be used for the production of WISE Reference GIS datasets and integrated into the WISE map viewer.

Figure 4.2.3a illustrates possible data flows according to reporting obligations using either the possibility to update WISE GIS data at any point in time or the submission of GIS data at reporting deadlines. The update process for legal and voluntary reporting can be structured according to reporting deadlines. A submission process with a definite reporting deadline will be followed by a QA/QC period and probably resubmission of data (with a resubmission period and resubmission deadline). After this deadline, the final dataset will be included in the WISE Reference Database.

Member State GIS data already available in WISE need not be reported again. MS need only to refer to the relevant dataset, reference period and reference date. The GIS data necessary to carry out the relevant legal processes will be taken from WISE.

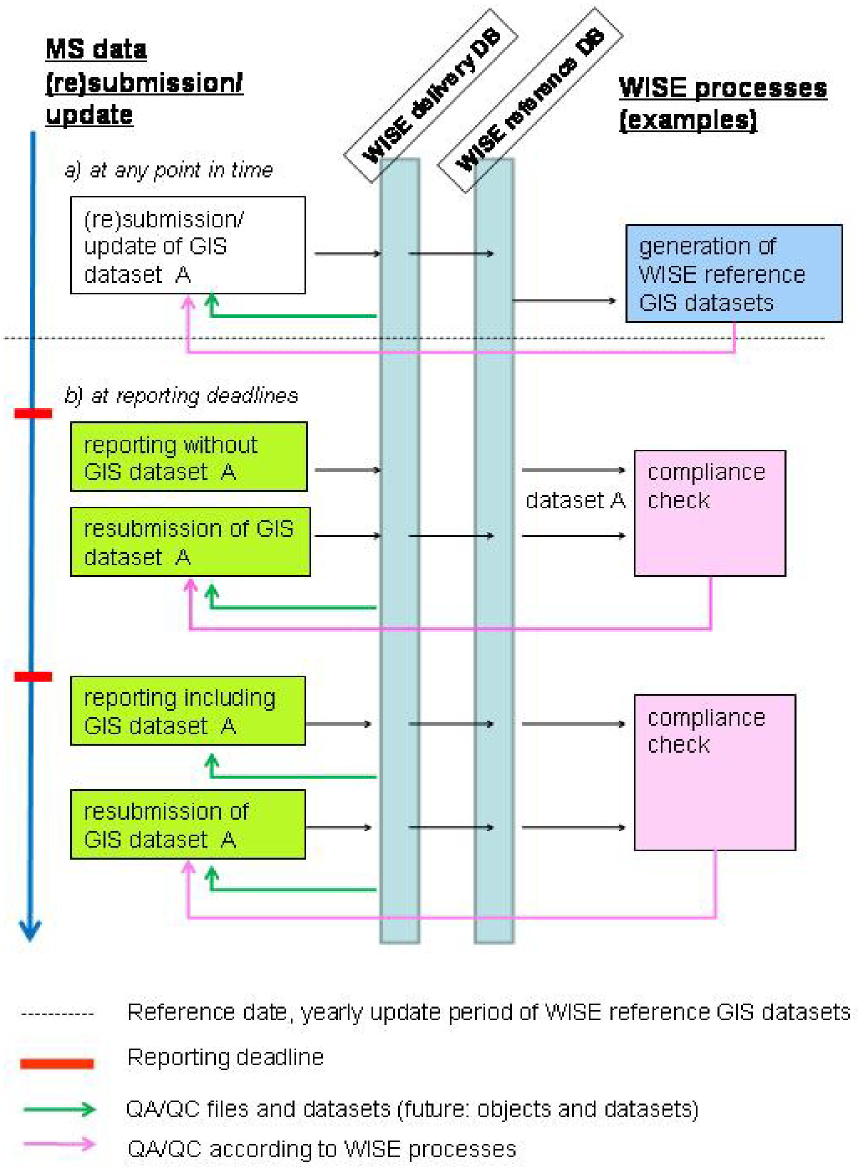

Figure 4.2.3a WISE GIS data flow and processes

4.2.3.2 Further principles:

- All submitted and resubmitted datasets will be stored in the system. The final dataset used for compliance checking will be tagged with the reference date of the reporting period;
- All datasets belonging to the reporting period have to refer to the same reference date or reference period;
- If data are submitted which are linked to already existing WISE GIS data, the proper reference to the relevant dataset has to be provided;
- Reporting cycles, the official reporting deadlines and the resubmission deadlines for each water-related directive and reporting periods within these directives will be published and made publicly available in WISE.

4.2.3.3 WISE Reference GIS datasets

As described in Chapter 3.1, there will be a set of WISE Reference GIS datasets prepared at the European level. The data source of these datasets will be:

- MS submitted GIS data:
    - Either according to the reporting obligations of the different water-related directives;
    - Or based on voluntary reporting (other GIS datasets).
- Pan-European datasets such as those from GISCO (background GIS datasets), Eurogeographics (e.g. Euro Regional Map) or JRC (CCM2). These are termed External GIS datasets.

WISE Reference GIS datasets will be **updated annually** (see Figure 4.2.3b). A near real time update will not be possible because these data will be harmonised and need an in-depth quality analysis and feedback to Member States. The update period will be closed by a defined reference date. All data submitted within the period up to the reference date will be processed. After the QA/QC period the dataset will be released and tagged with the reference date. The dataset will be available in the WISE Reference Database and the WISE web viewer.

The following principles will apply:

- The process of preparing the datasets using data provided by MS will be transparent for MS (see Chapter 6.2);
- During the time of data preparation for a WISE Reference GIS dataset and in the case of open questions, MS will be contacted to ensure the correct interpretation and use of submitted data. MS data will only be used for the compilation of WISE Reference GIS datasets if the QA/QC procedure could be finalised within a given period of time and the data are accepted and validated. All MS datasets used or not used (QA/QC not finished) for the WISE Reference GIS dataset will be marked accordingly;
- The WISE Reference GIS dataset will be released for further use by EC through the WISE portal;

- WISE Reference GIS datasets will be provided for download. They will be published with a version number and time stamp. Furthermore, detailed documentation of data sources of the respective WISE Reference GIS dataset will be available;
- WISE Reference GIS datasets will be published in the WISE viewer.

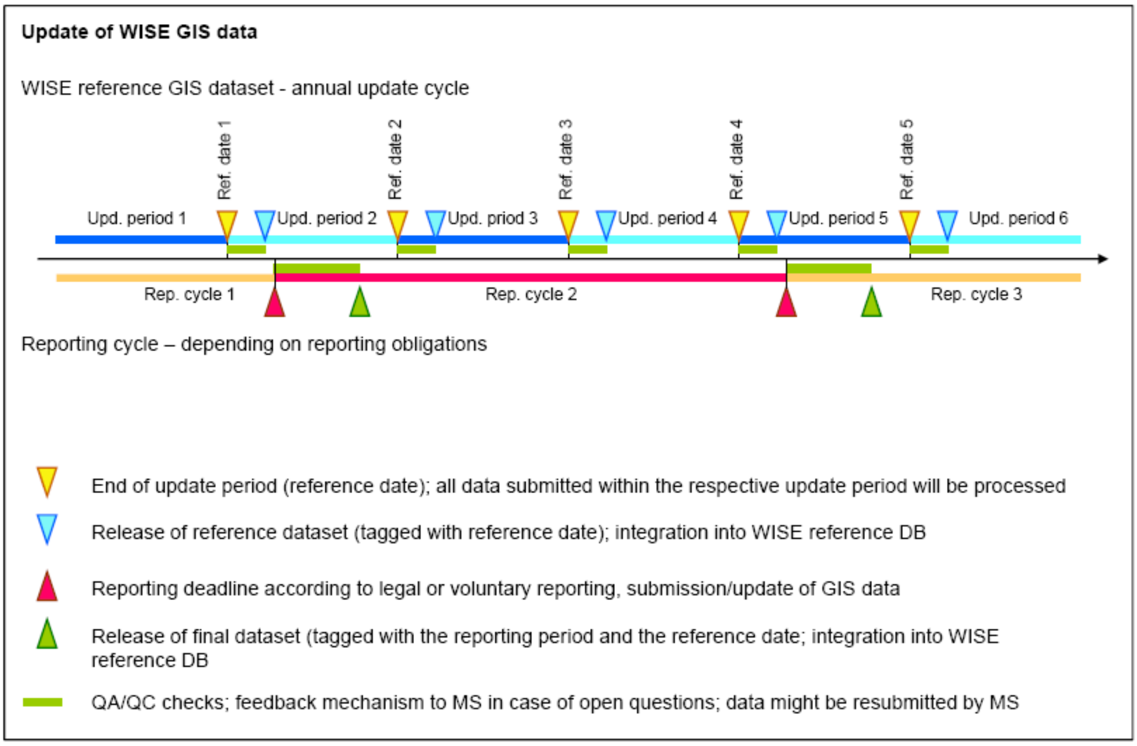

Figure 4.2.3b Update of GIS data according to the annual update cycles of WISE Reference GIS datasets or reporting cycles

4.2.4 General principles and responsibilities

The main principle of the update process should be "keep it simple". The amount of data reported under the various water-related directives is quite different. Although update of single records might be relevant it has for the time being been decided only to accept complete datasets regardless of the amount of changes.

The current decisions for WISE are:

- If data are updated/resubmitted complete datasets have to be submitted;
- All datasets related to each other will be tagged automatically at reception by EEA so that a) datasets belonging together can be easily identified and b) during an update process MS get informed which datasets are related and might need an update as well (e.g. WFD monitoring dataset includes water bodies and refer to the water body dataset);
- MS submitted data will be available in the WISE Reference Database and it will be traceable which datasets have been used for compliance checking purposes (reporting obligation, reporting period, reference date) and WISE Reference GIS datasets (update cycle reference date);

- All reporting and update cycles will be managed at EU level and published in WISE.

In future, with the realisation of the WISE distributed system architecture, update of single records or partial updates will be possible (Type I data flow).

EC and Water data centre (EEA) will be responsible:

- To set up a reporting system which allows an easy update of submitted data (and define the reporting steps and name a person responsible for each step);
- To define the reporting cycles and deadlines, the data flow and how the update has to be done in technical terms;
- To manage the reported data and update WISE Reference GIS datasets;
- To provide all relevant information and support to MS.

The **documentation of the updates** carried out for each dataset will be crucial. MS will be responsible for providing metadata describing the updated datasets (see Appendix 11 for detailed description of metadata content). EEA will be responsible for document updates of WISE Reference GIS datasets.

For various needs, in particular for QA/QC procedures carried out by WISE partners, it will be necessary to **follow changes in time and trace back information**. In several cases it might be necessary to know if all relevant features have been reported from one reporting period to the next one. This applies also for data resubmission and data update. More information about this can be found in Chapter 4.4.

Since WISE covers all water related reporting, **unique identification of spatial objects** is of fundamental importance for the reporting process. Details about identifier management are given in Chapter 4.4.

4.3 Creation of new datasets

Geo-referenced data form an important part of WISE, making WISE a building block for INSPIRE.[24] The integration of spatial information into WISE, the guidance given to Member States how to set up their water-related spatial information as regards reporting to WISE and particularly the creation of datasets for WISE should therefore be guided by INSPIRE principles.

"INSPIRE (such as WISE) *should be based on the infrastructure for spatial information that is created by the Member States and is designed to ensure that spatial data are stored, made available and maintained at the most appropriate level."*

Spatial information in WISE will be provided from several sources and will serve several purposes (see Chapter 2). The main differentiation of spatial information reported to WISE, prepared for WISE, used and visualised in WISE will be:

- Data provided by Member States (thematic data arising from reporting obligations);

[24] http://inspire.jrc.ec.europa.eu/

- Harmonised reference datasets at EU level: WISE Reference GIS datasets (see Chapter 3.1);
- Background data for visualisation (e.g. administrative boundaries, cities; to provide geographic orientation in maps);
- External GIS datasets to support further analysis and visualisation (e.g. CCM2).

The sources of spatial information and potentially new datasets are:

- Spatial information provided by Member States;
- Compilation of pan-European data from third party sources (e.g.CCM2 from JRC);
- Third party products (e.g. Eurogeographics – Euro Regional Map).

Third party products and third party sources of spatial information will not be addressed but this Chapter shall help:

- Authorities in Member States in creating water-related spatial information;
- EU bodies in compiling pan-European harmonised spatial information for WISE from Member States inputs (e.g. WISE Reference GIS datasets);
- EU bodies in planning to integrate the reporting of water-related directives into WISE.

Recommendations for the creation of new spatial information for WISE are given in Chapters 4, 5 and 6. Special attention has to be paid to the requirements given in:

- Chapters 4.4 Management of Identifiers and Codes and 5.4 European Feature Coding; set up of identifier management according to INSPIRE rules and guidance given in this document, including the specification of lifetime rules of objects and historic data management; description of object referencing between datasets and the maintenance of it;
- Chapter 5.1 General approach for the definition of datasets; development of data specification according to INSPIRE Implementing Rules;
- Chapter 5.5 Metadata;
- Chapter 6.1 Validation and harmonisation of geometry, data definitions, data models, naming.

4.3.1 GIS datasets reported by Member States

Member states will report spatial datasets to EU bodies under various articles of the WFD. These datasets come from national repositories which are not necessarily geometrically aligned across national borders or to a pan-European coastline. To connect borders of River Basin Districts or rivers across national borders, one option for Member States will be to align their data with a selection of EuroRegionalMap at scale 1:250 000. This data selection essentially comprises the national borders, the coastline and hydrological features that cut across national borders. Member States will be able to download these data sets free of charge from a dedicated section of

WISE provided they do not use these data for any other purpose. Download will be restricted to authorised persons in the water authorities.

The main concern of the Member States will be the correct use of their spatial information provided for WISE. To allow the correct:

- Use of spatial information in WISE - Member States shall provide metadata according to the WISE metadata profile (see Chapter 5.5);
- Linkage of different datasets (including non spatial data to spatial data) – Member States shall follow the principles of coding (see Chapters 4.4 and 5.4);
- Assessment of data at EU and RBD level - data should be harmonised, Member States shall follow the principles of coding and data update/resubmission (see Chapters 4.2, 4.3 and 4.4).

Furthermore, other guidelines to create and report spatial data for a specific reporting purpose have already been developed (UWWTD, NiD, BWD) and will be further developed and Member States should follow the specifications given there.

4.3.2 WISE Reference GIS datasets

The agreed WISE spatial data policy[25] allows the use of submitted data by the Commission and the EEA for deriving new geographic datasets (see Appendix 03). As described in Chapter 3.1 data provided by Member States will also be used to produce WISE Reference GIS datasets. The creation of the WISE Reference GIS datasets will follow INSPIRE principles.

In addition to the recommendations mentioned above the following specifications and descriptions for WISE Reference GIS datasets should be followed, if applicable:

- Special rules concerning the update of data (e.g. as regards ID management, development and maintenance of object referencing, historic data management, data harmonisation);
- References between the WISE Reference GIS datasets and Member State provided datasets and the maintenance of object referencing;
- Use of WISE Reference GIS datasets in WISE;
- Use of WISE Reference GIS datasets by Member States.

4.3.3 Integration of water related reporting mechanisms into WISE

The initial focus for WISE was the Water Framework Directive (WFD). However, WISE will step by step implement the data upload, sharing and analysis requirements of all water-related directives and supranational reporting. By now, in addition to the WFD, the integration of the UWWT Directive is under progress. The Bathing Water Directive will follow (see Chapter 1.2 for more detail). Guidance given to Member

---

[25] Guidance on practical arrangement for electronic reporting to the Water Information System for Europe (WISE); “WISE REPORTING ARRANGEMENTS ”; Final Document (01/03/2007)
http://circa.europa.eu/Public/irc/env/wfd/library?l=/framework_directive/w-wise_background/arrangements_1307doc/_EN_1.0_&a=d

States to prepare and report the relevant spatial information should follow this WISE GIS guidance. To cover all necessary aspects a template of a short GIS guidance for specific reporting has been developed (see Appendix 13).

4.4 Management of identifiers and codes

4.4.1 Introduction

Since WISE covers all water related reporting, unique identification of spatial objects and spatial datasets is of fundamental importance for the data management in WISE. Principles of identifier management are given in the data specifications of INSPIRE[26] and also apply to WISE. This Chapter specifies the common framework for the unique identification of spatial objects and the concept for identifier management in WISE. It deals in with specific aspects of identifier management as regards reporting of spatial data by Member States and the development of WISE Reference GIS datasets. Definition of terms – unique identifier, code, etc. – used in this GIS guidance can be found in Chapter 1.3 and Appendix 14.

The application of unique identifiers to spatial objects contributes to data harmonisation. Data harmonisation has two aspects – harmonisation of the content (attributes, metadata) and harmonisation of geometry (horizontal and vertical level). For further detail see Chapter 6.1). Unique identification of spatial objects is necessary to harmonise the content. Furthermore, feature coding is an important component of the linkage between GIS datasets (object referencing).

4.4.2 WISE specific aspects

There will be four main types of datasets available in WISE (see Chapter 1.3): (1) Member State submitted GIS datasets; (2) WISE Reference GIS datasets; (3) Background GIS datasets; and (4) External GIS datasets. The framework for the unique identification of spatial objects provided in this GIS guidance applies primarily to the Member State submitted GIS datasets and the WISE Reference GIS datasets. Background and External GIS datasets will have – in the framework of INSPIRE – their own specifications for identifier management.

Furthermore the spatial feature available in WISE can be classified into:

- **Hydrological features;**
    - River basins and sub basins;
    - Rivers;
    - River segments (reaching from confluence to confluence);
    - Lakes.
- **Non-hydrological features;**
    - Management units such as River Basin Districts, Sub-units, water bodies, sensitive areas, etc;
    - Monitoring stations;
    - Features indicating point source pollution, such as discharge points, waste water treatment plants, etc;

[26] INSPIRE Generic Conceptual Model. D2.5, Version 3 (2008-06-20 ; Drafting Team « Data Specifications » - deliverable D2.6 : Methodology for the development of data specifications. Version 3 (2008-06-20)

- Features indicating pressure information, such as dams, weirs, etc;
- Protected Areas, bathing waters;
- …

Hydrological features should carry a unique **hydrological feature code**. Non-hydrological reference features should be assigned with a **non-hydrological unique object identifier** but should carry the code of the hydrological feature to which they are related as a foreign key.

The **hydrological feature code** is structured in a hydrological sense and takes the drainage system of a river network into account. It follows the principles of the Pfaffstetter coding. This enables rapid manual or automated analyses without the need to refer to GIS. Hierarchical structured coding also tends to ease long-term unique code maintenance.

The **Non-hydrological unique object identifier** should consist of two parts:

- A namespace to identify the data source. This namespace can also include entity type codes;
- A local identifier, assigned by the data provider. The local identifier should be unique within the namespace. It is the responsibility of the data provider to guarantee uniqueness of the local identifier within the namespace.

Further detail about the structure of the hydrological feature code and the non-hydrological unique object identifier are provided in Chapter 5.4.

An important aspect for WISE with regard to unique identifiers will be the **object referencing**[2]. Unique identifiers will be used as primary keys or foreign keys in geographical datasets and databases to allow the linkage of different spatial objects and to reference tabular information to their respective spatial object. Object referencing in WISE will be relevant:

- Between different GIS datasets submitted by Member States, both reported under one and different water related directives (e.g. WFD monitoring stations should be linked to WFD water bodies; sensitive areas reported under the UWWTD directive should be linked to water bodies reported under the WFD);
- Between Member State submitted GIS datasets and WISE Reference GIS datasets (e.g. Member States reported GIS data under WFD should be linked to the WISE Reference GIS dataset "River Basin Districts").

Furthermore the linkage of attribute information (descriptive data) to spatial objects will be relevant for the reporting process (e.g. information related to water bodies like status information to the geographic feature water body; water quality data reported under the SoE process to monitoring stations or water bodies reported under the WFD).

It is strongly recommended that unique identifiers should be provided for spatial objects where references from other spatial objects are expected to be applicable.

Information on how datasets refer to each other will be available in WISE. As soon as a Member State updates a dataset, WISE will send an automatic note to inform the Member State which datasets are related to the one that has been updated. The Member State is responsible for maintaining referential integrity between the related datasets.

4.4.3 Non-hydrological identifier - general requirements and recommendations

According to INSPIRE[27] unique identification of spatial objects is provided by external object identifiers, i.e. identifiers published by the responsible data provider. In case of WISE, the responsible data providers will be the Member States, the EEA with regard to the WISE Reference GIS datasets, and the providers of the Background and External datasets.

The following requirements and recommendations for identifier management are given:

Requirements:

Uniqueness: No two spatial objects of spatial object types shall have the same identifier. The identifier has to be unique within all the spatial objects published in WISE. The identifier shall not be used again if an object is modified.

The same spatial object shall be reported always using the same identifier (e.g. monitoring stations reported to SoE, WFD, Nitrates Directive, etc).

Persistence: The identifier has to remain unchanged during the life-time of a spatial object. If features are re-coded, links to historical data and links to data related to these features will be lost. The specification of every spatial object type shall state which modifications (e.g. attribute changes, merging with other spatial objects) may change the identity of a spatial object, i.e. when the existing object is "retired" and a new object with a new identifier is created. Lifecycle rules for spatial object types in a spatial dataset should be documented in the metadata of the dataset (see Appendix 11 for more details on metadata). It will not be necessary to copy the lifecycle rules to the metadata, a reference to a source that provides information is sufficient.

New identifiers may be created if:

- The location of a point features changes (e.g. if a monitoring station is moved upstream or downstream); threshold 125 m in accordance to the positional accuracy recommended for GIS datasets (according to the scale 1:250,000);
- The location or length of a line feature changes (e.g. if a river water body is divided or merged with another);
- The location or size of a polygon changes (e.g. if a groundwater body is divided or merged with another).

The rules for unique identifiers of spatial objects shall apply for spatial datasets, too.

Recommendations:

The identifier should be as short as possible to avoid typing mistakes, yet as long as is required to support unique code maintenance at local operational levels. Precise structures are a matter for each Member State to decide upon.

---

[27] INSPIRE Generic Conceptual Model. D2.5, Version 3 (2008-06-20)

4.4.4 WISE Reference GIS datasets

WISE Reference GIS datasets will be published by the EEA (see Chapter 3.1). One purpose of these datasets will be to provide a reference for reporting. Member State submitted GIS datasets will be referenced against European-wide harmonised GIS datasets, i.e. WISE Reference GIS datasets. This will facilitate harmonised analysis of reported data and data visualisation.

The EEA will be responsible for the unique identification of spatial objects within WISE Reference GIS datasets, guaranteeing persistence over time. For the time being, identifiers and codes will be developed and maintained at EC level for the following WISE Reference GIS datasets:

- **Hydrological features codes** of the WISE Reference GIS datasets;
    - Main rivers and main lakes (this will include also the coding of the river basins of main rivers and large rivers).
- **Non-hydrological identifiers** of the WISE Reference GIS datasets;
    - River Basin Districts;
    - Sub-units;
    - Water bodies.

The management of the identifiers and codes at European level will include:

- The publication of the identifiers/codes in WISE and the description of their development;
- The registration of the namespace used (including entity type codes if used);
- The description of life-cycle rules of the spatial objects of the WISE Reference GIS datasets;
- An explanation if identifiers/codes have been changed or new identifiers/codes have been created (e.g. change of RBDs or Sub-units) during an update. The respective WISE Reference GIS datasets will be provided to Member States via WISE in time for the next reporting period (including a documentation of new/changed objects/identifiers);
- The description how Member States should use the identifiers/code, including how the referencing of objects provided by Member States to the objects of the WISE Reference GIS datasets will be performed.

4.4.5 Member State submitted GIS data and historical data management

Member States are responsible for the unique identification of spatial objects reported to WISE and to guarantee persistence over time. This applies to the hydrological and non-hydrological features mentioned above. However two major problems arise on implementing these rules:

- Objects in the real world change over time. For example a monitoring station is removed from a network, River Basin Districts are restructured (due to changes in administrative boundaries), etc. Detailed guidelines are required on how to handle identifiers for these spatial cases.

- As the objects are changing over time this also means that foreign keys or references to other datasets may become obsolete.

Member States will be responsible for:

- Maintaining the references between national data submitted to WISE as required by the respective reporting guidelines and described in the WISE data model (e.g. sensitive areas reported under UWWTD linked to water bodies reported under WFD);
- Referencing their spatial objects to the respective objects of the WISE Reference GIS datasets and maintaining these references;
- Maintaining correct linkages between datasets where objects have changed or new objects have been created, and updating all related datasets accordingly (e.g. if a new river water body dataset is submitted, the river monitoring stations also have to be updated because the stations are linked to river water bodies).

4.4.6 Identifier management and object transaction

Depending on the data, the reporting obligations and the intended use of the data, it will be necessary to establish a system that manages temporal changes of non-hydrological features including the identification of predecessors and successors. Changes will occur from one reporting period to another (submission of datasets according to reporting deadlines) but also in between reporting periods (update/resubmission of datasets).

The following changes within GIS datasets are possible:

- Change of identifiers only (e.g. wrong identifier was provided, geometry remains unchanged);
- Change of geometry and identifiers (e.g. a water body is divided);
- Change of geometry only (e.g. wrong geometry was provided, identifiers remain unchanged).

The current situation of reporting to WISE is described in Figure 4.4.1. Sets of spatial object instances having an agreed structure are reported at fixed points in time (reporting deadlines). They describe the situation at a certain reference date. The spatial objects carry identifiers which are unique within the dataset.

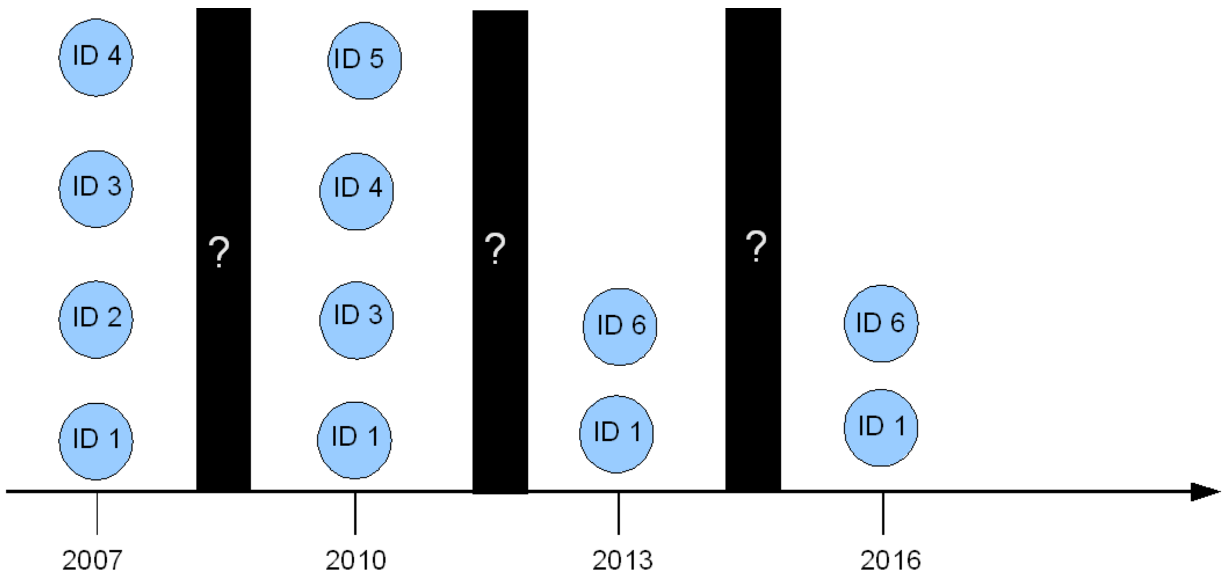

Figure 4.4.1 Time series information in existing reporting practices

Subsequent reporting cycles do not provide any explicit information on previously reported data, so the analysis of temporal development is mainly based on "best guesses", e.g. based on the invariance of names or locations. Analysis with on-going reporting exercises show that it is sometimes very difficult to link currently reported objects to objects reported in previous reporting cycles.

Information on temporal changes is needed for most of the data reported to WISE. WFD reporting demonstrates how data reported under different reporting obligations and at different dates are interlinked.

Example: WFD, water bodies – reporting of risk analysis 2005 and status 2010:

- In 2005 according to Article 5 of the WFD, water bodies at risk of failing to reach good status were reported;
- After this risk analysis, a monitoring network was put in place to obtain information on the status of the water bodies. The monitoring network was reported to WISE in 2007. At this time the first reference to historic data was made. The monitoring stations had to be linked to 2005 reported water bodies. If water bodies changed from 2005 to 2007, the water body dataset should have been updated as well;
- In 2010 the status of water bodies will be reported to WISE. According to the WFD it is necessary to analyse the status of water bodies previously reported in 2005. This can only be done if linkages can be made between the datasets and any changes made to water bodies between 2005 and 2010 are also reported.

Thus the data and update cycles needed to maintain a complete, historic view of the data are dependent on the level of the "temporal coupling" required in WISE. In future WISE should allow the tracking of changes between different data submissions, resubmissions and updates (see Figure 4.4.2 on the proposed history management in WISE).

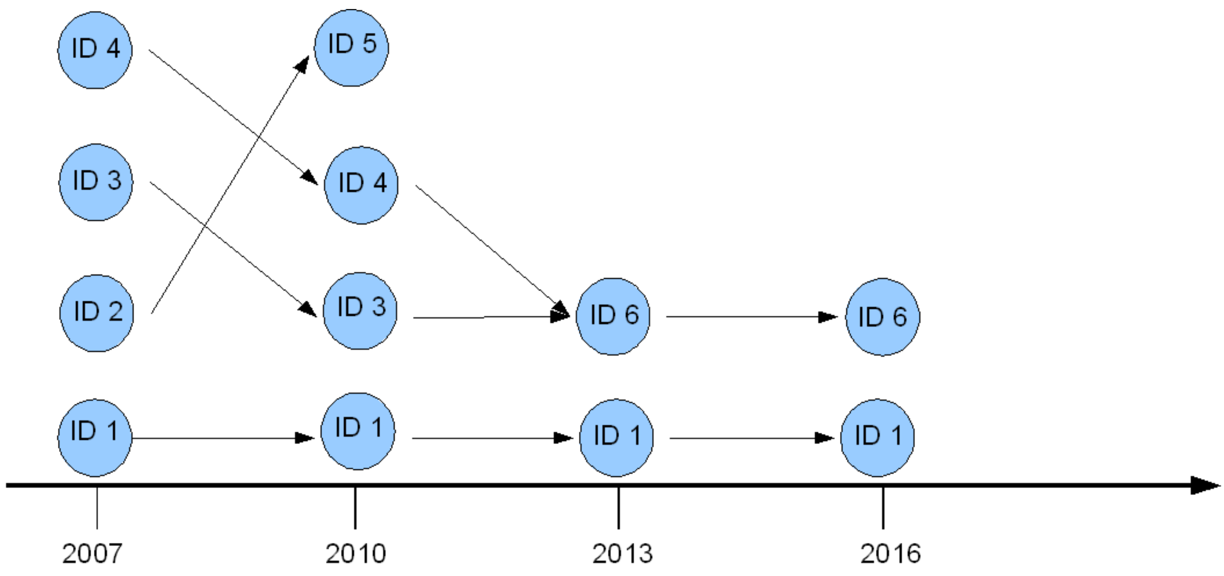

Figure 4.4.2 Proposed history management in WISE

Several concepts exist relating to historic data management and these are described in Appendix 09. In principle either predecessors or successors can be identified. Within each WISE reporting process it should be defined whether historic data management of GIS data is necessary and how this will be achieved. The data model and dataflow should be developed accordingly.

TECHNICAL CHAPTERS

5 Technical Descriptions

5.1 General approach for definition of datasets

	Look out! Guidance may change as INSPIRE and WISE develop *This Chapter has been developed in parallel with INSPIRE developments and discussions at COM and EEA on the implementation of INSPIRE recommendations in WISE. The content and advice may thus change as INSPIRE and WISE develop.*

5.1.1 How to develop the data specifications

The WISE data specifications are targeted towards meeting the needs of a wide audience and should fulfill legal requirements as well as from the GIS technical side. The specifications should be sufficiently unambiguous so when they are applied by GIS specialists throughout Europe they lead to harmonised datasets which, with minimal additional effort, can be viewed and analysed in a comparable way.

INSPIRE is targeted towards providing Europe with a spatial data infrastructure. INSPIRE is developing guidance for the data specification process. The INSPIRE drafting team "Data Specifications" has issued a document "Generic Conceptual Model"[28]. The following figure (Figure 5.1.1) from ISO 19109 ("From reality to geographic data") illustrates the modeling process.

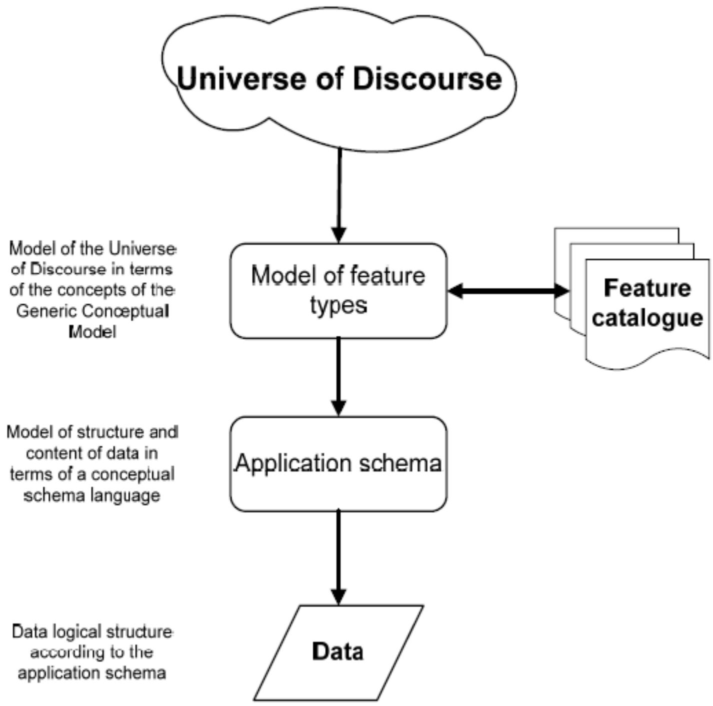

Figure 5.1.1 Data modelling process (from ISO 19109)

[28] http://www.ec-gis.org/inspire/reports/ImplementingRules/inspireDataspecD2_5v2.0.pdf

5.1.1.1 Universe of Discourse

The data modeling process originates in the concepts found in the area of interest described as the “Universe of Discourse”. The concepts are found for example by text analysis of the legislation. The target for WISE application of the developed spatial data is however wider than reporting purely for documentation of legal compliance. The wider applicability thus requires more than a simple analysis of legal texts.

5.1.1.2 Conceptual model

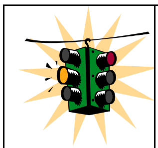
The conceptual model should include all the concepts (not only spatial objects) and their properties (attributes, operations and the relationships that exist among the objects). In this part of the modeling process, the focus is on common understanding and agreement of the concepts (features) involved including the level of details needed (resolution) and the relationships between the concepts. In this phase there are no considerations about technical detail of delivery etc. The WISE outputs from this phase are Reporting sheets (first drafts of feature catalogues) and UML overview diagrams.

5.1.1.3 Application schema

When a common understanding of the concepts involved has been agreed, the application schema may be developed. The application schema is a rigorous description of how the Universe of Discourse should be described as data. The application schema takes the form of UML static structure diagrams (class diagrams) supported by data specifications and a data dictionary. The “INSPIRE Generic Conceptual Model” recommends to express the constraints in OCL (Object Constraint Language) and include them in the UML diagrams. Although preferable for the long term implementation in WISE data flows, the UML diagrams in this guidance do not include constraints.

5.1.1.4 Reporting schemas

The application schema may also be converted and expressed in the logical form specifying the structure for (for example) reporting the data. The WISE reporting schemas have so far taken the simple approach of ESRI shape file templates. Geography Markup Language (GML) may be an alternative to express the reporting schemas in a vendor independent form. GML would be a requirement for compliance with INSPIRE.



Look out! The format of reporting GIS may change

The change to GML schemas is to be confirmed, (see Chapter 5.6)

The INSPIRE drafting team "Data specification" has issued a draft document "Methodology for the development of INSPIRE data specifications[29], which provide further details of the data specification process.

5.1.2 Principles to be applied during data specification work

Article 8 of the INSPIRE Directive provides a set of principles (see text box below) to be applied in the INSPIRE context when defining implementing rules (data specifications) of INSPIRE Annex I and Annex II data. Furthermore, the document "INSPIRE Generic Conceptual model" recommends to apply a "keep it simple" approach to the development of rules for data specifications. Simplicity should be the focus in particular for two aspects:

- The processing and use of (INSPIRE) data should be as simple as possible for users and their software applications.
- For data providers, the transforming/harmonising of their existing data sets should be as simple as possible.

INSPIRE Article 8:

1. In the case of spatial data sets corresponding to one or more of the themes listed in Annex I or II, the implementing rules provided for in Article 7(1) shall meet the conditions laid down in paragraphs 2, 3 and 4 of this Article.

2. The implementing rules shall address the following aspects of spatial data:

(a) a common framework for the unique identification of spatial objects, to which identifiers under national systems can be mapped in order to ensure interoperability between them;

(b) the relationship between spatial objects;

(c) the key attributes and the corresponding multilingual thesauri commonly required for policies which may have an impact on the environment;

(d) information on the temporal dimension of the data;

(e) updates of the data."

3. The implementing rules shall be designed to ensure consistency between items of information which refer to the same location or between items of information which refer to the same object represented at different scales."

4. The implementing rules shall be designed to ensure that information derived from different spatial data sets is comparable as regards the aspects referred to in Article 7(4) and in paragraph 2 of this Article."

[29] http://www.ec-gis.org/inspire/reports/ImplementingRules/inspireDataspecD2_6v2.0.pdf

The "INSPIRE Generic Conceptual Model" also recognises that a major part of INSPIRE data specifications will be the result of a harmonisation process based on existing data specifications. The situation regarding WISE data will, to large extent, also be based on the harmonisation of existing data.

From the first years of WFD implementation a number of useful principles can be provided which help a smoother process of data specification. The principles include:

- Use UML models for communicating the relationship between concepts. The UML modelling (graphic) language is becoming a de facto standard, which is also recommended by INSPIRE guidance documents. The graphic models present the complex relationships in a simple way to an audience with a non-technical background. The UML models help in analysing the relationships between data;
- Be clear and explicit in describing the intended content. In areas where different communities apply a similar terminology and/or set of concepts, confusion may arise from the fact that the perception and interpretation of the concept may originate in different approaches. The perspective on a particular concept will be different depending on the tradition of application. The *implicit* understanding of a concept by each party may thus be different and should be made *explicit*. If ambiguity of terms is suspected the semantics should be supported with clear rules for (for example) data capture and validation;
- Clarify expected resolution and spatial properties. As a major part of the (harmonised) data in question will originate from existing data collections, the issue of data capture is very important. If only a subset of a particular feature class is expected the selection criteria should be specified. Similarly, if the set of features is expected to have certain application properties, e.g. main rivers are expected to be connected through lakes and artificial stretches (canals) and have an outlet at the coastline;
- Be clear on how the object will be identified (primary identifier). Each object should have at least one persistent unique identifier. The identifiers should be of data type text string. Although slower in matching and indexing, the use of text string prevents problems with different numerical encoding;
- Consider the separation of the geometry and primary identifier from other attributes in reporting specifications;
- Keep the spatial feature class slim. Usually several attributes may be assigned to a specific feature class. Care should be taken that only stable attributes are included in the class. Attributes describing a state or a classification subject to a potential change should be modelled in separate tables and linked through unique identifiers. In a similar way, attributes which can be deduced from spatial relationships with other spatial objects should be avoided. During a reporting delivery cycle some redundant information may be included for verification purposes;
- Attribute names should be informative;

- Codelists for attributes should be applied to the maximum extent possible. Wherever possible attribute domains should be enumerated and explained to reduce ambiguity;
- When an attribute contains geographic names, the language as well as the character set allowed should be made clear.

5.1.3 General specifications

5.1.3.1 Spatial reference system

The use of a common geodetic datum (horizontal and vertical) is a first step towards the harmonisation of geographic information across Europe. The adoption of a common reference system makes it possible to maintain seamless distributed spatial data set, assigned to different custodians and avoiding or simplifying the work of geometric harmonisation. A common geodetic datum is particularly important for GIS users who require a seamless dataset. Furthermore, the fact that spatial data provided by Member States is often insufficiently documented (e.g., the used Datum may be unknown or only partially or ambiguously described), is a source of error when national data are converted to a European system. To avoid these problems, it will be the responsibility of Member States to provide data according to the proposed European datum.

ETRS89[30] is recognised by the scientific community as the most appropriate European geodetic datum to be adopted. It is defined to 1cm accuracy, and is consistent with the global ITRS[31]. ETRS89 is now available due to the creation of the EUREF[32] permanent GPS station network and the validated EUREF observations.

For islands not belonging to the European continental landmass the use of ETRS89 may not be applicable. For those areas the WGS84 (World Geodetic System 1984) should be used as the geodetic datum.

The IAG[33] sub-commission for Europe (EUREF) has defined a European vertical datum based on the EUVN[34] /UELN[35] initiative. The datum is named the EVRS[36] and is realised by the EVRF2000.This vertical datum should be applied for deliveries requiring absolute 3-D coordinates.

The National Mapping Agencies (NMA) (or comparable institutions and organisations) provided the information for the descriptions of the national Coordinate Reference Systems and for the transformation parameters between the national Coordinate Reference Systems and the European Coordinate Reference System ETRS89. Formulae can be requested from the NMAs or are directly accessible at http://crs.bkg.bund.de/crs-eu/.

---

30 ETRS : European Terrestrial Reference System; EPGS code 3035, http://www.epsg-registry.org/
31 ITRS : IERS Terrestrial Reference System (IERS : International Earth Rotation Service)
32 EUREF : European Reference Frame
33 IAG : International Association of Geodesy
34 EUVN : European Vertical Reference Network
35 UELN : United European Levelling Network
36 EVRS : European Vertical Reference System

We make the following recommendations:

Spatial Reference System:

- To adopt ETRS89[37] as geodetic datum and to express and store positions in ellipsoidal co-ordinates (decimal degrees), with the underlying GRS80 ellipsoid [ETRS89];
- To use the official formulae provided by NMAs or comparable National Institutions for the transformation between National Co-ordinate Reference systems and the ETRS89;
- To document National Co-ordinate Reference systems according to ISO19111;
- To further adopt EVRF2000 for expressing practical heights (gravity-related).

5.1.3.2 Geometric representation

The spatial features may be represented using simple geometry types only (i.e. points, lines, polygons). Optionally, a part of the same set of real world entities could be modeled as a simple or complex network.

Linear referencing systems and topologic networks are supported in some GIS systems and have been applied in several Member States. The implementation may be performed in several ways and the exchange of data between systems is not yet adequately supported. Although the two data structures have many benefits in data management as well as spatial analysis, the application of linear referencing and topologic network is thus not recommended for the data specification work inside WISE.

Network analysis may however be supported using the hydrological feature coding approach described in Chapter 5.4, provided that the simple lines reported are geometrically connected (node to node). Needs for later network analysis should be reflected in the topology rules in the specific data specifications.

When specifying the spatial properties in the application schema it is recommended to apply only the following simple geometry types (See Table 5.1.3.2, from ISO 19107 Geographic Information –Spatial Schema").

Table 5.1.3.2 Recommended ISO Geometry types

ISO Geometry types	**Description**
GM_Point	Single point features
GM_MultiPoint	Multi-point features
GM_LineSegment	A line-segment between two vertices
GM_LineString	A line composed of simple line-segments
GM_Polygon	Polygon features

[37] Except for islands out of the European continental landmass, here WGS84 should be applied.

5.1.3.3 Scale, resolution and positional accuracy

When specifying the spatial data characteristics, the (recommended) scale of the visualisation of data can be regarded as an indicator of the resolution (which level of detail is available for map making). In the WISE context, where data mainly are based on harmonisation of existing, more accurate, national data, the traditional perspective of the scale as an indicator of positional accuracy (which is the possible difference between the true real world co-ordinates and the co-ordinates of the data) is less relevant though positional accuracy by itself is very important.

The resolution determines both the size of the smallest object in the data set and the amount of detail that might be discerned. On a large scale map (i.e. 1:250.000) a river is presented with more points than on a small scale map (i.e. 1:1.000.000), where, for example, small meanders may not be visible. While in theory a dataset at 1:1.000.000 scale might cover the same set of entities (objects) as a dataset at 1:250.000 scale, the latter can present the information in a better way (i.e. the positional accuracy is higher and the shapes of the entities are represented more accurately). Showing a dataset intended for large scale use e.g. 1:50.000 of a meandering stream together with a dataset with an intended scale of 1:250.000 without prior generalisation will emphasise the large scale data. The large scale streams give the impression of being drawn with a broader (but uneven) line symbol. The generalisation rules may be defined as "the features should be registered by as few co-ordinate pairs as possible, though the distance between a vertex and the true position of the feature should never exceed 125 metres". The value of 125 metres can be considered as the simplification tolerance.

Member States are recommended not to simplify spatial data before submitting to WISE. The accuracy of the data should however be documented in the metadata so the simplification process performed in WISE during e.g. reference data production can respect the original accuracy.

If linear or area entities are represented as points (centroids) these should be 'geometric' centroids in the sense that the point should fall inside a polygon representation or for linear features be a point on the line. It is generally recommended not to apply centroids as the representation for features. Whether a given entity is at all represented in a data set is specified by the harmonisation component "Data Capture."

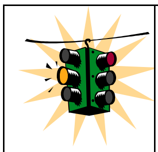
The generally agreed scale of presentation in WISE ranges from 1:250.000 to 1:10.000.000.

The following table (Table 5.1.3.3) shows the relationships between scale, resolution, simplification tolerance and spatial (positional) accuracy.

Table 5.1.3.3 The relationship between scale, resolution, simplification tolerance and spatial accuracy

Scale	Resolution	Simplification tolerance	Spatial accuracy
1:250.000	0.5 km^2	125 metres	125 metres
1:1.000.000	8 km^2	500 metres	500 metres

1:10.000.000	800 km^2	5000 metres	5000 metres



Look out! The requirement for accuracy has been modified

The previous guidance document had a spatial accuracy of 1000 metres. It has been evaluated that the accuracy of the spatial datasets have improved and an accuracy better than 500 metres may be expected.

Considering both the WISE needs and the practical constraints of data availability, the GIS Working Group recommended that the required positional accuracy for reported data should be better than 125 metres. The positional accuracy should always be kept as high as possible and ideally be similar to the national operational datasets.

5.1.4 Data layer characteristics

From the "INSPIRE Generic Conceptual Model" an overview of necessary harmonisation components can be provided, see Figure 5.1.4. Each of the harmonisation components contributes with a specific element to the data specifications. Table 5.1.4 further elaborates the scope of each of the harmonisation components.

For the development of WISE GIS data specifications, (see Chapters 5.2 and 5.3 and Appendices 05 and 06) a subset of the component are considered. For some of the component a few decisions cover all WISE layers. As an example, the previous GIS guidance (as well as the current) recommends to adopt ETRS89 as the geodetic datum and to express and store positions, as far as possible, in ellipsoidal coordinates, with the underlying GRS80 ellipsoid [ETRS89]. This is a part of the general specifications which (partly) fulfil the component "(G) Coordinate referencing and units model".

Other harmonisation components are considered in Chapters 5.4 to 5.7 and 6.1.

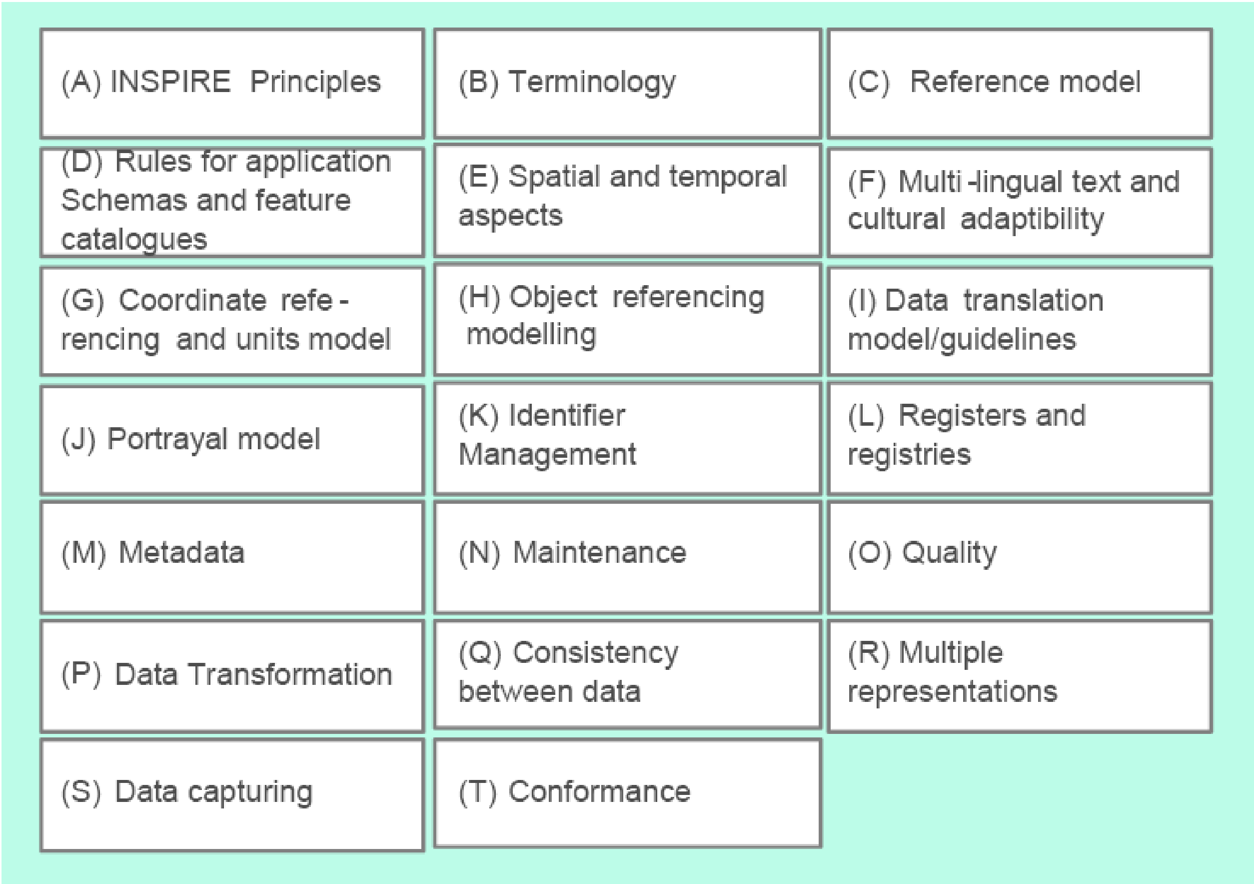


Figure 5.1.4 Data Harmonisation Components from INSPIRE D2.5 Generic Conceptual Model

Table 5.1.4 Scope of INSPIRE harmonisation components from INSPIRE D2.5 Generic Conceptual Model

Component	**Description**
(A) Principles	The principles cited in recital (6) of the Directive are considered to be a general basis for developing the data harmonisation needs. The first three of the five principles are to be considered to help define the data harmonisation process: • *That spatial data are stored, made available and maintained at the most appropriate level;* • *That it is possible to combine spatial data from different sources across the Community in a consistent way and share them between several users and applications;* • *That it is possible for spatial data collected at one level of public authority to be shared between other public authorities.*
(B) Terminology	This component will support the use of a consistent language when referring to terms via a glossary. This needs to be registered and managed through change control with multi-lingual support. The ESDI needs to select a common terminology from all of the existing terminologies and/or their translations.
(C) Reference model	This component will define the framework of the technical parts including topics like information modelling (i.e. conceptual modelling framework with rules for application schemas) and data administration (i.e. reference systems). It will provide a structure which allows the components of INSPIRE which are related to data specifications to be described in a consistent manner.
(D) Rules for application schemas and feature catalogues	The purpose of this component is to • Provide a computer-readable data description defining the data structure - enabling automated mechanisms for data management; • Achieve a common and correct understanding of the data, by documenting the data content of the particular theme, thereby making it possible to unambiguously retrieve information from the data. Feature catalogues define the types of spatial objects and their properties (attributes, association roles, operations) as well as constraints and are indispensable to turning the data into usable information. Feature catalogues promote the dissemination, sharing, and use of geographic data through providing a better understanding of the content and meaning of the data. The full description of the contents and structure of a spatial dataset is given by the application schema which is expressed in a formal conceptual schema language. The feature catalogue defines the meaning of the spatial object types and their properties specified in the application schema. Text elements in the feature catalogues should be maintained at least

	in the official European languages.
(E) Spatial and temporal aspects	Conceptual schema for describing the spatial and temporal characteristics of spatial objects: • Spatial geometry and topology; • Temporal geometry and topology; • Coverages (examples of coverages include rasters, triangulated irregular networks, point coverages, and polygon coverages); • etc. While the component "reference model" specifies an overall framework, this component deals with the spatial and temporal aspects in more detail, for example, the types of spatial or temporal geometry that may be used to describe the spatial and temporal characteristics of a spatial object.
(F) Multi-lingual text and cultural adaptability	Conceptual schema for multi-lingual character strings in spatial objects and supporting information: • To be used in all application schemas and as a result in data instances: all string valued properties that may be provided in a language shall use this type; • To be used in the dictionary model so that dictionaries may be multi-lingual, e.g. the feature catalogue, the feature concept dictionary or codelists. Since the feature catalogue and the feature concept dictionary are multilingual, the definition and names of all spatial object types, their attributes/associations and their attribute values provided by enumerations/codelists are multi-lingual. So far representation of constraints in the different languages has not been formally required, but such a requirement may be added in the future. At the moment, it is not planned to document the formal application

	schema (classes, attributes, associations, constraints) in multiple languages as the definitions are part of the feature catalogue and data dictionary. In principle, cultural differences have to be taken into account, e.g. not all terms may be translatable from one language to another. Furthermore, cultural differences between communities working in the same language can be at least as much a problem as multi-lingual issues. Ontologies may help to capture multi-cultural aspects.
(G) Coordinate referencing and units of measurement model	This component will describe methods for spatial and temporal reference systems as well as units of measurements – including the parameters of transformations and conversions. The focus is on reference systems that are valid across Europe (in case of projected systems split into zones this will be a collection of such systems covering the different zones). This component will also support European geographical grids.
(H) Object referencing modelling	This component will describe how information is referenced to existing objects, typically base topographic objects, rather than directly via coordinates. It will be specified how the spatial characteristics of a spatial object can be based on already existing spatial objects. As a result, this component will support the generation and maintenance of application-specific "user geographies" based on reference data. The aim is to promote the easy and reliable exchange of data that is associated with spatial objects (e.g. river quality sample records) across several users who use a common base (thus avoiding spatial inconsistencies and massive data transfers to support regular reporting).The approach improve data integrity across distributed systems and services as well as more reliable data sharing. Object referencing is especially relevant in referencing spatial objects of Annex III themes to those of the themes in Annex I and II.
(I) Data translation model / guidelines	This component is about translating from a national/local application schema to the INSPIRE application schema and vice versa. Translations are required for data and for queries. NOTE No well-defined set of translation capabilities has been standardised in the GI community at this time. It is not yet clear, if there will be a need to specify translations also between different European application schemas, e.g. for different representations or for creating specific information products, e.g. for reports or from base data etc. Also, further research would be required to identify how consistent adoption of ontologies could be exploited here.
(J) Portrayal model	This component will define a model for portrayal rules for data according to a data specification. It will clarify how standardised portrayal catalogues can be used to harmonise the portrayal of data.
(K) Identifier management	Spatial objects from Annexes I and II should have an external object identifier. This component will define the role and nature of unique object identifiers (or other mechanisms) to support unambiguous

	object identification. To ensure uniqueness some form of management system will be required. This does not mean that all organisations need to adopt a common form of identifier or other mechanism but the identifier management mechanisms (e.g. registers) in use at national level will need to be synchronised/mapped to ensure pan European integration. Note that the same real-world phenomenon may be represented by different spatial objects (with their own identifiers).
(L) Registers and Registries	Registers will at least be required for: • All reference systems used in spatial data sets; • All units of measurement used in spatial data sets; • All codelists / thesauri used in the application schemas (multi-lingual, at least in all official European languages); • The feature concept dictionary for elements used by application schemas (multi-lingual, at least in all official European languages); • Identifier namespaces; • All feature catalogues; • All application schemas. The registries will be available through registry services. Metadata on dataset level will be available through catalogue services.
(M) Metadata	This component will cover metadata on the following levels: • Discovery; • Evaluation; • Use. Metadata associated with individual spatial objects will in general be described as part of the application schemas.
(N) Maintenance	This component will define best practice in ensuring that application data can be managed against updates of reference information without interruption of services. This will require the definition of mechanisms by different stakeholder areas to manage where this is required and it is feasible: • Change only updates; • Versioning of objects (and their properties); • Object lifecycles. Propagation of changes across scale and between dependent objects is required in general to maintain consistency of the data (automatic or manual processes).
(O) Data & information quality	This component will advise the need to publish quality levels of each spatial dataset using the criteria defined in the ISO 19100 series of standards, including completeness, consistency, currency and

	accuracy. This will include methods of best practice in publishing: • Acceptable quality levels of each spatial dataset; • Attainment against those levels for each spatial dataset. Quality information associated with individual spatial objects is part of the metadata associated with the respective spatial object (see component "Metadata") and will in general be described as part of the application schemas.
(P) Data transfer	This component will describe methods for encoding application and reference data as well as information products. The encoding of spatial objects will in general be model-driven, i.e. fully determined by the application schema in UML. To support network services that are implemented as web services, spatial objects are expected to be primarily encoded in XML/GML for the exchange of spatial data. Coverage data is expected to use existing encodings for the range part.
(Q) Consistency between data	This component will describe guidelines how the consistency between the representation of the same entity in different spatial datasets (for example along or across borders, themes, sectors or at different resolutions) shall be maintained. The custodians of such spatial datasets will decide by mutual consent on the depiction and position of such common spatial objects or they will agree on a general method for edge-matching or other automatic means to maintain data consistency.
(R) Multiple representations	This component will describe best practices how data can be aggregated: • Across time and space; • Across different resolutions ("generalisation" of data). Such aggregation processes are used in particular to create the following results: • Multiple representations; • Derived reporting (example: typically water samples at 1 km intervals are reported to the European level).
(S) Data capturing rules	This component will describe the data specification-specific criteria regarding *which* spatial objects are to be captured and which locations/points will captured to represent the given spatial object (e.g. all lakes larger than 2 ha, all roads of the Trans European Road Network, etc.). For INSPIRE data specifications it is in general not relevant, *how* the data is captured by the data providers.
(T) Conformance	This component will describe how conformance of data to a data specification is tested, i.e. it will be necessary to apply conformance tests as specified in the individual data specification. Ideally these will be automated.

	In addition, all INSPIRE data specifications will conform to the Generic Conceptual Model as well as, since Data Specifications are specified using ISO 19131 (Data product specification), to ISO 19131.

5.2 Overview of the GIS layers and their relationships

5.2.1 Overview of GIS layers

WISE provides a repository for a wide range of GIS datasets. These datasets include those compiled by Member States for regulatory reporting and for other voluntary purposes as well as the WISE Reference GIS datasets.

Each set of data is termed a theme. The themes within WISE are:

1. **WISE Reference GIS datasets***
2. **Member State submitted GIS datasets, including data relating to:**
   - Water Framework Directive;
   - State of the Environment Reporting (WISE-SoE);
   - Urban Waste Water Treatment Directive;
   - Bathing Waters Directive;
   - Nitrates Directive*;
   - Drinking Water Directive*;
   - Floods Directive*;
   - Marine Strategy Directive*;
   - E-PRTR.*

* Data models are not yet available for these themes.

The WISE viewer also accommodates a number of background and external GIS data sets – a list of these datasets may be found in Appendix 05.

Further details of the GIS layers in each theme are provided below. The availability in WISE indicates when data have been accepted and entered into the WISE production data bases.

An updated list of publicly visible layers can be found at: http://www.eea.europa.eu/themes/water/mapviewers.

5.2.1.1 WISE Reference GIS datasets (based on WFD reporting)

Layer Code	Layer Name	Feature Type	Availability in WISE
Large Rivers and Large Lakes			
REF1a	Large Rivers	Line	2007
REF1b	Large Lakes	Polygon	2007
Main Rivers and Main Lakes			
REF2a	Main Rivers	Line	2009
REF2b	Main Lakes	Polygon	2009

Layer Code	Layer Name	Feature Type	Availability in WISE
Water Bodies			
REF3a	River Water Bodies	Line/Point	2007
REF3b	Lake Water Bodies	Polygon/Point	2007
REF3c	Transitional Water Bodies	Polygon/Point	2007
REF3d	Coastal Water Bodies	Polygon/Point	2007
REF3e	Groundwater Bodies	Polygon/Point	2007
River Basin Districts			
REF4	River Basin Districts	Polygon	2007
Sub-units			
REF5	Sub-units	Polygon	2009

5.2.1.2 Member State submitted GIS datasets

- **Water Framework Directive**

Layer Code	Layer Name	Feature Type	Availability in WISE
Article 3			
WFD_RBD1	River Basin Districts	Polygon	2007
WFD_RB1	River Basin, Sub-basin	Polygon	Not yet available but reported
WFD_SW1a	Main River	Line	Part of REF2A
WFD_SW1b	Main Lakes	Polygon	Part of REF2B
WFD_SW1c	Transitional Waters	Polygon	Part of REF4
WFD_SW1d	Coastal Waters	Polygon	Part of REF4
WFD_GW1	Groundwaters	Polygon	Part of REF4
WFD_CA1	Competent Authorities	Point	2007
Article 5			
WFD_SW2a	River Water Bodies	Line/Point	2007
WFD_SW2b	Lake Water Bodies	Polygon/Point	2007

Layer Code	Layer Name	Feature Type	Availability in WISE
WFD_SW2c	Transitional Water Bodies	Polygon/Point	2007
WFD_SW2d	Coastal Water Bodies	Polygon/Point	2007
WFD_GW2	Groundwater Bodies	Polygon	2007
WFD_PA1	Drinking Water Protected Areas	Polygon	Not yet available but reported
WFD_PA2	Economically Significant Aquatic Species Protected Areas	Polygon	Not yet available but reported
WFD_PA3	Recreational Waters Protected Areas	Point	Not yet available but reported
WFD_PA4	Nutrient-Sensitive Protected Areas[38]	Polygon	Not yet available but reported
WFD_PA5	Habitats Protected Areas	Polygon	Not yet available but reported
WFD_PA6	Birds Protected Areas	Polygon	Not yet available but reported
Articles 7 and 8			
WFD_SW3a	Operational Monitoring Sites	Point	2008
WFD_SW3b	Surveillance Monitoring Sites	Point	2008
WFD_SW3c	Drinking Water Abstraction Points from Surface Water	Point	Not yet available
WFD_SW3d	Investigative Monitoring Sites	Point	Not yet available but reported
WFD_SW3e	Reference Monitoring Sites	Point	2008
WFD_GW3a	Groundwater Monitoring Network	Point	2008
WFD_GW3b	Operational Monitoring Network Chemical	Point	2008

[38] Nutrient sensitive protected areas means sensitive areas and their catchments falling under Urban Waste Water Treatment Directive (91/271/EEC), and Nutrient Vulnerable Zones falling under Nitrates Directive (91/676/EEC). It shall be ensured that if these are reported under UWWTD and NiD there will be no request for reporting those under WFD (2000/60/EC), as the reported geo-data/files will have the same requirements/structure for reporting and the link between UWWTD and WFD and NiD and WFD will be clearly identified by the Member States when reporting both ways (for WFD or NiD&UWWTD).

Layer Code	Layer Name	Feature Type	Availability in WISE
WFD_GW3c	Surveillance Monitoring Network Chemical	Point	2008
Other data requested by the European Commission			
WFD_SU1	Sub-units	Polygon	2009
WFD_ECO1	Ecoregions	Polygon	Not yet available but reported

- **State of the Environment Reporting (WISE-SoE)**

Layer Code	Layer Name	Feature Type	Availability in WISE
SOE1	WISE-SoE River Stations	Point	Yearly
SOE2	WISE-SoE Lake Stations	Point	Yearly
SOE3	WISE-SoE Quantity Stations	Point	Yearly
SOE4a	WISE-SoE Transitional, Coastal and Marine Water Stations	Point	Yearly
SOE4b	WISE-SoE Transitional, Coastal and Marine Water Flux Stations	Point	Not yet available
SOE5a	WISE-SoE Groundwater Bodies	Polygon	Not yet available but reported
SOE5b	WISE-SoE Groundwater Sampling Sites	Point	Not yet available
SOE5c	WISE-SoE Groundwater Saltwater Intrusion	Polygon/Point	Not yet available but reported

- **Urban Waste Water Treatment Directive**

Layer Code	Layer Name	Feature Type[39]	Availability in WISE[40]
UWWT1	Agglomerations	Point	2008
UWWT2	Urban Waste Water Treatment Plants	Point	2008

[39] Point feature types (e.g. agglomerations, treatment plants, discharge points) layer can be generated from the tabular data (coordinates) provided by the Member State when reporting under UWWTD
[40] Geo-data in sense of the Shapefiles of sensitive areas and their catchments was requested by the Commission for the first time in UWWTD questionnaire of 2007 for the reference year 2005 or 2006 (Member States could choose the reference year to report).

Layer Code	Layer Name	Feature Type[39]	Availability in WISE[40]
UWWT3	Discharge Points	Point	Not yet available but reported
UWWT4	Sensitive Area - River	Line	Not yet available but reported
UWWT5	Sensitive Area - Lake	Polygon	Not yet available but reported
UWWT6	Sensitive Area – Coastline	Line	Not yet available but reported

Layer Code	Layer Name	Feature Type	Availability in WISE

Layer Code	Layer Name	Feature Type	Availability in WISE
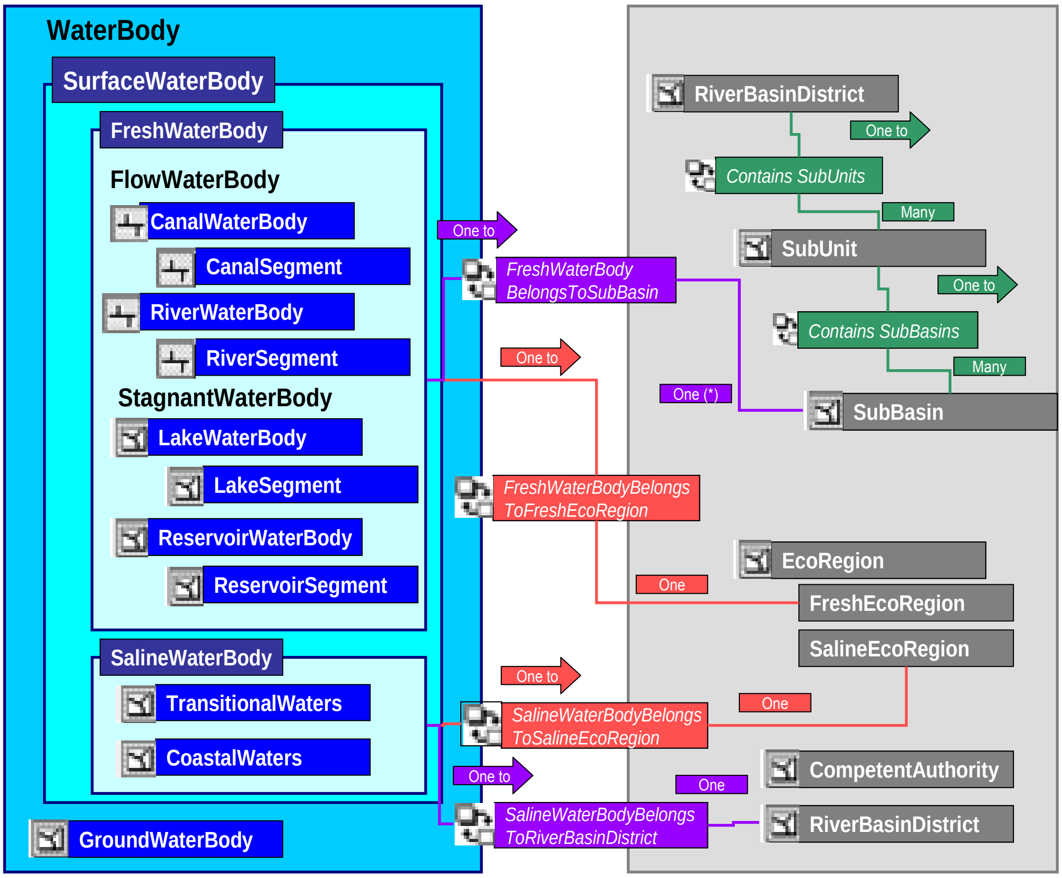
EPRTR1	Location of Sites	Point	EPER 2006

Detailed information on the GIS layers within each theme, including technical data specifications as defined by the INSPIRE Data Specification Methodology, is available in Appendix 05.

Under the WFD reporting requirements, several of GIS layers will have relationship to each other. Figure 5.2.1 shows the relationship between the WFD Articles 3 and 5 submitted data.



(*) A canal may belong to many subbasins, depending on how it was constructed

Figure 5.2.1 Relationship between features reported under WFD Articles 3 and 5

Further information on the data models associated with each of the themes is available in Chapter 5.3 and Appendix 06.

Data models and schemas are made available at the schema repository on the web site of the European Topic Centre on Water[43].

Short reporting guidelines are being developed for each obligation, see the template in Appendix 13.

[43] http://water.eionet.europa.eu/schemas/dir200060ec

5.3 Data Model

5.3.1 Purpose of the data model

Data models and data modeling are used in many parts of information system design and are also an important element of WISE development and documentation. Data models define the interaction between objects and their associated attribute information.

Data modeling is the first step in database and data exchange design: it is the blueprint from which the data structures and database will be built. By modeling, complexity is reduced in order to understand the essence of the data and its relationships.

Data models provide the basis of a common understanding of all of the features in a database, and how they can be used and accessed. Data models also aim to encourage consistency in data structures and so facilitate improved data sharing.

Data models describe how objects relate and link to other objects and also describe the attribute information associated with the objects. These descriptions are termed ‘data dictionaries’.

The use of the modeling language UML (Unified Modelling Language) is recommended by the INSPIRE Directive[44]. UML as well as other modeling languages, in conjunction with data dictionaries, are used to describe the data models in WISE.

There are other conventions that describe the basic building blocks required for data modeling, namely:

- Structure diagrams that describe the inter-relationships between objects;
- Entity descriptions that describe the data object types and their attributes;
- Data dictionaries that provide detail about each attribute.

The use of other modeling conventions are therefore acceptable if the data modeling work has already been completed, in particular where schemas have been defined that can be used to automatically generate data dictionary definitions.

Data models and data dictionaries describe the inter-relationships of objects in each of the WISE datasets, or themes, and their associated attribute information. The data dictionary will include the following detail: field name, text description, field type and length, flag to indicate whether the field is mandatory or optional, any restrictions and enumeration or code lists (see Appendix 06).

5.3.2 INSPIRE – WISE models

The INSPIRE Directive requires that data structures used by multiple themes are modelled against a common conceptual model for a European Spatial Data Infrastructure, taking into account the following:

- Abstract types are used to model properties shared by objects across the different themes;

[44] http://inspire.jrc.ec.europa.eu/

- The conceptual model includes generic mechanisms to support simple integration or inter-linking of objects based on a common methodology for references to other features;
- A minimal base application schema is developed and types are moved to the base schema as become of general use.

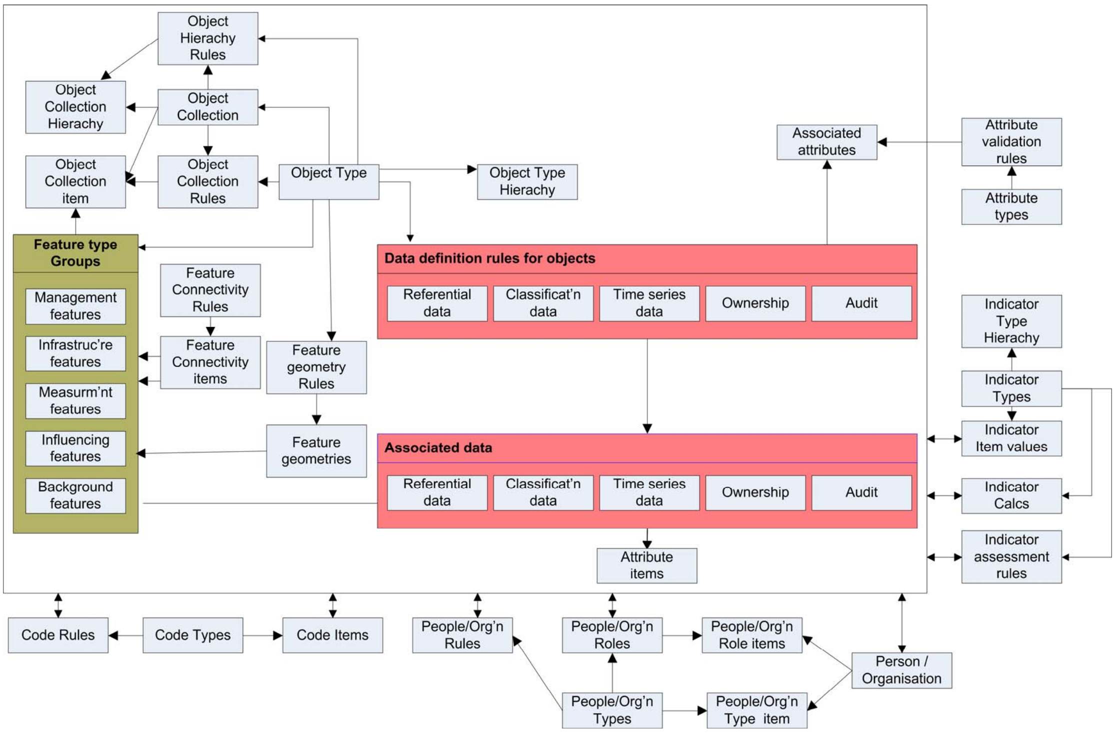


Figure 5.3.1 WISE conceptual model

The purpose of the WISE conceptual model is to identify commonality and to determine the building blocks that will enable integration and harmonisation. It is not the intention to create a single data model or database holding all data.

The WISE conceptual model is a meta-model and does not replace the data models associated with each theme within WISE, but allows the data for the themes to be put into the context of WISE, identifying inter-operability and harmonisation.

5.3.3 Description of the WISE conceptual model

Each geographic object (feature) falls into one of five group types:

- **Infrastructure features** - the basis of the water environment, e.g. rivers, lakes, groundwater, coastal waters, etc;
- **Management features** – the features used in sub-dividing the water environment into manageable units, e.g. River Basin Districts, water bodies and Sub-units;
- **Influencing features** – features that impact upon the water environment, e.g. Urban Waste Water Treatment Plants, Discharge Points, etc;
- **Measurement features** – where measurements are made on the above features, e.g. monitoring stations, gauging stations, sampling points, etc;

- **Background features** – features and objects that provide context to the above, e.g. cadastral maps, CCM, Corine Land Cover, etc.

Each feature has a specific feature type. Each feature type falls within a feature type hierarchy. For example, WaterBody can be sub-divided into SurfaceWaterBody and GroundwaterBody.

Each feature type has data associated with it. Data attributes are sub-divided into the following discrete types of data:

- **Referential data** - e.g. description, name;
- **Classification data** - e.g. typology;
- **Time series data** - e.g. value, unit of measurement, parameter, etc;
- **Ownership data** - e.g. responsible authority, External GIS dataset owner, etc;
- **Audit data** - e.g. date created, date last updated, etc.

Each of these types of data may be time-stamped as detail may change over time and the history may need to be retained.

Features can be grouped to form collections of objects, e.g. catchments, River Basin Districts, etc. Collection objects fall within a hierarchy, e.g. River Basin Districts contain Sub-units. Rules, based on feature type, determine which features can be grouped into collections of features. A collection object can also have attribute data associated with it, e.g. a River Basin District has associated referential, ownership and audit data.

Features also have a connectivity associated with them, e.g. monitoring station (measurement feature type) to river (infrastructure object), etc. Rules ensure that valid connectivity is defined. Connectivity rules will also be required for some collection features, e.g. catchment A flows into catchment B.

Calculation and assessment rules are identified to enable presentation and analysis.

Data standards are required to enable integration and ensure inter-operability. They apply to defined attributes and include the validation that should be applied, the rules needed to determine values, and the common codes that should be agreed and maintained so that common values can be shared across different datasets.

The WISE conceptual model recognises that there will be a need to maintain an agreed set of users and organisations. The data model identifies the need to determine ownership at various levels either through an organisation or a person within that organisation and to declare what role that user or organisation is undertaking.

5.3.4 Examples of the use of the WISE conceptual model

The various feature types can be grouped in accordance with their overall clasification.

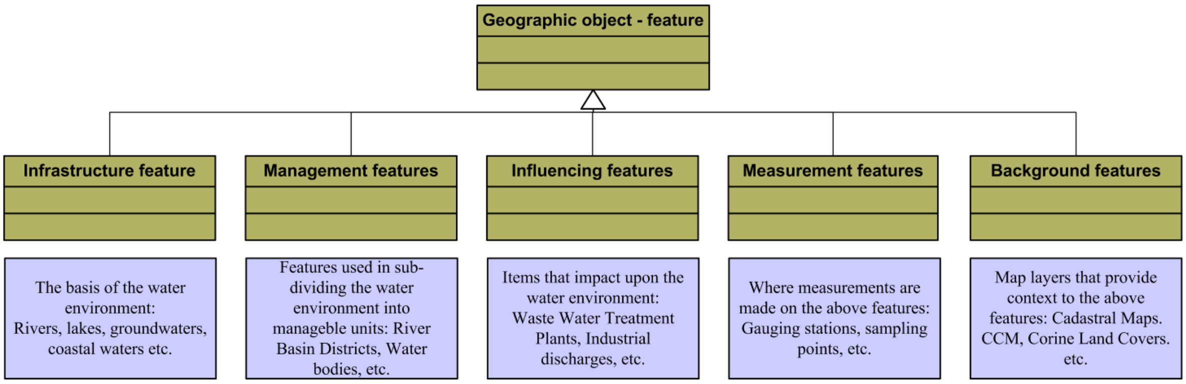

Figure 5.3.4a Groups of WISE feature types

Objects can be grouped into collections of objects, have sub-types and have attribute data. Relations between objects and feature types are also illustrated in the following diagram.

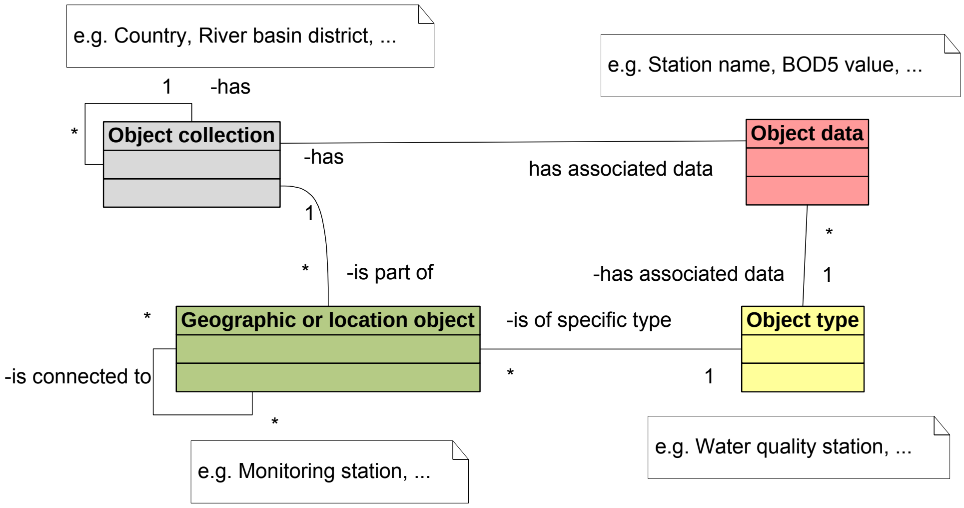

Figure 5.3.4b Example of relationships between objects and features

Objects can be part of hierarchies, as illustrated below.

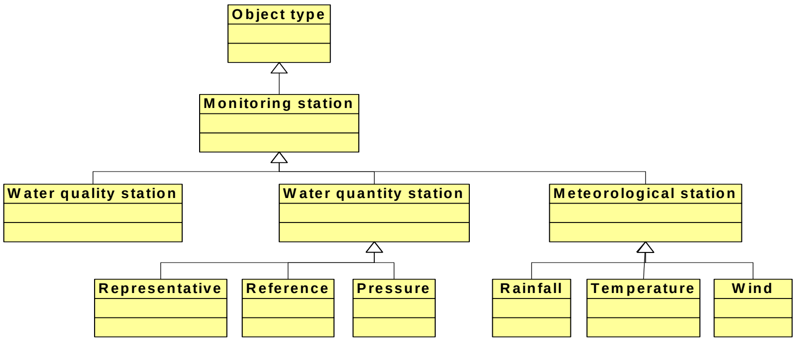

Figure 5.3.4c Object type hierarchies

Objects can have different types of data attributes associated with them.

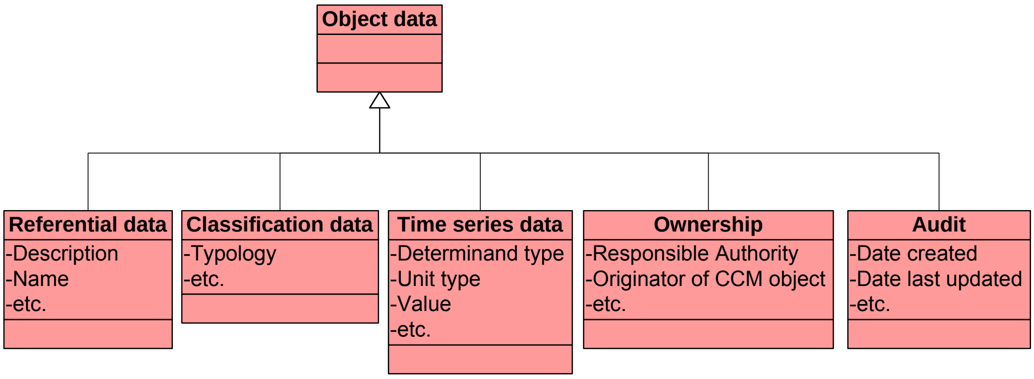

Figure 5.3.4d Types of attributes associated to objects

A transformation model can be used to describe data in terms of the WISE conceptual data model. This example refers to data relating to the Bathing Waters Directive.

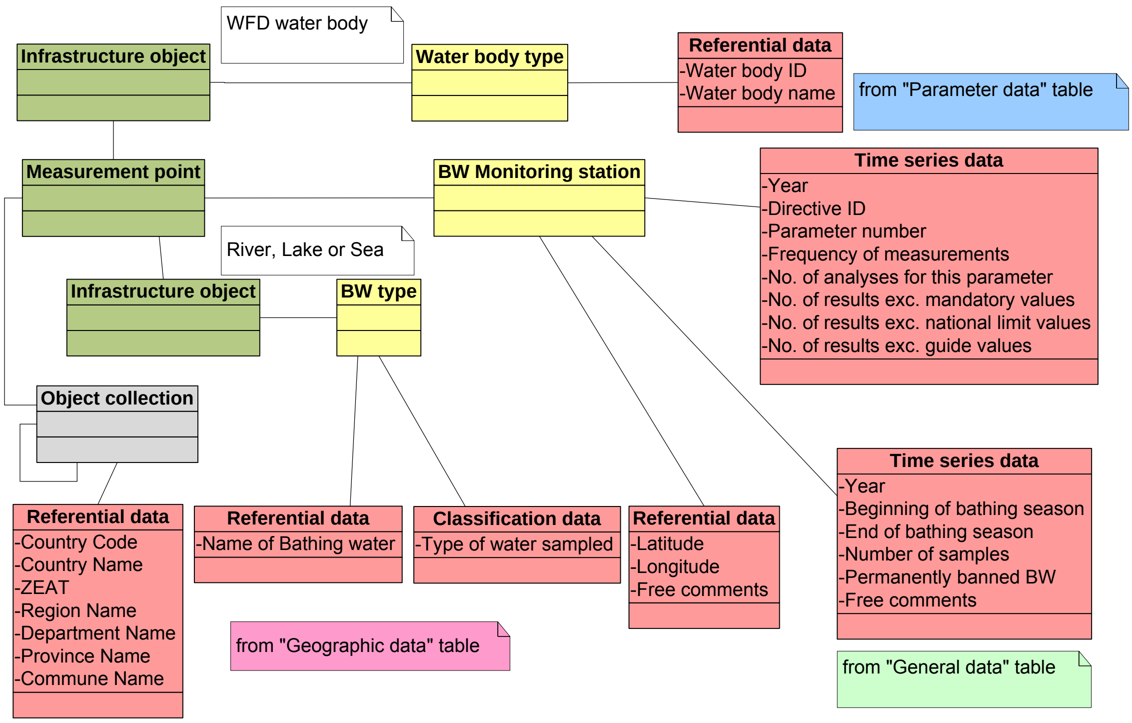

Figure 5.3.4e Transformation data model for the Bathing Water Directive theme

5.3.5 Data structure (class) diagrams

Within the WISE conceptual data model, data structure or class diagrams describe how logically related features are grouped together. For example, within the Water Framework Directive theme there are basic groups of features that have interactions: water bodies fall within River Basin Districts that in turn are managed by Competent Authorities.

These are represented by class diagrams within UML. The following data structure diagram describes conceptually a part of the Water Framework Directive data structures.

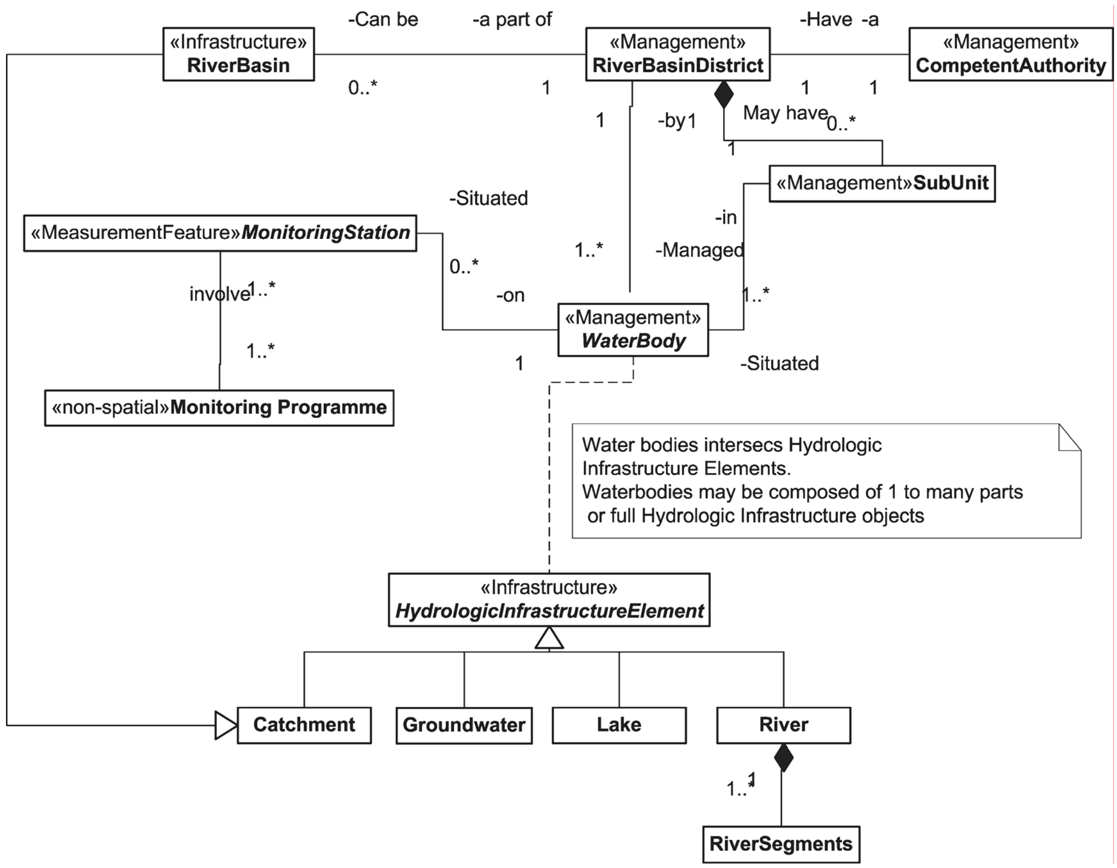

Figure 5.3.5 Part of the WISE conceptual data model relating to the Water Framework Directive

5.3.6 Feature classes

Feature classes group objects within the data model which contain explicit geometry. Feature classes are therefore either point, line or polygon features. All features in the feature class have geometry and a unique internal identifier in the database. Feature classes cannot mix geometry types: they must be exclusively points, lines or polygons.

Feature classes can be grouped and further sub-divided into nested hierarchies.

Example:

Feature

RiverBasinDistrict

Sub-unit

CompetentAuthority

RiverBasin

SubBasin

Feature *WaterBody*

- GroundwaterBody
- *SurfaceWaterBody*
  - *FreshWaterBody*
    - *Flow Water Body*
      - RiverWaterBody
        - RiverSegment
      - CanalWaterBody
        - CanalSegment
      - LakeWaterBody
        - LakeSegment
      - ReservoirWaterBody
        - ReservoirSegment
  - *SalineWaterBody*
    - TransitionalWaters
    - CoastalWaters

Feature

- EcoRegion

Feature

- *ProtectedArea*
  - HabitatsProtection
  - BirdsProtection
  - NutrientSensitiveArea
  - NitratesVulnerableArea
  - EconomicSpeciesProtection
  - Drinking water protection
  - RecreationalWater

Feature classes named in italics are abstract types never being realized. Inheritance allows classes to be related to parents through generalisation. The more specific class inherits attributes from the more general class. The Figure 5.3.6 show a small extract of the WISE logical data model, inheritance is in UML shown with a hollow triangle.

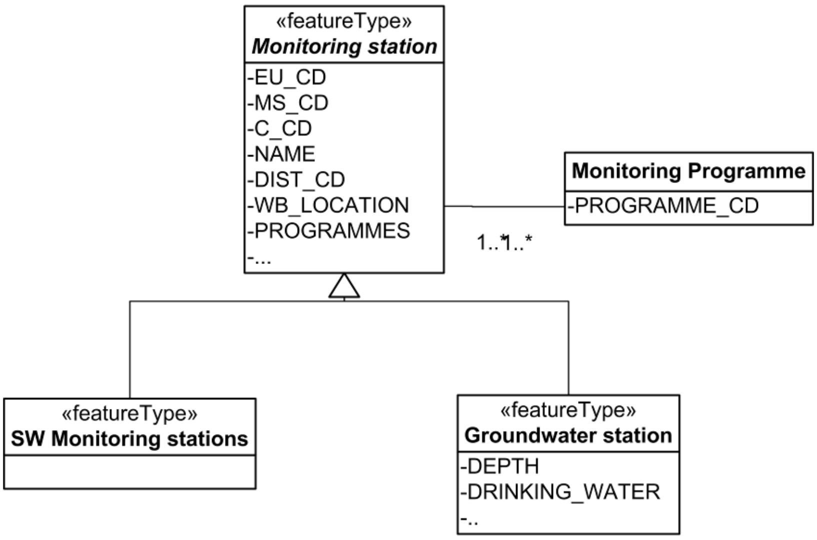

Figure 5.3.6 An extract of WISE logical data model

5.3.7 Object descriptions

In practical terms, every UML feature class becomes a table. Every UML feature class has attributes associated with it.

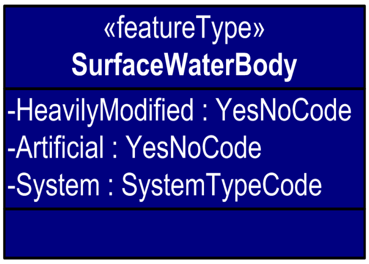
Two examples of object descriptions are shown below:

<u>WaterBody</u>

The WaterBody feature class defines the following attributes:

- **EuropeanCode** – a unique identifier at the European level (cf WG Coding Systems), including the 2 character ISO 3166 country code;
- **Name;**
- **MSCode** - the unique code for the water body defined by the Member State;
- **EcoRegionCode** - the relationship between a water body and its parent EcoRegion is via the EcoRegionCode;
- **InsertedWhen;**
- **InsertedBy;**
- **RiverBasinCode** - the relationship between a water body and its parent River Basin District is via the RiverBasinCode;
- **StatusYear.**

SurfaceWaterBody



All SurfaceWaterBody feature classes inherit from the WaterBody feature class. A SurfaceWaterBody feature class defines attributes which are associated specifically with the SurfaceWaterBody feature class:

- **HeavilyModified** - True/False;
- **Artificial** - True/False;
- **System** - whether the water body is Type A or Type B.

Each attribute in a class becomes a field in a database table. Data dictionaries contain further detail about the attributes. The domains shown refer to the common data types defined in the XML schema WFDCommon.xsd.

5.3.8 Data dictionary

All the attributes that are associated with each GIS layer and dataset, or theme, in WISE are detailed in data dictionaries. The following information is provided for each attribute:

- Its given name;
- Its data type;
- Its data length;
- Any associated codes;
- Any associated constraints.

The following is an example of a data dictionary entry:

EcoRegion

Attribute	FieldName	Definition	Type	Length	Restrictions
Shape	SHAPE	Geometry (polygons)	Geometry		
Name	NAME	Locally used name	String	40	
EcoRegionCode	REGION_CD	Codes as specified by Annex XI	String	2	{1-25} {AT = Atlantic, NO = Norwegian, BR = Barents, NT = North Sea, BA = Baltic, ME = Mediterranean}

Figure 5.3.8 Example of an entry in a data dictionary

More details of a data dictionary can be found in Appendix 06.

The Eionet-Water data dictionary is an example of an on-line data dictionary: http://dd.eionet.europa.eu/. Direction to the proper part of the data dictionary may also be obtained from the relevant reporting obligation from the (on-line) Reporting Obligations Database: http://rod.eionet.europa.eu/.

5.4 European Feature Coding

5.4.1 Introduction

GIS feature coding is the assignment of unique identifiers or codes to each spatial object that will be referenced by GIS. This assignment needs to be managed to ensure uniqueness at national and international levels. Standard identifier formats will ease electronic data transfer and enhance the possibility of central querying against distributed storage.

The common framework for the unique identification of spatial objects and the concept for ID management in WISE are described in Chapter 4.4. It deals with specific aspects of identifier management as regards reporting of spatial data by Member States and the development of WISE reference GIS datasets.

The spatial feature available in WISE can be classified into **Non-hydrological features** and **Hydrological features:**

- **Non-hydrological features** should be assigned with a **non-hydrological unique object identifier** but should carry the code of the **hydrological feature** to which they are related as foreign key;
- **Hydrological features** should carry a unique **hydrological feature code**.

This Chapter provides details of the structure of the non-hydrological unique object identifier and the hydrological feature code.

5.4.2 Non-hydrological unique identifiers

The structure of the non-hydrological unique identifiers will be as follows:

- A namespace to identify the data source. The namespace is owned by the data provider;
- A local identifier, assigned by the data provider. The local identifier should be unique within the namespace.

5.4.2.1 Member States submitted GIS data

If the data provider is a Member State, the namespace shall be the two letter ISO 3166 code of the Member State. The local identifier can be 22 characters long at maximum. Thus, the unique non-hydrological identifier provided by Member States should have the following structure:

MS$\#_1\#_2\ldots\#_{22}$ where:

MS . = a 2 character Member State identifier, in accordance with ISO 3166-1-Alpha-2 country codes; and

$\#_1\#_2\ldots\#_{22}$ = an up to 22 character feature identifier that is unique within the Member State.

(symbol # = wildcard character (a wildcard character can be used to substitute for any other character or characters in a string)).

The maximum total length of the identifier therefore will be 24 characters.

Example:

a *Groundwater Body in Germany* might have the identifier DE45734

or a *Lake Monitoring Station in Spain* might have the identifier ES67003800958730

Special advice given is that:

- The local identifier shall only use the following set of characters: {“A”…”Z”, “a”…”z”, “0”…”9”, “_”, “.”, “-“, “,”}, i.e. only letters from the Latin alphabet, digits, underscore, point, comma, and dash are allowed;
- Alphabetical characters should always be in upper case;
- Special characters must be avoided, such as ‘$’, ‘!’, ‘&’, ‘ë’, ‘á’, etc;
- Digits should be used where practical to help avoid the above problems.

Entity types can be used to identify the type of a feature. The entity type code segment is fixed to two characters. An example is given below. The list can be extended as needed, but has to be managed at the European level in order to prevent creating ambiguous codes.

- Non-hydrological features (examples);

Entity type	Code
o Monitoring station	MO
o River Basin District	BD
o …	

- Specifications for reporting geographical data under UWWTD (examples)

Entity type	Code
o Sensitive Area	SA
o Sensitive Area – river	RI
o Sensitive Area – lake	LK
o …	

5.4.2.2 WISE Reference GIS datasets

So far the WISE Reference GIS datasets: **Large Rivers and Large Lakes** and **River Basin Districts** have been developed. The datasets are available in the WISE map viewer (See Chapter 3.2 for an illustration of the River Basin Districts WISE Reference GIS dataset). The identifiers of the River Basin Districts (identifying the

RBD irrespective of country borders) and the Member State parts of RBDs can be seen at:
http://dataservice.eea.europa.eu/dataservice/metadetails.asp?id=1041.

5.4.3 European coding system for hydrological features

If rivers are already substantially identified, it may be pragmatic to extend the existing approach to uniquely identify objects. However, the number of rivers to be identified may amount to many times the number already coded. Codes may also need to be reviewed to achieve harmonisation with Member States involved in shared RBDs. Coding could be as simple as sequential identifiers; however, structured hydrological codes are recommended. This enables rapid manual or automated analyses without the need to refer to GIS. This includes tracing facilities including rivers, catchments and associated objects (upstream/downstream identification). Furthermore connectivity between rivers across boundaries has to be created and thus data analysis within international RBDs will be facilitated. Hierarchical structured coding also tends to ease long-term unique code maintenance.

A modified version of the Pfafstetter system is proposed as the European coding system for hydrological features. The hydrological code is composed of different segments, which together uniquely identify a hydrological feature. The hydrological code consists of 6 hierarchical related items. The first item is a character defining the Ocean or Endorheic system. It is followed by one digit numbering of the seas into which the Ocean can be subdivided. In the case of islands subsequently a sequence number of the island order along the coast is defined. The landmasses thus defined can be subdivided at sea outlet level using the 5 digit length commencement code. Finally the river system can be coded up to the river reach level using the Pfafstetter methodology. Furthermore an entity type code segment will define the type of feature that is referenced by the code. These are e.g. river segments, lakes and basins.

Table 5.4.3a Elements of the Hydrological Coding

Abbreviation	**Logical Element**	**Relation to**	**Data type**	**Min., Max. Length**
H or HDM_ID	Coastline, Hydrological system		String	1
S or SEA_ID	Coastline, Sea	Hydrological system	Number 1-9,	1
II or Island sort	Landmass, Island sort	Sea and Hydrological system	Hexadecimal number	2
CCCCC or Commencement	Sea outlet commencement code	Sea and Hydrological system and Island	Number 11111 – 99999,	5
P or Pfafstetter	River segments, lakes, river basins Pfafstetter	Seaoutlet	Number	1-12
E or Entity type	Entity type code		Character	2

L or Lake identifier	Lake identifier		Character	0,2

In a database typically these codes are to be stored in separate files, allowing a programmer to use the various data elements in a flexible manner. For data exchange functions it is useful to concatenate the elements, thus simplifying the exchange procedures and the eventual need to type in the code by a user.

The format of the code will be as follows:

HSIICCCCCPPPPPPPPPPPPEELL

Hydrological system and Sea region code (**HS**IICCCCCPPPPPPPPPPPPEELL)

The identification of the sea region constitutes the first segment of the whole code. The hydrological coding system reveals into which sea the various European watersheds are flowing and how those seas are connected to the ocean, the ordering of data can be enhanced. A limited hierarchical model is used in order to make these connections explicit in the coding system for the oceans and seas.

The coding of the sea region would be mandatory for all hydrologic reference features. It is proposed to define a unique identifier of one letter to mark the various Hydrological Systems or oceans that can be distinguished. The seas that are part of these oceans can subsequently be marked with one number. If the number is higher (9) than the distance of the sea to the ocean it exchanges water with is longer, in accordance with the Pfafstetter coding in which digit 9 marks the longest flow path and 1 the outlet of a river system into the sea. Thus the length of the code segment would be two characters, a letter for the Hydrological System or ocean and a number for the seas.

We propose to distinguish seven Oceans: Arctic Ocean, Northern Atlantic Ocean, Southern Atlantic Ocean, the Indian Ocean, the Pacific Ocean and the Mediterranean Sea. In the coding system these oceans all receive one letter as proposed in Table 5.4.3b.

Table 5.4.3b Definition of an Ocean letter to identify into which hydrographic system water from a surface water body eventually flows into.

Code	**Oceans**
A	Northern Atlantic Ocean
M	Mediterranean Sea
N	Arctic Ocean
S	Southern Atlantic Ocean
I	Indian Ocean
P	Northern Pacific Ocean
B	Southern Pacific Ocean

For endorheic systems relevant for Europe, including Turkey and the Caucasus, the codes proposed can be found in Table 5.4.3c.

Table 5.4.3c Definition of endorheic systems with surface water flow in Europe including Turkey and the Caucasus

Code	Endorheic System
C	Caspian Sea
H	Orumiyeh Lake
V	Van Lake
Z	Tuz Saltlake

There are two more endorheic systems, Prespa Lake and Trasimeno Lake. These systems are quite small and for the purpose of the WISE, they are integrated into the surrounding drainage area.

Most of the thus defined hydrographic systems can be subdivided by subsystems such as seas, bays or straits. For the use of grouping data within European policies we only propose here a subdivision of the Northern Atlantic Ocean East coasts. In order to code the seas relevant to the European Subcontinent it is proposed to distinguish the following seas (Table 5.4.3d):

Table 5.4.3d Numeric code of the Seas around Europe

Hydrographical System	Sea number	Sea Name
North Eastern Atlantic	1	Open Ocean
	2	Norwegian Sea
	4	Celtic Sea and Channels
	5	North Sea
	6	Baltic Sea
Mediterranean Sea	2	North Western Basin
	4	North Eastern Basin
	5	Black Sea
Arctic Ocean	7	Barents Sea East
	8	White Sea
	9	Barents Sea West
Caspian Sea	1	No subdivision
Indian Ocean	1	Persian Gulf

Island coding (HS**II**CCCCCPPPPPPPPPPPPEELL)

A proposal to code islands can be found in Appendix 08. The islands can be identified by the code of the sea they lie within, followed by a sequence number. The sequence number is generated by selecting the closest continental coast line segments ordering number. It is proposed to relate the sequence number to the coastal segment at the shortest distance to the island. In some cases many islands are to be connected to the same coastal segment. In such cases the final sequence number can be generated by using the shortest distance to the coastal segment.

Pfafstetter commencement code (HSII**CCCCC**PPPPPPPPPPPPEELL)

The second code segment would identify the primary catchment or a coastal catchment within the respective sea region. The commencement code will be defined at the European level based on the basins and sub-basins of the national datasets that have been reported according to Article 3 of WFD. The determination of the code should follow the same logic as the Pfafstetter code. The four largest sea outlets (river basins) within each sea region should be assigned with the figures 2, 4, 6 and 8 in clockwise rotation. The coastal region between these sea outlets (river basins) should be assigned with odd numbers 1,3,5,7 and 9 (see Figure 5.4.1).

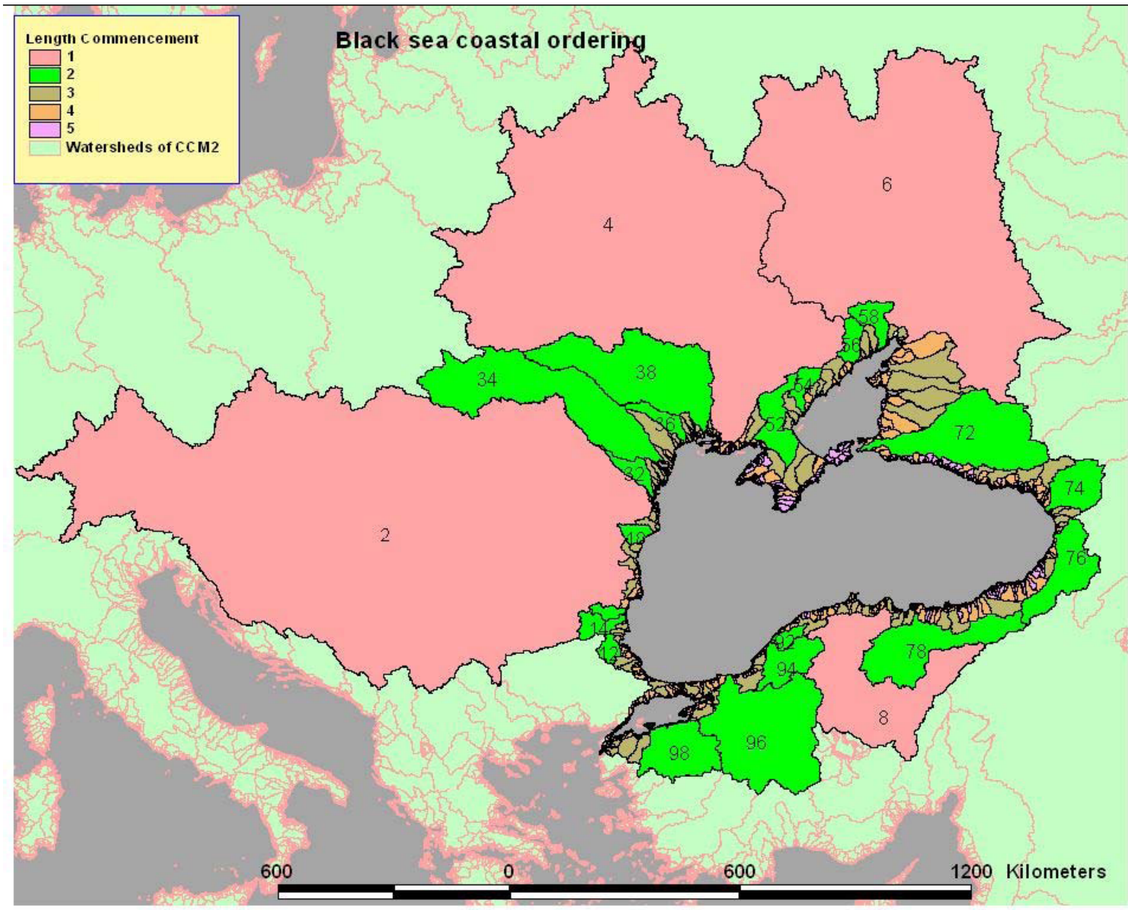


Figure 5.4.1: Commencement code for the Black Sea related Seaoutlets. The length of the code yields an indication of size

This commencement code has already been defined for CCM2 and the data can be downloaded at http://desert.jrc.ec.europa.eu/water/ccm/php/index.php.

River segments, lakes and river basins (HSIICCCCC**PPPPPPPPPPPP**EELL)

The Pfafstetter approach is recommended for providing a structured hydrological code segment, identifying river basins and river sub basins. Codes identified for river basins and sub-basins can be assigned to the associated river segments. The Pfafstetter system follows a systematic approach as it is derived from topological relationships of the underlying drainage system. The numbering schema is self-replicating from the largest to the smallest drainage system. With Pfafstetter codes it is possible to identify all nested sub-basins within the larger basin and the “parent” basin from a sub-basin. All upstream sub-basins or river segments as well as all downstream segments are identifiable at each location of the river network. More details of the creation of the code can be found in Appendices 07 and 08. (The principles of the system are explained in Appendix 07. Appendix 08 gives more details about the application of the system, taking also the island coding into consideration and the extension of the ocean and sea region coding as explained in this Chapter).

Lakes should be included in the Pfafstetter coding system. If they are connected to the river network, they should receive the Pfafstetter code of the river segment to which they drain (the outlet). If they are not connected to the river network, they should receive the code of the lowest level river (sub-) basin or interbasin in which they are located. In case that more than one isolated lake is located within one sub- or interbasin, lakes should be distinguished by a specific identifier. This specific identifier should be appended after the entity code to be able to code international lakes. A maximum of 2 characters are reserved for this segment. The code segment should only contain digits. Examples of lake coding are illustrated in Appendix 07.

For the implementation of a Pfafstetter system, the river network must be fully connected also within the lakes. These hypothetical river segments are sometimes called continua. As a consequence, water bodies within a lake can be identified according to the codes of the underlying river segments, if required.

Entity type (HSIICCCCCPPPPPPPPPPPP**EE**LL)

As described with the coding system for non-hydrological reference features, an entity type code can be used to identify types of hydrological features. A list of possible entity type codes is given in Appendix 07. Examples are given below. The list can be extended as needed, but has to be managed at the European level in order to prevent ambiguous codes being created.

- Hydrological features (examples)

Entity type	**Code**
o River basin	BA
o River segment	RS
o …	

Conditional lake identifier (HSIICCCCCPPPPPPPPPPPPEE**LL**)

An additional unique string is required for identifying lakes that are not connected to a river network. The identifier is necessary if there is more than one lake within a specific river basin. International lakes should be identified with one code (identifying the total lake and not only national parts of the lake). As a consequence, the identifier has to be managed within an international river basin on the European or international level.

It is proposed to reserve a maximum of two characters for this code segment. The code could consist of numbers and characters.

Other identifiers

The coding of special cases such as bifurcations, karst phenomena and canals is described in Appendix 07.

5.4.4 Application of the European coding system for hydrological features

The application of the code to hydrological features requires a topologically correct and connected river network including lakes and a dataset of basins with the catchment boundaries. There has to be a spatial relationship between the basins dataset and the river network as the order of Pfafstetter code assignment is determined by the size of the catchments. International basins, rivers and lakes have to be consistent across national boundaries.

The European coding system for hydrological features will be applied at EU level to the WISE Reference GIS datasets of main rivers (including river segment coding and river codes) and main lakes. The coding system is being tested in the Danube River Basin District at rivers with a catchment > 1000 km². The methodology and results will be available as Appendix 09 from March 2009.

5.4.4.1 Application of the coding system at EU level - Hydrological Reference Features

The European coding system for hydrological features will be applied at the European level to hydrological reference features used in harmonised European reference datasets (WISE Reference GIS datasets). These will be the Main Rivers and Main Lakes and, in future, the correlated river basins, sub-basins and catchments. The codes will be defined using the European dataset of catchment areas and derived rivers (CCM2). The generated codes will then be transferred from CCM2 to the submitted national datasets which form the reference datasets of Main Rivers and Main Lakes. The datasets will be created at the European level and provided to Member States.

Each river segment of the European reference dataset Main Rivers will carry the European hydrological feature code for river segments, the European river code and the RBD code. Each lake of the European main lakes dataset will carry the European hydrological feature code of the lake and the European RBD code.

5.4.4.2 Application of the coding system at Member State level (rivers, lakes)

Member States are not requested to apply the proposed European coding system for hydrological features to their national hydrological features as they probably have a national hydrological coding system already in place. However, Member States are invited to apply the European coding system for hydrological features at the national level. The Pfafstetter commencement code can be obtained from the CCM2 dataset.[45]

To allow the linkage of national hydrological features to European hydrological reference features, it is recommended that Member States add the following as attributes to their national hydrological river and lake datasets:

- European river code of the WISE Reference GIS dataset main rivers;
- European lake code of the WISE Reference GIS dataset main lakes;

[45] http://desert.jrc.ec.europa.eu/action/php/index.php?action=view&id=23

- European Pfafstetter codes of transboundary rivers segments (including border river segments) and transboundary lakes.

Of particular importance are transboundary features, border rivers and border lakes. It is proposed to harmonise these features respectively at national and international River Basin District levels (see Chapter 6.1). As long as these features are not harmonised, harmonisation will take place at EU level (see Chapter 3.1) and the dataset and the corresponding codes will be provided to Member States. As soon as national/international harmonised features are available they will substitute features harmonised at EU level.

5.5 Metadata

5.5.1 What are metadata?

Metadata are information that describe the content, quality, condition, origin and other characteristics of data or other pieces of information related to the data. Metadata are important since they make data understandable and they make it easier for data to be shared. As we are witnessing a rapid increase in the availability of digital data, the need for effective metadata increases so that users can properly discover and evaluate relevant data resources.

5.5.2 Structured and unstructured metadata

Although in many cases metadata can be inferred from data resources, a structured approach to collecting and publishing metadata is beneficial since it increases consistency. The advent of sophisticated Internet-based indexing and search engines and tools have gone a long way to help locate digital information resources, but basic problems remain in that categorisation and cataloguing of resources remains limited.

5.5.3 Metadata standardisation

5.5.3.1 International Standards Organisation (ISO)

In the domain of geographic information a number of standardisation activities have taken place which provide a formal basis for describing geographic data and services.

In 2003 the International Standards Organisation (ISO) adopted the standard ISO19115:2003 Geographic Information – Metadata.

In 2005 this was followed by the adoption of ISO19119:2005 Geographic Information – Services.

With the adoption of ISO19139:2007 Geographic Information – Metadata – XML Schema Implementation, developers now have access to a comprehensive metadata implementation specification.

The ISO standards are over-arching. ISO19115 has approximately 300 elements, an exhaustive list, but of course many of these are redundant for certain applications. As a consequence, many communities have developed profiles, an agreed sub-set of elements.

5.5.3.2 Other standardisation initiatives

The development of the US FGDC Metadata format (CSDGM) preceded ISO19115, and has been widely adopted outside the US. CSDGM is now being aligned to ISO19115. The other widely used metadata standard is the DCMI (Dublin Core Metadata Initiative).

5.5.4 INSPIRE and WISE metadata profiles

The elements required for describing geographic data and services falling under the scope of INSPIRE are detailed in the INSPIRE Directive[46].

The INSPIRE metadata elements have been selected to support the primary function of discovery. For 10 categories, there are a total of 27 metadata elements.

It is important to note that whilst in general INSPIRE advocates the use of recognised standards it is not a requirement to fulfil the obligations of the INSPIRE metadata regulation to adopt ISO19115 or related standards for implementation. However, in practical terms, many organisations will choose to adopt such an approach, and non-binding guidelines have been published, see: http://inspire.jrc.it/reports/ImplementingRules/metadata/Draft_Guidelines%20_INSPIRE_metadata_implementing_rules.pdf which "map" INSPIRE metadata elements to their corresponding ISO elements.

The WISE metadata profile should support the functions of discovery and usage. The original WFD GIS Guidance Document (Vogt 2002) defined a metadata profile based on the draft version of ISO19115 that existed at the time, and further work was undertaken with the SDIGER-project.

Since the majority of WISE datasets and services will fall under the scope of INSPIRE, this guidance recommends the adoption of a profile which extends the INSPIRE metadata to include all those additional elements already agreed by the WISE community.

This guidance recommends the use of INSPIRE terminology for element names wherever possible, thus ensuring compatibility with metadata created in other environmental policy areas.

An overview of the WISE metadata profile is provided below with a more elaborated version found in Appendix 10. Details of implementation of the metadata elements are provided in Appendix 11.

Table 5.5.4 Overview of the WISE metadata profile

Category	Element Name	Description	Condition	Value Domain	Multiplicity
IDENTIFICATION	1.1 Resource title	This is a characteristic, and often-unique, name by which the resource is known.	Mandatory	Free text	1
	1.2 Resource abstract	This is a brief narrative summary of the content of the resource	Mandatory	Free text	1
	1.3 Resource type	This is the type of	Mandatory	Part D.1. of the	1

[46] http://inspire.jrc.ec.europa.eu/

Category	Element Name	Description	Condition	Value Domain	Multiplicity
		resource described by the metadata		MD IR	
	1.4 Resource locator	The resource locator defines the link(s) to the resource and/or the link to additional information about the resource	Mandatory if a URL is available to obtain more information on the resource, and/or access related services	Character string expressed by a URL	0..*
	1.5 Unique resource identifier	A value uniquely identifying the resource	Mandatory	Character string + character string namespace	1..*
	1.6 Coupled resource	*Identification of the target spatial data set(s) of the services trough their Unique Resources Identifiers (URI)*	*Mandatory if linkage to the service is available*	*Character string code + character string namespace*	*0..**
	1.7 Resource language	The language(s) used within the resource	Mandatory if the resource includes textual information	ISO 639-2	0..*
CLASSIFICATION OF SPATIAL DATA SETS & SERVICES	2.1 Topic category	High-level classification scheme	Mandatory	Part D.2 of the MD IR	1..*
	2.2 Spatial data service type	*This is a classification to assist in the search of available spatial data services*	*Mandatory*	*Part D.3 of the MD IR*	*1*
KEYWORD	3.1 Keyword value	A commonly used word, formalized word or phrase used to describe the subject	Spatial data set or spatial data set series: at least one keyword from GEMET	Free text	1..*
			Spatial data service: at least one keyword from Part D.4 of the MD IR	*Part D.4 of the MD IR*	*1..**
	3.2 Originating controlled vocabulary	The citation of the originating controlled vocabulary shall include at least its title and a reference date (publication, last revision or creation)	Mandatory if the keyword originates from a Controlled vocabulary	Free text + date	1..*
GEOGRAPHIC LOCATION	4.1 Geographic bounding box	Extent of the resource in the geographic space	Spatial data set or spatial data set series: Mandatory	Decimal degrees with at least two decimals	1..*
			Spatial data service: Mandatory for services with an explicit geographic extent	*Decimal degrees with at least two decimals*	*0..**
TEMPORAL REFERENCE	5.1 Temporal extent	Time period covered by the resource as an individual date, an interval of dates or a mix of both	At least one of the metadata elements referred to points 5.1 to 5.4	ISO 8601	1..*
	5.2 Date of	Date of publication or	At least one of	ISO 8601	1..*

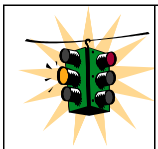
Category	Element Name	Description	Condition	Value Domain	Multiplicity
	publication	entry into force of the resource	the metadata elements referred to points 5.1 to 5.4		
	5.3 Date of last revision	Date of last revision of the resource	At least one of the metadata elements referred to points 5.1 to 5.4	ISO 8601	1
	5.4 Date of creation	Date of creation of the resource	At least one of the metadata elements referred to points 5.1 to 5.4	ISO 8601	1
QUALITY & VALIDITY	6.1 Lineage	Statement on process history and/or overall quality of the spatial data set	Mandatory	Free text	1
	6.2 Spatial resolution	Level of detail of the dataset: it shall be expressed as a set of zero to many resolution distances or equivalent scales	Mandatory	Equivalent scale expressed as an integer; resolution distance expressed as a numerical value	0..*
CONFORMITY	7.1 Specification	Citation of the implementing rules adopted under Article 7(1) of Directive 2007/2/EC or other specification to which a particular resource conforms	Mandatory	Free text + date	1..*
	7.2 Degree	Degree of conformity of the resource to the implementing rules adopted under Article 7(1) of Directive 2007/2/EC or other specification	Mandatory	Part D.5 of the MD IR	1
CONSTRAINT RELATED TO ACCESS & USE	8.1 Conditions applying to access and use	Conditions for access and use of spatial data sets and services, and where applicable, corresponding fees	Mandatory	Free text + URL if applicable for information on any fees	1..*
	8.2 Limitations on public access	Limitations on public access and the reasons for them	Mandatory	Free text	1..*
ORGANISATIONS RESPONSIBLE FOR THE ESTABLISHMENT, MANAGEMENT, MAINTENANCE AND DISTRIBUTION OF SPATIAL DATA SETS AND SERVICES	9.1 Responsible party	Description of the organisation responsible for the establishment, management, maintenance and distribution of the resource	Mandatory	Free text + e-mail address as a character string	1..*
	9.2 Responsible party role	Role of the responsible organisation	Mandatory	Part D.6 of the MD IR	
METADATA ON METADATA	10.1 Metadata point of contact	Description of the organisation responsible for the creation and maintenance of the metadata	Mandatory	Free text + e-mail address as a character string	1..*
	10.2 Metadata date	Date the metadata	Mandatory	ISO 8601	1

Category	Element Name	Description	Condition	Value Domain	Multiplicity
		record was created or updated			
	10.3 Metadata language	Language in which the metadata are expressed	Mandatory	ISO 639-2	1
WISE METADATA	11.1 Distribution format	Provides a description of the format of the data to be distributed	Mandatory	Free text	1..*
	11.2 Metadata standard name	Name of the metadata standard (including profile name) used	Mandatory	Free text	1
	11.3 Metadata standard version	Version (profile) of the metadatastandard used	Mandatory	Free text	1
	11.4 Metadata file identifier	Unique identifier for this metadata file	Optional	Free text	0..1
	11.5 Metadata character set	Full name of the character coding standard used for the dataset	Optional	MD_CharacterSet Code <<CodeList>> (B.5.10)	0..1
	11.6 Reference system	Description of the spatial and temporal reference systems used in the dataset	Optional	MD_ReferenceSys tem (B.2.7)	0..*
	11.7 Spatial representation type	Method used to spatially represent geographic information	Conditional: if the resource is a dataset or dataset series	MD_SpatialRepres entationTypeCode	0..*
	11.8 Credit	Recognition of those who contributed to the resource(s)	Optional	Free text	0..*
	11.9 Presentation form	Mode in which the resource is represented	Optional	CI_PresentationFo rmCode	0..*
	11.10 Purpose	Summary of the intentions with which the resource(s) was developed	Optional	Free text	0..*
	11.11 Specific usage	Brief description of the resource and/or resource series usage	Optional	Free text	0..*
	11.12 Vertical extent	Provides vertical component of the extent of the referring object	Optional	EX_VerticalExtent	0..*

Note: Metadata elements marked in italics are only relevant for metadata covering services.

5.5.5 Which WISE components require metadata?

Metadata should be created with all geographical information being reported to, developed in the context of, or disseminated through WISE. A sub-set of the metadata elements found in the WISE profile for spatial data would also be applicable for non-spatial data submitted by Member States.



Look out!

Mandatory delivery of metadata may develop further

The application of mandatory metadata using specific elements from the profile may be extended to reporting outside the scope of GIS data.

5.5.6 Metadata creation methods

The authoring and editing of metadata in WISE can be done in a number of ways including:

- The use of a dedicated WISE metadata web-based entry page, with basic client-side validation. At the present time this does not exist, but could be developed in the future;
- The use of a metadata editor, capable of outputting metadata according to the recognised WISE metadata XML schema. This can be direct (i.e. if the tool can be configured to export according to this schema), or indirect (i.e. using XSL transformations to map from the native XML schema of the specific tool to the WISE XML schema).

There are many tools which allow metadata editing and which are based on the ISO standards.

5.5.7 WISE XML Schema

An XML schema for the WISE metadata will be available from the WISE portal.

5.6 Standards for data exchange

5.6.1 Purpose for standards in data exchange

In addition to the optimisation of data collection and the reuse of data, one of the major goals of WISE is to streamline the data exchange between the Member States and the European Commission (EC).

The way data is collected and stored, its quality and coverage will vary from organisation to organisation responsible for the managing and reporting of data. Each organisation will have to implement procedures and modules that facilitate the data exchange processes according to formats agreed between the data provider and the data user.

The development of common standards serving the WISE community has a number of benefits:

- The users may reduce the cost for development and implementation of a specific reporting flow;
- The development of the reporting specifications will be easier and may reuse previously developed components;
- Given that GML is recommended, the developed application and data structure schemas may provide a basis for both file exchange and web service development.

In 2004, the WFD guidance document no. 9 Implementing the Geographical Information System Elements (GIS) of the Water Framework Directive[47] identified a short term approach and a long term approach.

The short term approach pointed to the use of Geography Markup Language (GML) as best practise and the published open standard file format ESRI shape file[48] as a minimum standard. The long term approach (for 2009) recommends the use of web services, which is covered in more detail in Chapter 5.7.

The recommendation of GML has recently been supported by the INSPIRE Drafting Team on Data Specifications in the document D2.7: Guidelines for the encoding of spatial data, Version 2.0[49]. The application of GML and GML application schemas are in line with the development of web services.

The common standards for data exchange can be viewed and developed at different levels. This Chapter will not discuss the choice of GML as a common standard for the encoding of spatial data to be exchanged, but rather bring recommendations on how the GML standard should be exploited in the context of WISE.

5.6.2 GML – a natural choice with decisions to take

The OpenGIS® Geography Markup Language Encoding Standard (GML) is an ISO standard (ISO 19136:2007) that defines data encoding in XML for geographic data and a grammar to express models of such data using XML Schema. GML provides a means of encoding geographic information for both data transport and data storage, especially in a web context. It is extensible, supporting a wide variety of spatial tasks, from portrayal to analysis. It separates content from presentation (graphic or otherwise) and permits easy integration of spatial and non-spatial data. Clients and servers with interfaces that implement the OpenGIS® Web Feature Service Interface Standard read and write GML data.

The following diagram shows how GML would integrate with the reporting process:

[47] Document is available on CIRCA at:
http://circa.europa.eu/Public/irc/env/wfd/library?l=/framework_directive/guidance_documents/gds09sgisspolicysummary/_EN_1.0_&a=d (policy summary), and on
http://circa.europa.eu/Public/irc/env/wfd/library?l=/framework_directive/guidance_documents/guidancesnos9sgisswgs31p/_EN_1.0_&a=d (complete guidance no.9)

[49] http://www.ec-gis.org/inspire/reports/ImplementingRules/DataSpecifications/inspire_dataspec_D2.7_v2.0.pdf

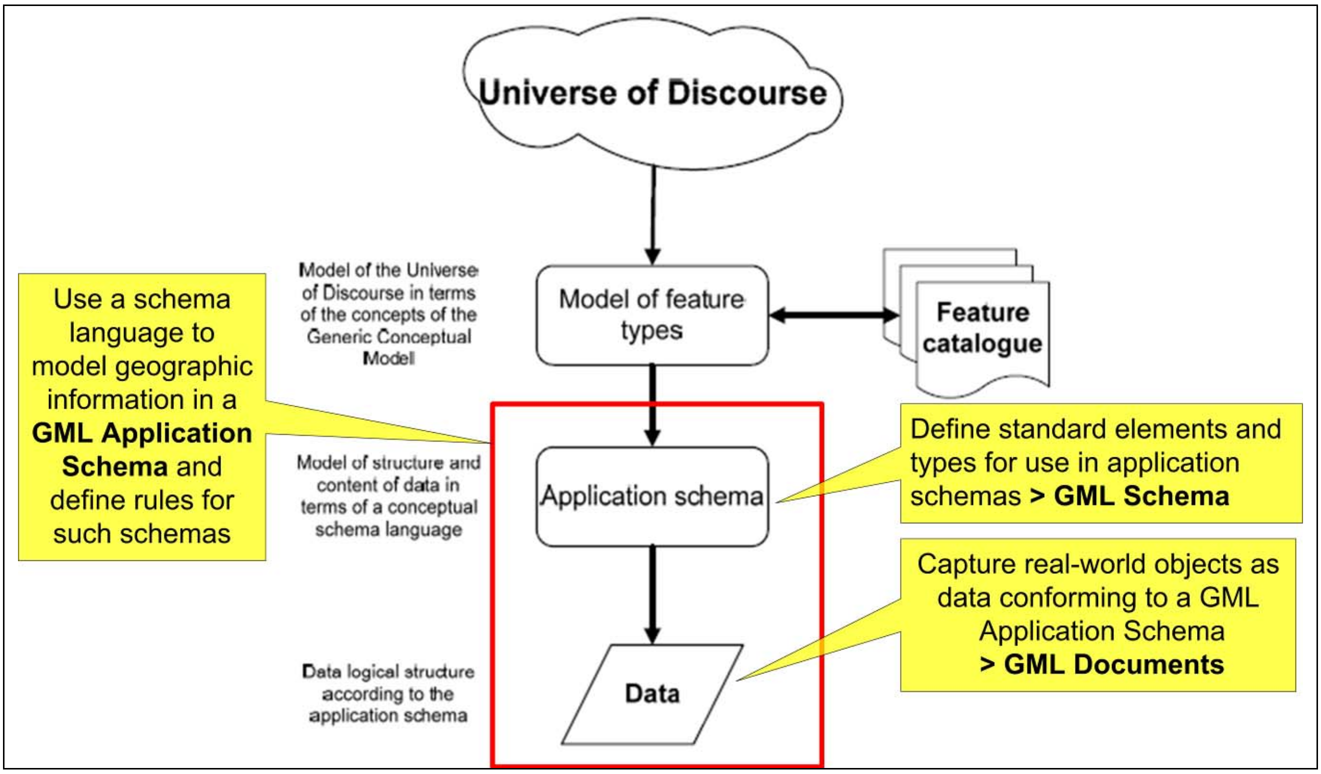

Figure 5.6.2 Development of data exchange specifications in the reporting process

The GML standard (currently version 3.2.1) is an exhaustive and flexible standard covering a wide set of possible spatial data structures and service types. It is thus beneficial both to restrict the application of GML to a common sub-set of the standards and to define a set of encoding rules to be applied to the standard. The INSPIRE Drafting Team on Data Specifications already specify, in the document D2.7, a number of recommendations on such encoding rules.

5.6.2.1 GML in a nutshell

Version

GML is jointly developed by ISO/TC 211 and OGC and published as ISO 19136:2007. The current version is GML version 3.2.1 (available from http://www.opengeospatial.org/standards/gml). GML version 3.x.x provides the option of encoding several elements: geometry properties, topology properties and time properties. A major benefit of using GML is that all necessary information can be encoded in a single GML document and be validated according to the GML application schema. No specific recommendations are provided regarding use of version. It is anticipated that the data receiver will have to implement the capability of translating more than one version.

At the time of writing GML version 3.1.1 has some advantages:

- This version is stronger than the previous version 2. by supporting e.g. topology and time;
- GML version 2 is more open and leaves several implementation choices for the same aspect;

- The software support is wider for this version than the latest version 3.2.1.

Profiles

One way of restricting the application of GML is through the application of profiles. Profiles are distinct from application schemas. Profiles are part of GML namespaces (Open GIS GML) and define restricted sub-sets of GML. Profiles are often created in support for GML derived languages (see application schemas) created in support of particular application domains such as commercial aviation, nautical charting or resource exploitation. OGC has defined a few data type specific profiles of which the Simple Features Profile[50] is recommended for WISE. The GML-Simple Feature Profile has three compliance levels: level 0, 1 and 2 (SF-0, SF-1, SF-2).

Example:

An example of the structure of GML application schemas and the encoding of elements can be found in Appendix 12.

Software support

GML is to a varying degree supported by commercial as well as Open Source GIS packages. As software is constantly developing this guidance will not provide specific software recommendations, but rather point to the OpenGeospatial[51] website for the updated information.

As GML is based on XML many of the existing XML tools may also be applied to read, write, manipulate, and validate GML documents.

5.6.3 GML and data modelling

Application schemas are XML vocabularies defined using GML and which live in an application-defined target namespace. Application schemas can be built on specific GML profiles or use the full set of GML schemas. In order to expose an application's geographic data with GML, a community or organisation creates an XML schema specific to the application domain of interest, i.e. the application schema. This application schema describes the object types whose data the community is interested in and which community applications must expose. For example, WISE may define object types of coastal water bodies, transitional water bodies etc in its application schema. Those object types in turn reference the primitive object types defined in the GML standard.

Based on the application schema, a data structure schema will be developed to facilitate the specific data exchange. Typically a GML data structure schema should include:

- Metadata section;
- Extent element;
- Features;
- Feature attributes.

[50] http://www.opengeospatial.org/standards/gml
[51] http://www.opengeospatial.org/resource/products

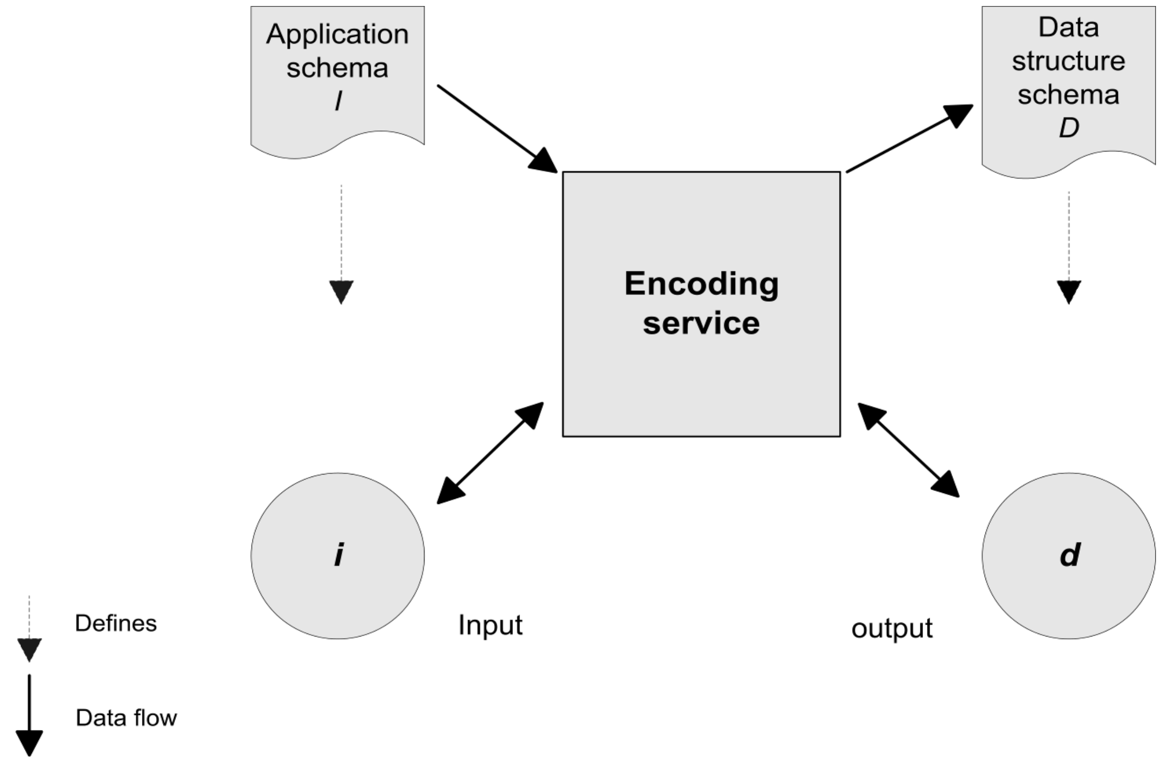

Figure 5.6.3a Overview of encoding process (ISO 19118)

Schema coding patterns for compliance level SF-0:

The schema fragments in a GML application schema that complies to GML-Simple Feature Profile level 0 are:

- Root element encoding;
- Identifying the compliance level;
- Importing and including schemas (among them the GML schema);
- Defining a feature collection (only one per application schema);
- Defining features types;
- Defining properties encoding within the feature types (including geometry properties).

The structure of each of these fragments is presented in Appendix 12.

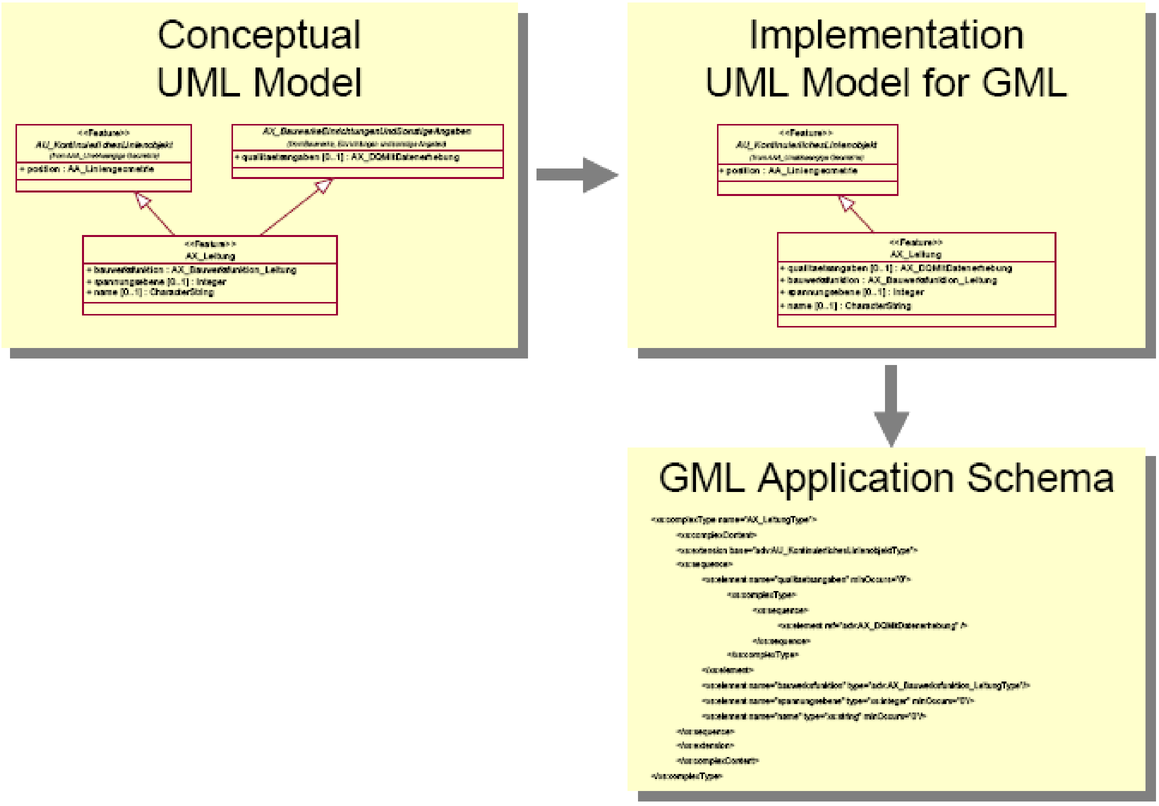

Figure 5.6.3b Process of creating the GML application schema (from INSPIRE D2.7)

5.6.4 GML in WISE

The use of GML will gradually be extended in WISE with the development of WISE GML application schemas and translation of previous Shapefile based reporting templates and schemas into data structure schemas. GML will have a role both in the further development of file based data exchange and in the development of web service specifications to be applied by the WISE and SEIS community. Figure 5.6.4 shows the relation between GML and the web services.

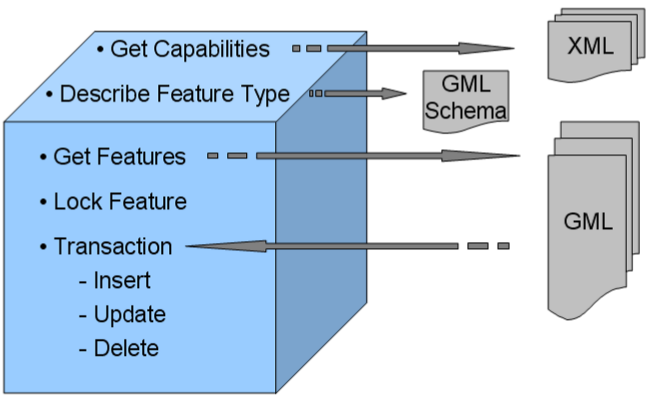

Figure 5.6.4 Relation between GML and OGC WFS web service

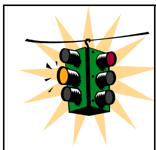
5.6.5 Encoding rules for WISE

During the development of GML in WISE a number of rules should be followed. The INSPIRE Drafting Team on Data Specifications has developed a set of recommendations for encoding rules in INSPIRE, a number these are adopted by WISE either directly or in a slightly modified way. The full set of recommendations (there are currently fifteen) and their details can be found in INSPIRE D2.7 Guidelines for the encoding of spatial data.



Look out!

The URN NID may change

INSPIRE work on the assumption that the URN NID “inspire” will be registered and applied. INSPIRE use ”x-inspire” as the placeholder.

In the context of WISE it still remains to be decided whether a specific namespace will be registered and which acronym it will take.

Extract of rules recommended by INSPIRE Drafting Team on Data Specifications:

- Encoding rules should be based on open standards (INSPIRE Recommendation 2);
- Additional encoding rules should only be added, if the new encoding rule has unique characteristics required by the encoded data that are not fulfilled by an encoding rule that has already been endorsed (INSPIRE Recommendation 3).

Recommendations for GML application schemas:

- The encoding rule specified in ISO 19136 Annex E should be applied. For types within the scope of the ISO/TS 19139 encoding rule, the encoding rule of ISO/TS 19139 should be applied. To identify the applicable encoding rule, a tagged value “xsdEncodingRule” should be provided for packages and classifiers. A value “iso19136_2007” (the default, if no value is provided) indicates the GML encoding rule, “iso19139_2007” indicates the ISO/TS 19139 encoding rule (INSPIRE Recommendation 5);
- The transformation from the application schema on the conceptual level to the UML implementation profile from which the GML application schema is automatically derived should follow a common set of rules across all themes (INSPIRE Recommendation 6);
- All navigable feature association roles should be assigned a tagged value "inlineOrByReference" with the value "byReference" (INSPIRE Recommendation 7).

Recommendations for XML documents:

- XML documents should be encoded using UTF-8 or UTF-16 as character encodings (INSPIRE 9).

Recommendations for the use of URNs:

- The target namespace of the GML application schema should be a URN of the form:

  urn:x-inspire:specification:<name>:<version>

  where

  <name> is a name of the GML application schema

  <version> identifies the particular version (INSPIRE Recommendation 10).

Encoding of an external identifier:

- URNs should be used to encode unique identifiers including the namespace and the local identifier part. The URNs should use the following structure:

  urn:x-inspire:object:id:<namespace>:<local identifier>[:<version>]

  where

  <namespace> is the namespace of the object identifier;

  <local identifier> is the local identifier part of the object identifier;

  <version> is an optional version qualifier to be added only if a specific version of the object shall be identified. (INSPIRE Recommendation 11)

Encoding of a reference to a spatial object:

- To reference a spatial object or a specific version of a spatial object the URNs specified in Recommendation 11 should be used (INSPIRE Recommendation 12).

Encoding of a reference to a registered item:

- URNs should be used to encode item identifiers of items in registers and to reference such items.

  The URNs should use the following structure:

  urn:x-inspire:def:<item class>:<register>:<item identifier>

  where

  <item class> is the name of the item class (ISO 19135: RE_ItemClass) of the registered item;

  <register> is the name of the register (ISO 19135: RE_Register);

  <item identifier> is the item identifier of the registered item (ISO 19135: RE_RegisterItem).

  Other URIs may be used, too. It is recommended to register them as an alias of the item in the INSPIRE register (INSPIRE Recommendation 13).

Modified INSPIRE rules:

- To support interoperability and enhance coherence across communities, the encoding rules and output data structure schemas in WISE should be as consistent across the various themes as possible (INSPIRE Recommendation 1);
- For every WISE application schema, a GML application schema should be specified (INSPIRE Recommendation 4);

- All code lists should be assigned a tagged value "asDictionary" with the value "true". Instance should reference the WISE register that is used to manage this code list (INSPIRE Recommendation 8).

Rules for exchange of metadata:

- For data transfer, using the transfer model (download of a complete spatial dataset), the dataset should include the dataset metadata for evaluation (MD_Metadata as specified in the WISE data specification) and use (INSPIRE Recommendation 14);
- For data transfer, using the interoperability model (download of a spatial objects based on a query), the response of the download service should not include any dataset metadata but should provide a reference to the dataset or dataset series metadata in a discovery or registry service (INSPIRE Recommendation 15).

WISE-specific rules:

- Although GML allows more than one geometry to represent a feature which could lead to, for example, water bodies that are presented as point features and as Linestring or Polygon feature, WISE recommends separating each geometry type in different GML documents which will keep it simple to manage the upload and metadata of exchanged data

5.6.6 Role of Shapefiles in WISE

The available reporting interfaces developed between 2004 and 2007 were based on Shapefile formats and XML schemas as a bundle completing the electronic reporting content on Articles 3, 5 and 8 of the Water Framework Directive. These reporting interfaces will remain for updating the information on the mentioned Articles under the first River Basin Management Plan and following reporting phases. Alternatively GML schemas (covering the content of the Shapefile formats and XML schemas) can be used to substitute the former reporting formats. The GML schemas will be made available by the EEA as they are developed.

The use of GML in WISE will gradually be extended and further use of Shapefiles will not be stimulated. Although quite widespread the Shapefile format has some major disadvantages:

- No validation rules can be applied directly to the set of files;
- The format does not fit into the service oriented architecture;
- Problems with controlling and determining the character set applied in attribute tables;
- Multiple files needed for transmitting a single theme;
- Vendor-specific origin (though openly documented).

5.7 Web services

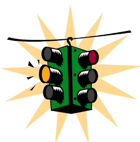
5.7.1 What are spatial data web services

5.7.1.1 Service definitions

Network services are designed to perform machine-to-machine communication which may be embedded in end user applications. The primary purpose of the network services is to provide information in a standardised way independent of the underlying application software, platform or framework.

Spatial data may be disseminated and shared in real-time through the use of these web-based network services. Open Geospatial Consortium, Inc (OGC) has drafted a number of OpenGIS® Web Service (OWS) interface specifications. These service specifications have been widely adopted by the user community, ISO, CEN and INSPIRE.

Each of the network services is implemented using a specific interface specification. Examples of such interfaces are OGC-WMS (Web Map Services), OGC-WFS (Web Feature Services) etc. described further in Chapter 5.7.2. From a user perspective the various network services together should be able to support a workflow following a "publish – find – bind" design pattern. However, users do not necessarily have to follow this pattern; they can also invoke services directly.



Look out!

Definition OGC Web Services (One Geology)

An OGC Web Service (OWS), or open web service, is a 'self-contained, self-describing, modular application that can be published, located, and invoked across the web. Web services perform functions that can be anything from simple requests to complicated business processes. Once a web service is deployed, other applications (and other web services) can discover and invoke the deployed service.' (Ref: OGC).

Typically a web server is a computer placed on the Internet that offers an OGC Web Mapping Service or WMS (responds to requests from a computer client to send a map in the form of a raster or image over the Internet) and/or an OGC Web Feature Service or WFS (responds to queries from a computer client to send an application of GML representation of some data often with a geographic part in an XML document based on a schema such as GeoSciML).

A web server can publish more services than WMS and WFS and there are other OGC web servers that publish mapping services.

The OGC WMS specification standardises the way in which web clients request maps. Clients request maps from a WMS instance in terms of named layers and provide parameters such as the size of the returned map as well as the spatial reference system to be used in drawing the map.

	The OGC WFS specification supports INSERT, UPDATE, DELETE, QUERY and DISCOVERY of geographic features. WFS delivers GML representations of simple geospatial features and other feature attributes in response to queries from HTTP clients. Clients access geographic feature data through WFS by submitting a request for just those features that are needed for an application.

5.7.1.2 Services within Spatial Data Infrastructures

Thanks to new legislation such as INSPIRE and several initiatives to (re)use geographical data more efficiently, the concept of Spatial Data Infrastructures (SDI) has gained more attention. Network services are seen as one of the core elements of SDIs and are paramount in fulfilling the target of interoperability and data distribution.

The conceptual organisation (i.e. the logical architecture) of the services within an SDI is still subject of discussion. Two major examples of possible architectures are the INSPIRE Network Services Architecture[52] drafted by The INSPIRE Network Services Drafting Team and the Web Service Architecture (WSA)[53] which is a standardised architecture for services on the Internet and is drafted by the W3C. Figure 5.7.1.2 provides an overview of the INSPIRE Network Services Architecture.

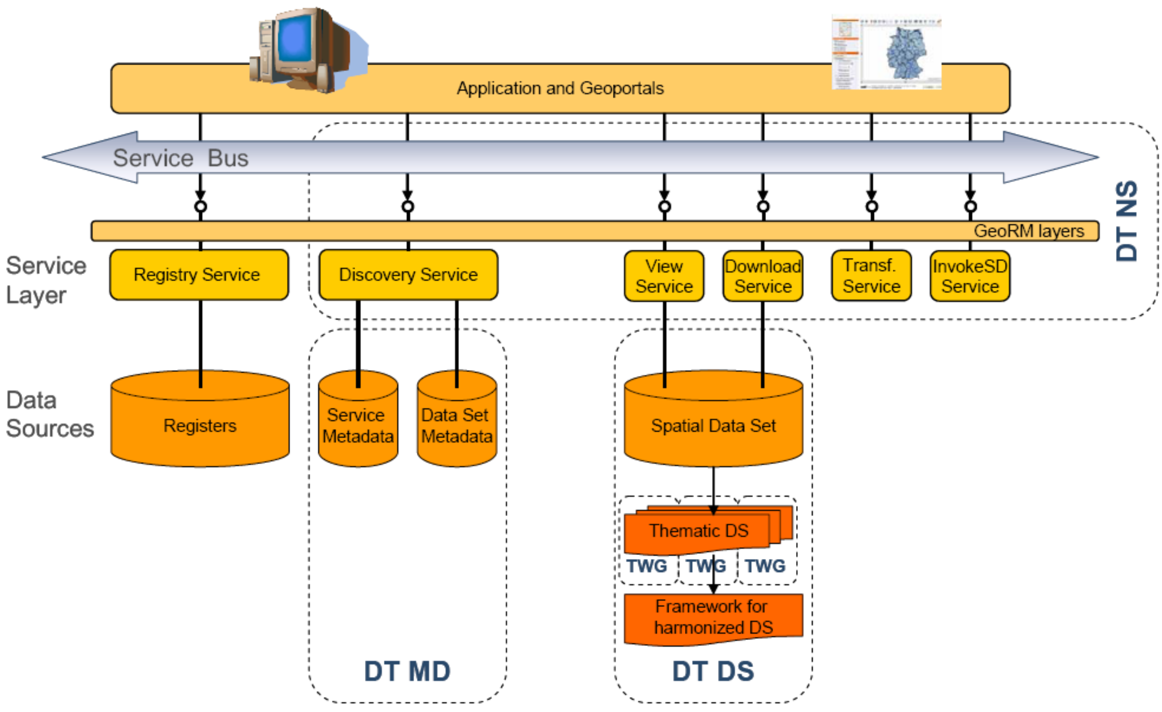


Figure 5.7.1.2 Overview of the INSPIRE Network Services Architecture

The INSPIRE Network Services Architecture aims at providing guidelines towards all initiatives in Europe that implement SDIs under the umbrella of the INSPIRE

[52] http://www.ec-gis.org/inspire/reports/ImplementingRules/network/D3%205_INSPIRE_NS_Architecture_v2.0.pdf
[53] http://www.w3.org/TR/2004/NOTE-ws-arch-20040211/

legislation and the related implementation of this European initiative by Member States.

The control of access from applications and GeoPortals to view and exploit spatial data services is, under the INSPIRE Network Services Architecture, performed through the Geo Rights Management layer (GeoRM), see Figure 5.7.1.2. The GeoRM should allow public authorities to electronically specify licence terms and conditions in such a way which supports the automated transfer of legal rights to use the spatial data or service, provide services to enable e-government integration of network services, manage authentication, authorisation, pricing, billing, logging, etc.

5.7.1.3 Software

OGC Web Services are to a varying degree supported by commercial as well as Open Source GIS packages. As software is constantly developing this guidance will not provide specific software recommendations, but rather point to the OpenGeospatial[54] website for the updated information.

5.7.2 Types of web services

Architecture of services ISO 19119 classifies the services as follows:

- Human interaction services (GIS clients, Geo Portals, catalogue clients, etc, also WS-BPEL viewers for workflow definition);
- Model/Information management services (management and access to data, WMS, WFS, CSW, etc);
- Workflow services (chain definition and enactment such as the WS-BPEL standard);
- Geo-processing services (spatial, thematic, temporal and metadata);
- Communication services (encoding and infrastructure, application servers and Enterprise Service Bus ESB).

The INSPIRE Network Services Architecture classifies the network services slightly differently and uses more a usage perspective.

The following services are defined in INSPIRE: (text taken from D3.5_INSPIRE_NS_Architecture_v2.0.pdf):

- **Discovery services:**

  Discovery services make it possible to search for spatial data sets and services on the basis of the content of the corresponding metadata and to display the content of the metadata. Within the geographic community various names have been assigned to instruments for discovering spatial data and services through the metadata properties; examples are Catalogue Services, Spatial Data Directory, Clearinghouse, Geographic Catalogue and Geodata Discovery Service. In INSPIRE these services are referred to as Discovery Services. The goal of discovery is to support discovery, evaluation and use of spatial data and services through their metadata properties. Metadata is the information

[54] http://www.opengeospatial.org/resource/products

and documentation, which makes these resources understandable and sharable for users over time. Indexed and searchable metadata provide a controlled vocabulary against which discovery can be performed. INSPIRE Discovery Services shall provide the functionality for users both to manage and search catalogues or the purpose of discovery and evaluation within the context of the INSPIRE Directive. The network of services should also include the technical possibility to enable public authorities to make their spatial datasets and services available. The INSPIRE Directive specifies that Member States shall ensure that public authorities are given the technical possibility to link their spatial datasets and services to the network. This 'linking' service is also offered in the context of a discovery service as a capability of the discovery service.

- **View services:**

  View services make it possible, as a minimum, to display, navigate, zoom in and out, pan or overlay viewable spatial data sets and to display legend information and any relevant content of metadata". Member States shall ensure that e-commerce and GeoRM services are available for view services if required.

- **Download services:**

  Download services will enable copies of spatial data sets, or parts of such sets, to be downloaded and, where practicable, accessed directly. In addition, where public authorities levy charges for the download services, Member States shall ensure that e-commerce and GeoRM services are available.

  A download service supports:

  - Download of a complete dataset or datasets; or
  - A part of a dataset or datasets; and
  - Where, practicable, provide direct access to complete datasets or parts of datasets;
  - Gazetteer-like services are also covered by a type of download service.

- **Transformation services:**

  Transformation services, enable spatial datasets to be transformed with a view to achieving interoperability.

- **Invoke spatial data services:**

  The Invoke Spatial Data Service allows the definition of both the data inputs and data outputs expected by the spatial service and define a workflow or service chain combining multiple services. It also allows for the definition of the external web service interface of the workflow or service chain.

Guidance from INSPIRE

The INSPIRE roadmap[55] foresees the development and implementation of INSPIRE Implementing Rules (IR) for each of the service types. The timeline for services is

[55] http://www.ec-gis.org/inspire/inspire_roadmap.cfm

outlined in Table 5.7.2. Based on the roadmap it is anticipated that more specific guidelines in relation to WISE nodes will be provided in later amendments to this guidance document. It should be noted that the INSPIRE IR will not prescribe a specific service implementation (e.g. WFS) but rather specify the interfaces requested from the various types of INSPIRE services.

Table 5.7.2 INSPIRE Implementing Rules (IR)

Milestone date	Description
IR adoption	
2008-11-15	Submission for opinion of the INSPIRE committee of IR for discovery and view services
2009-05-15	Submission for opinion of the INSPIRE committee of IR for download services
2009-05-15	Submission for opinion of the INSPIRE committee of IR for coordinates transformation service
2010-05-15	Submission for opinion of the INSPIRE committee of IR for schema transformation and "invoke spatial data service" services
IR implementation	
2010-11-15	Discovery and view services operational
2011-05-15	Download and Coordinates transformation services operational
2012-11-15	Schema transformation and "invoke spatial data service" services operational

5.7.3 How web services will expand the WISE coverage

5.7.3.1 WISE distributed system

Since January 2008 discussions have started to establish an architecture for the WISE distributed system (WISEds). The WISEds is based on GIS web services and will allow the WISE community to work according the INSPIRE regulations.

To understand the use of web services in WISE one has to differentiate between a REPORTING and a DISSEMINATION flow;

- REPORTING will be defined as the data flow from Member States to the European commission;

- DISSEMINATION will be defined as the data flow out from the WISE database.

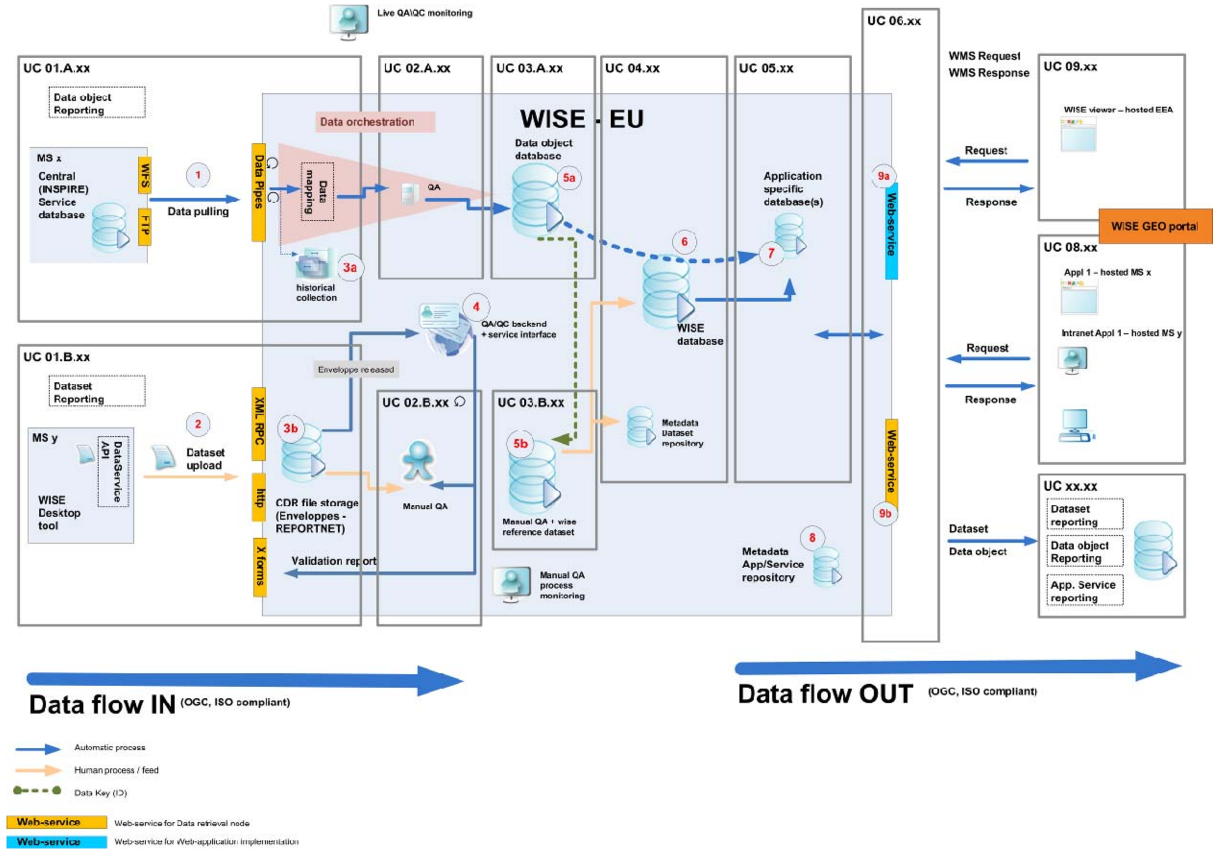

Figure 5.7.3.1 Overview of WISE distributed system

5.7.3.2 REPORTING data flow

Figure 5.7.3.2 illustrates how four types of REPORTING data flow can be distinguished based on the amount of data and the transaction frequency.

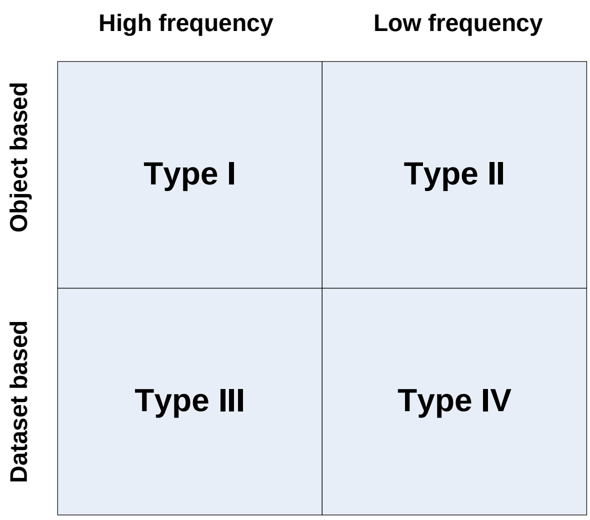

Figure 5.7.3.2 Data reporting types

At present WISE is almost only using Type IV data flows organised through a file based exchange mechanism (Reportnet). This type of communication will continue to exist in the future. However the introduction of GIS web services into WISE aims at opening the REPORTING data flow towards all other types and to introduce new possibilities for Type IV. Typical usage of each type are:

- Type I: This type of communication could occur when a Member State reports any change they make in their database related to WISE data. It means that every transaction in the central database of the Member States is directly pushed to the WISE distributed system. Each transaction might have a single object (record) or a limited list of objects. It also should be related to datasets that are changing frequently, such as weekly bathing water quality measurements;
- Type II: A typical data flow could be the update of a River Basin District. A single object is reported but most likely a Member State is not updating its River Basin Districts every month;
- Type III: This is a less common type but could be used to exchange, for example, aggregated datasets;
- Type IV: Some Member States might have revised the complete dataset of their rivers (new surveys). In this case the Member State reports a complete dataset on a certain topic. Based on WFS and GML based SOAP services upload mechanisms could be foreseen to handle this type of input data.

How these new types of data flow will be implemented is still subject of discussion as it relies on the implementation rules of INSPIRE, which are still being drafted, and several stakeholders are involved with the set-up of the infrastructure which requires strong coordination and consultancy.

5.7.3.3 DISSEMINATE data flow

The DISSEMINATE data flow will be used to disseminate the data that has been collected and processed under the reporting obligations covered by WISE. The flow is the machine-to-machine complement to the human interfaces of the WISE map viewer and will distribute all WISE data with a public access license.

The Member States can expect download, view, discovery etc services from the WISE output service node. The detailed specifications of each service will be defined based on:

- Current services provided by the WISE website;
- New user requirements;
- SEIS implementing rules (when available).

Member States that have the interest or capability may integrate the WISE web services directly into their own applications.

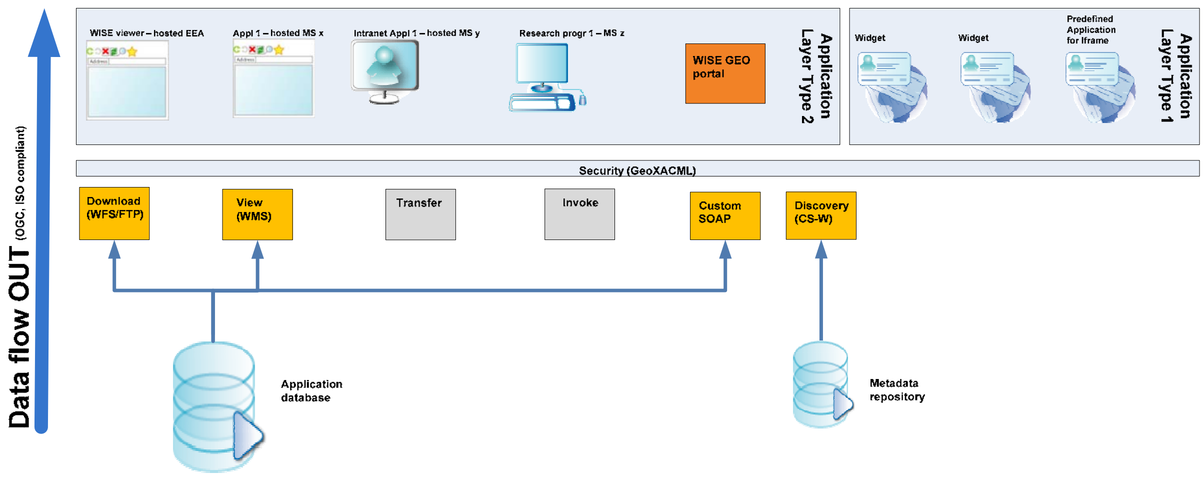

Figure 5.7.3.3 DISSEMINATE Data Flow

5.7.3.4 Role of MS provided web services

WISE compliant web services provided by the Member States will complement the WISE map viewer in several ways:

- Web services with data according to common WISE specifications will provide access to up-to-date information operationally in use in the Member States;
- National web services with data outside the scope of WISE specifications can extend the information available to the European users in two dimensions:
    - The granularity of information may be expanded, so the full set of information available at the Member State level may be exploited rather than a potentially sub-selected and aggregated set reported. The WISE map viewer currently operates with a threshold of scale 1:250,000 when providing web map services. Data with a better resolution should be provided and visualised by connection to national SDI nodes;
    - Feature types and parameters outside the WISE data specifications may be made available outside the Member State. These parameters and features could, for example, relate to the locally relevant pressures, monitoring data, potential measures or socio-economic conditions.

5.7.4 Recommendations for the set up of WISE compliant nodes

Member States that wish to extend the WISE coverage with national web services are encouraged to do so. While INSPIRE IR are not yet in place some recommendations can be given for implementation in the short term, as follows:

Software:

- WMS services should be implemented using SLD compliant software to allow a common (client specified) symbology to be applied.

Services to be provided:

- It is recommended that the data provision services as WFS, WMS and download services are established (see also data policy below);
- The services should be provided using the application schemas developed in WISE;
- Services outside the scope of WISE should be documented in English;
- Metadata services should be available from WISE and from the Member States;
- Service registry will be available from WISE.

Data policy:

- Provision of a spatial dataset specified as Member State submissions under European legislation should always be provided as free and open WFS and be downloadable;
- National spatial data established in relation to the implementation of water environmental policies should, as much as possible, be provided as free and open WFS and download services alternatively as WMS services.

A manual on the set-up of a WISE service node will be drafted once the architecture of the WISE distributed system is defined in detail and has been tested for robustness, scalability and performance.

6 Harmonisation

6.1 Validation and harmonisation of geometry, data definitions, data models, naming

Given that WISE is aimed at multiple use of the information reported from MS, the importance of harmonising has increased. The target of having comparable quality in data submissions from MS for assessment of compliance as well as the basis for developing reference datasets at the European level requires a common understanding of the harmonisation and validation procedures required.

Harmonisation of the national submissions has so far been one of the most resource consuming tasks at European level.

6.1.1 The purpose of harmonisation and validation of MS data

There are several reasons for harmonising MS data into common European data specifications:

- By conforming to European specifications the MS ensure that the provided data comply with the requirements given by the directives and other requests calling for the data;
- The Commission can streamline their evaluation of MS compliance with a directive when the input data conform to a common set of specifications;
- The Commission can streamline the process of producing and updating the pan-European WISE Reference GIS datasets from the MS submitted data;
- A streamlined process is particularly important when datasets are being updated or resubmitted;
- Harmonised data is a requirement for comparable analysis, reporting and visualisation of the European state of implementation of directives and state of the environment reporting;
- Working with harmonised datasets reduces the risk of misinterpretation as the harmonisation process ideally eliminates the national differences in data structures, encoding data schemas and level of detail.

Harmonisation starts at the MS/RBD level, where the primary information is available. A part of the harmonisation may take place at either MS level or EC level. The validation of data submitted by the Member States is the first step of the verification that the MS are fulfilling the requirements of reporting specified in the directives in question. Secondly, a data quality assessment to ensure that the data are of sufficient quality for further application has to be made. Finally, a single harmonised feature dataset can only be produced at the European level. Figure 6.1.2 depicts where the various processes takes place.

6.1.2 Harmonising MS data for submission to WISE

Harmonisation of data in the Member States prior to submission into WISE is the most crucial part of the harmonisation process. As the data specifications from the implementing rules of the INSPIRE Directive have not yet been implemented, the data collections at MS level will be of varying structure, thematic content and quality.

The starting point is the selection of a spatial dataset covering the proper spatial object type (monitoring stations, river segments etc.) and having a resolution complying with the data specification.

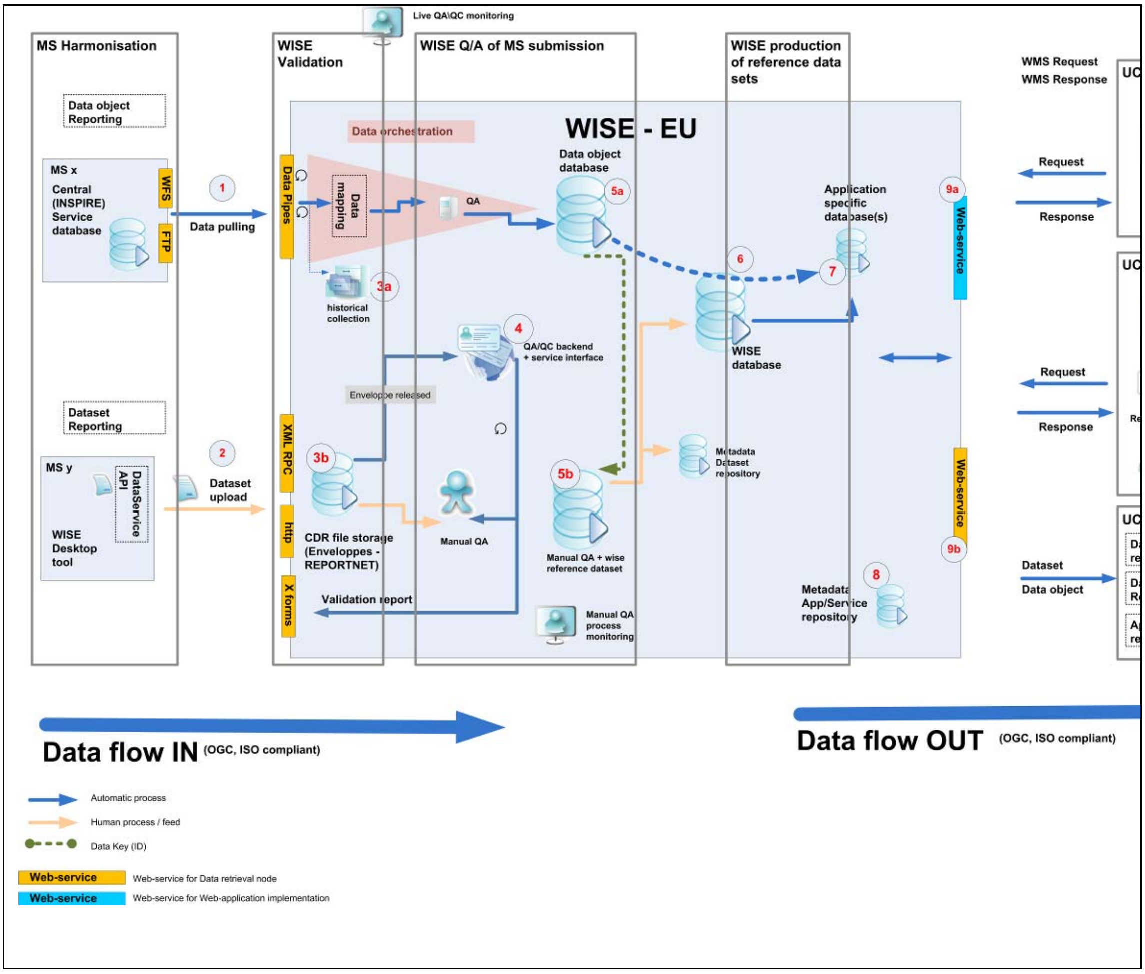

Figure 6.1.2 Harmonisation and validation processes in the WISE architecture. (Detailed explanation in the WISE architecture document available from https://svn.eionet.europa.eu/projects/Reportnet/wiki/WiseDS)

Member States have, in many cases, several spatial datasets with the proper object type. The dataset to be used will be selected on criteria such as:

- Having a level of detail and resolution similar to or better than requested;
- Being up-to-date;
- Having an operational use in the relevant national implementing authorities;
- Having features attributes that either contain similar feature attributes as specified or can, through feature identifiers, be linked to such information.

Spatial reference system transformation:

MS should deliver the spatial dataset in the agreed coordinate reference system (see Chapter 5.1.3) using ETRS89 as the geodetic datum and using ellipsoidal coordinates (decimal degrees).

As experience has shown that the transformation formulae from the national coordinate reference system to the ETRS89 system in some areas are less accurate, it is recommended to validate the transformation using e.g. boundary data from the EuroRegionalMap. The feature harmonisation with neighbouring regions/countries may also be used as a part of this validation.

Feature harmonisation:

Harmonisation of features to the data specifications has two main elements:

Harmonisation of features with neighbouring regions and countries:

The RBDs and MS are expected to deliver data that has been harmonised with the neighbouring countries/RBDs. Experience still has to be gained to identify the usage of River Convention data. Appendix B of the INSPIRE document D2.6 Methodology for the development of Data specifications, provides recommendations regarding harmonisation of continuity of linear and polygon features across borders.

Member States will report spatial datasets to EU bodies under various articles of the WFD. These datasets come from national repositories which are not necessarily geometrically aligned across national borders or to a pan-European coastline. To connect borders of River Basin Districts or rivers across national borders, one option for Member States will be to align their data with a selection of EuroRegionalMap at scale 1:250 000. This data selection essentially comprises the national borders, the coastline and hydrological features that cut across national borders. Member States will be able to download these data sets free of charge from a dedicated section of WISE provided they do not use these data for any other purpose. Download will be restricted to authorised persons in the water authorities.

As recommended in Chapter 5.1.3.3. Member States need not to simplify their datasets before submitting to WISE. Thus, if agreed within the respective RBD, also larger scale data can be used for the geometrically alignment across national borders. EU bodies will align these submissions to EuroRegionalMap.

Feature attribute harmonisation (schema transformation)

The feature attribute names and associated code lists in the national databases will rarely be the same as specified in the WISE application schema. The harmonisation will require a transformation of the national database schema into the application schema and similarly a transformation of the feature attribute values to fit into the code lists of both the data model and the data dictionary. The XML schemas and end-user tools support the correct feature attribute transformation by applying code lists and schemas.

Format transformation:

The GIS data and the associated feature attributes should be converted to either shape files or GML according to the Data Structure schema specified for the specific reporting obligation. More details on GML may be found in Chapter 5.6.

File naming:

Applying common file naming conventions helps streamlining the validation process when data is received into the WISE system. The file naming include the following elements:

- Country ID;
- River Basin District ID;
- Feature set name;
- Date.

Specific guidelines for the naming of files will be included in short GIS reporting guidelines for each reporting obligation.

6.1.3 WISE validation of MS submissions

The validation of a MS submission ideally takes place immediately after the upload of data. The validation process is a set of technical tests to check whether or not data conform to the data specifications.

Validation steps:

- Does submission include the expected files?
    - Is the naming of files in line with the specifications?
    - If the submission is split into more than one region – are all regions provided?
    - If the submission is split into several themes – are all themes provided?
- Is each set of files complete and in conformance with the specifications?
- Within each set of files:
    - Is the type and format of files correct?
    - If the delivery is in XML:
        - Can the file be validated against the defined application schema?
- Metadata:
    - Do the referenced data sets exist in WISE?
- Spatial coverage:
    - Is the spatial reference system documented and in conformance with the data product specifications?
    - Does the provided spatial data set have the expected coverage (MS, River Basin District, Sub-unit etc.)?
    - EuroRegionalMap should be applied to verify that:
        - all features fall inside the proper territory (evaluated within the tolerance of the spatial accuracy)

        - that features with continuity into neighbouring countries have an end-point on the border (evaluated within the tolerance of the spatial accuracy).

- Feature attributes (If the delivery is in non-XML format):
    - Have the right feature attribute names been defined?
    - Are mandatory feature attributes given valid information?
    - Are attribute values, including size, within the specified domain?
- Feature associations:
    - Do features that are referenced to through matching feature IDs exist (previous deliveries or other feature data set in same submission)?
    - Is there consistency between the feature extent and the position/extent of the referenced features (e.g. is a monitoring station situated inside the RBD it belongs to)?
- Topological relations:
    - Does the coverage fulfil the topological rules defined for the feature data set – e.g. no gaps and no overlaps between features, connected features etc?

Determining data quality:

The spatial data submitted by the MS should in general comply with:

- Fitness for use. The data submitted by the MS should fit the requirements expressed in the Reporting sheets (to be replaced by the Consolidated Guidance on Reporting) and data specifications;
- Customer satisfaction (in close relationship with the previous point). The final layer should satisfy the expectations of the MS with regards to the WISE reference layers;
- Conformance to requirements, standards and expectations.

After the MS submission, it is a requirement to have a clear assessment of:

- Completeness (contains no missing features or values);
- Consistency;
- Accuracy (closeness to reality);
- Resolution.

Discovering errors:

Two forms of analysis should be undertaken:

- Exploratory – look for the unusual;
    - Visual checks: completeness, positional accuracy, etc.;
        - Verify: spatial reference, scale, resolution, positional accuracy, existence of metadata (following standards), completeness of the metadata, etc.

- Confirmatory – verify rules and criteria have been met;
    - o Automated checks: To discover geometry/topology/attribute errors, supported by the use of GIS tools.

6.1.4 Harmonisation at European level:

Harmonisation at the European level has the purpose of producing a single feature dataset of homogenous quality according to an application schema. If the European dataset is to be produced with the same specifications as MS deliveries, the process is ideally a simple merge of national submissions that only should consider duplicated features forming the borders between MS.

A few manual checks may however be applied, if they are not already integrated as a part of the validation process:

- Does the variation in the density of features across each Sub-unit, RBD, MS and Europe as a whole reflect the expected variation or have e.g. the data-capturing rules been applied differently?
- Is there continuity of matching features of same object meeting at the border (rivers or lake borders)?
- Where the border is formed by a feature (river or lake) there is a risk of duplication:
    - o Do they share same geometry, can one geometry be substituted by the other or should they be dissolved into a single geometry?
    - o Transmission of feature attribute values from both countries to a harmonised feature.

6.2 Production of the WISE Reference GIS datasets

The WISE Reference GIS datasets are managed and maintained by the EEA and have been compiled from data provided by Member States under WFD Articles 3 and 5, or, in the case of Sub-units, at the request of the European Commission.

Some additional processing is applied to the data provided by the Member States, where necessary, in order to produce the WISE Reference GIS datasets, including:

- The harmonisation of ‘duplicate’ features and geometrical inconsistencies at national borders using EGM (up to 20% of the features[56]) or ERM (up to 10% of the features;
- Complementation of geometries using ERM data where data provided by MS do not fulfil the WISE Reference GIS dataset specification;
- The selection of rivers with specific catchment areas from submitted data using CCM2.1 or the EEA’s European River Catchments (external GIS datasets);

---

[56] Due to copyright restrictions, Eurogeographics allows for public distribution of parts of EGM and ERM (20% and 10% of features, respectively). If a larger share of the features in a feature class is used the resulting dataset cannot be publicly distributed.

- The application of consistent and stable hydrological codes to features in order to successfully manage the linkages between WISE Reference GIS datasets.

Many Member States are already involved in bilateral co-operation agreements with, for example, International River Commissions, in an effort to harmonise their data and resolve geometrical inconsistencies at national borders. Data resulting from these important agreements will be beneficial for the production of WISE Reference GIS datasets and MS are encouraged to document/identify when the submitted data are outcomes of such agreements.

The European Commission is in the process of reviewing the WFD Articles 3, 5 and 13 Reporting sheets with the aim of producing a consolidated Guidance on Reporting in time for the reporting of RBMPs under Article 13. This may require Article 3 and 5 data resubmissions from MS where there were gaps in the original submissions or where details have changed. The aim is to produce a more efficient and streamlined reporting system through WISE in the future.

In the following Chapters, the processing of WISE Main Rivers and Main Lakes are provided as examples.

6.2.1 Approach for the processing of the WISE Main Lakes and Main Rivers layers

6.2.1.1 Main Lakes:

The development of the Main Lakes layer for WISE is based on the objects reported by the Member States under WFD Articles 3 and 5 complemented with data from ERM (EuroRegionalMap v2.0).

Two main issues are related to the processing of WFD Articles 3 and 5 data into the WISE Main Lakes dataset:

- The size criterion for WFD Article 3 Main Lakes is different from the WISE Main Lake specification (lake surface area of 100 km^2 versus 10 km^2).
- Lake Water Bodies reported in WFD Article 5 may be reported as centroids instead of polygons. Furthermore, does the definition of a Lake Water Body allow for the option that a) a lake may be divided into more than one Lake Water Body and b) a Lake Water Body may consist of more than one lake.

Since the WFD Articles 3 and 5 data are not in all cases sufficient to build the polygon layer of WISE Main Lakes, an additional layer has been taken into account. The ERM (EuroRegionalMap[57] v2.0 - feature class LakesresA) was selected as that additional layer.

The main objective for the production of the WISE Main Lakes layer is a good set of geometries representing the lakes submitted by Member States under Articles 3 and 5. As the same lake might be represented differently in the input layers a list of priorities has been established:

- First priority - WFD Article 3 Main lakes;
- Second priority – WFD Article 5 Lake Water Bodies;

[57] http://www.eurogeographics.org/eng/04_products_regionalmap.asp

- Third priority – ERM, feature class LakesresA.

The main principle has been that if a lake with a surface area above 10 km^2 has not been delivered as a polygon feature under either WFD Articles 3 or 5 then the proper geometry has been selected from ERM using WFD Article 5 centroids. The workflow of the processing the geometries of the features is summarised in Figure 6.2.1.1.

The results of processing the WISE Main Lakes layer were:

- Total number of lakes based on Articles 3 and 5 submissions: 9822 lakes;
- Main Lakes (Area ≥ 10km2): 856 lakes, where:
    - o 576 geometries (67.3%) originate from Articles 3 and 5;
    - o 280 geometries (32.7%) originate from ERM.

More information about the input layers, GIS processes applied and the methodology will be made available from the WISE web site.

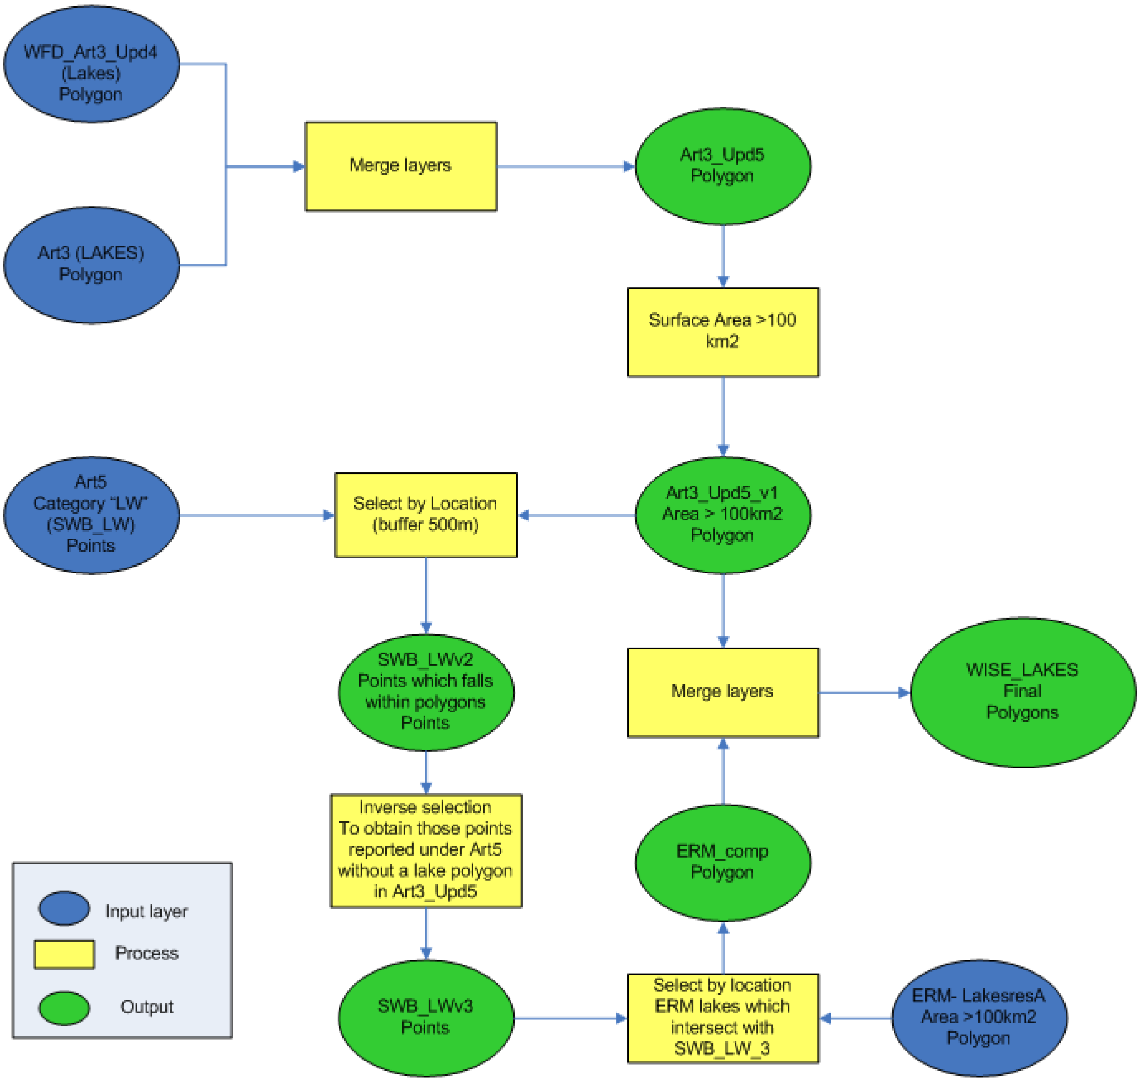

Figure 6.2.1.1 GIS workflow for the construction of the Main Lakes layer based on Articles 3 and 5 submissions and ERM v2.0. Lakes with an area equal or larger than 10 km2 are considered to be Main Lakes.

6.2.1.2 Main Rivers

As for lakes, the development of the Main Rivers layer for WISE is based on the objects reported by the Member States under WFD Articles 3 and 5, complemented with data from ERM (EuroRegionalMap v2.0). Catchments from CCM2.1 are used to ensure a consistent data capture criteria throughout Europe.

A number of issues are related to the processing of WFD Art. 3 and Art 5 data into the WISE Main Rivers dataset:

- Although the WFD Article 3 Main Rivers and the WISE Main Rivers have the same catchment size criterion (catchments > 500 km^2) an overview of the submitted data show differences;
- River Water Bodies reported in WFD Article 5 may be reported as centroids instead of polylines. Furthermore does the definition of a River Water Body allow for the option that:
  - a river/ river segment is divided into more than one River Water Body and;
  - a River Water Body may consist of set of rivers/river segments.
- As WFD Article 5 data consists of water bodies for evaluation of ecological status, continuity through lakes and heavily modified stretches is not ensured.

Analysis of the data submitted by the Member States revealed several problems, basically due to quality aspects, completeness, geometry consistency, connectivity, attributes, etc. More information about the input layers, error analysis, GIS processes applied and the methodology will be made available from the WISE web site.

Since the WFD Articles 3 and 5 data are not in all cases sufficient to build the WISE Main Rivers layer with a connected set of rivers for all rivers with a catchment area above 500 km^2, a complementary layer, ERM (EuroRegionalMap v2.0 (feature class WaterCourses) has been selected.

The input GIS layers used for the analysis and for the development of the methodology are:

- Article 3 submissions (and its update) line feature classes;
- Article 5 submission (point and line type geometries);
- ERM v2.0 (WaterCourses) as complementary source of features.

The main objective for the production of the WISE Main Rivers layer is a good set of geometries representing the rivers submitted by Member States under Article 3 and Article 5. As the same river might be represented differently in the input layers a list of priorities has been established:

- First priority - WFD Article 3 Main Rivers;
- Second priority – WFD Article 5 River Water Bodies;
- Third priority – ERM, feature class WaterCourses.

The main principle has been if the Main River in a catchment with an area greater than 500 km^2 has not been delivered as a polyline feature under WFD Articles 3 or 5 then the proper geometry has been selected from ERM using WFD Article 5 centroids. In the future, Member States may provide features that may supersede the ERM features.

If the aggregation of the geometries of the selected Articles 3 or 5 data do not result in a continuous geometry, complementary data are obtained from the ERM data. If neither river segments nor water body centroids are present for a CCM2.1 catchment with an area greater than 500 km^2, ERM data are also used.

6.3 WISE reference features for visualisation

6.3.1 Purpose of WISE reference features for visualisation

WISE reference features for visualisation are features such as River Basin Districts or water bodies available in a European wide topological harmonised dataset (WISE Reference GIS dataset). They will be used to:

- Visualise data reported by Member States in a harmonised way;
- Provide comparable units for data analysis and the development of indicators.

WISE reference features can also be used to link tabular reported data and information to GIS data that is already available in WISE. The reference established between WISE reference features and Member State reported data will be either:

- The reference between different features based on a specified relationship (e.g. Member States reported river monitoring stations to WISE reference river water bodies); or
- The reference between the same entities:
    - o Either between Member States reported not harmonised GIS data and harmonised WISE GIS datasets (Member States River Basin Districts to WISE River Basin Districts); or
    - o Between Member States reported tabular information and harmonised WISE features (e.g. status information on Groundwater bodies to WISE Reference Groundwater bodies; data reported for WISE-SoE monitoring stations to already reported WFD (Article 8) monitoring stations).

The reference will be done by means of a database. Spatial overlay of geographical datasets to link and analyse data will not always give the required results because of different data quality, level of detail and positional accuracy. Furthermore, problems might occur in handling of coordinates, reference systems and projections as well as during transformation of data. The exercise to locate WISE-SoE river monitoring stations to a European wide river dataset proved to be very troublesome. River monitoring stations are quite often located near the mouth of a river. To receive the correct location at the river overlaying point information (which is most of the time quite accurate) with a river dataset in the scale of 1:250.000 or even smaller will fail in many cases. Thus it will be necessary to refer monitoring stations to rivers in the dataset itself (attribute).

Relationships as regards case (a) mentioned above need to be defined in the data model. As regards case (b); Member States reported data should also include the identifier of the WISE objects as attribute (foreign key) either in the GIS dataset or in the table (e.g. Member States River Basin District (RBD) code and WISE RBD code).

Visualisation:

Data reported by Member States to WISE can be visualised either by:

- Displaying the Member States data regardless of whether data have been harmonized with neighboring countries or not, and regardless of whether or not data specifications developed for specific reporting have been taken into consideration (in this case Member States data will be marked accordingly);or

- Displaying the reference features and the harmonised data linked to them.

Example: Visualisation of river water bodies

In WFD Article 5 reporting, Member States were requested to provide information on the centroids of all water bodies. During this exercise, some Member States also provided information on river stretches. This has resulted in a variety of non-homogeneous information being provided (see Figure 6.3.1a): centroids-only, centroids & river network, and centroids and river stretches.

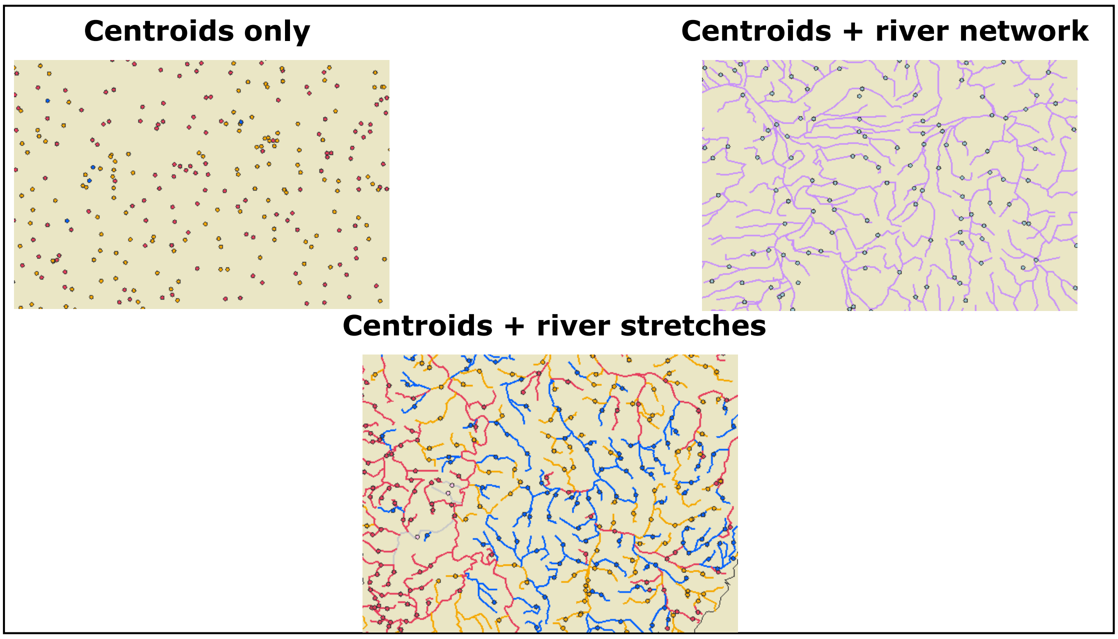

Figure 6.3.1a Information provided by Member States for visualisation of water bodies (WFD Art. 5 2005 submission)

Furthermore, Member States have used different methods to calculate the centroids of water bodies (see Figure 6.3.1b).

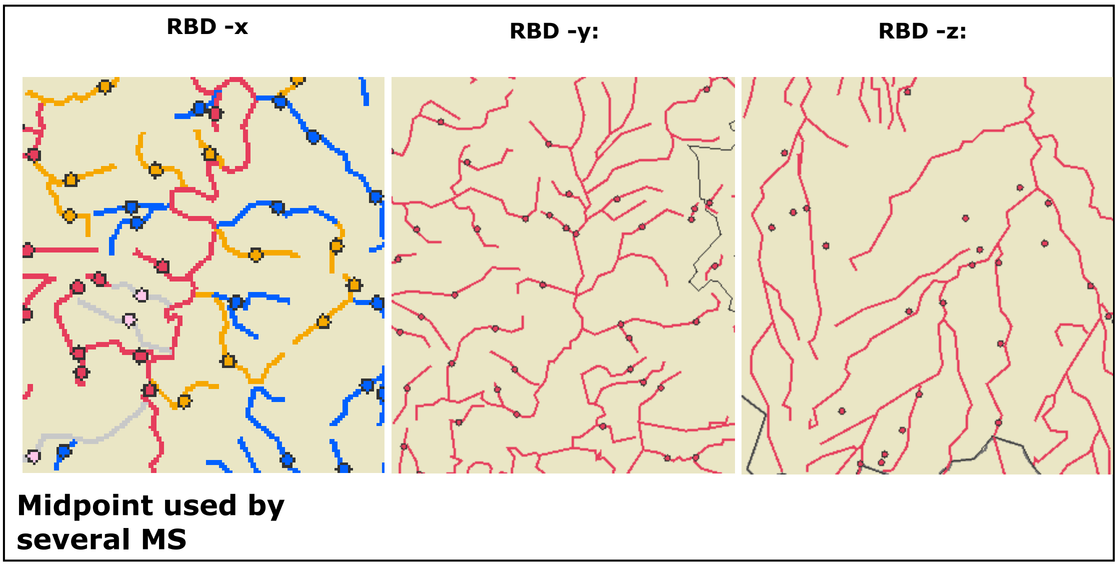

Figure 6.3.1b Representation of water body centroids provided by MS (WFD Art. 5 2005 submission)

This has resulted in an heterogeneous EU-wide dataset on 'water bodies'. To solve these problems it has been proposed to visualise river water bodies based on the WISE Reference GIS dataset Main Rivers. River water bodies located on Main Rivers should now be reported as hydrologically connected and harmonised river stretches (line features).[58] Thus a harmonised visualisation of reported data on river water bodies will be achieved in future.

Analysis:

Data and information reported to WISE will be used to present an EU-wide picture of water- related issues. The detailed information provided by Member States will be aggregated and visualised using meaningful spatial units at a European scale. To meet these demands, WISE reference features allowing comparable statistics and the development of indicators, have been defined (see Chapter 5.2).

As regards statistics, WISE reference features will be:

- Meaningful units to present information at a European scale (in relation to the aspired visualisation scale);
- Comparable depending on the specified statistical analysis and assessments.

Thus the definition of WISE reference features will also accommodate the purpose of use (e.g. compliance check; indicator development) and the required statistical analysis into consideration.

Example: River Basin Districts – Sub-units

Reporting under WFD is related to River Basin Districts. There was a general agreement that the portrayal of information at RBD scale is of value given the breadth of information associated with it. However, it was concluded that the use of the RBD scale alone could distort the comparison of data between Member States, due to the existence of a few RBD’s that are much larger than the rest (see Figure 6.3.1c).

There was agreement between the EC and Member States of the need to subdivide the larger RBDs to provide Sub-units of more similar size for better comparable analysis. A WISE reference GIS dataset of Sub-units will be developed (see Chapter 3.1) and in future, in addition to RBDs, data reported under the WFD should also be linked to Sub-units.

[58] Presentation at WISE conference on 22-23 March 2007: http://circa.europa.eu/Public/irc/env/wfd/library?l=/framework_directive/implementation_conventio/european_conference/presentations_speeches/part_4_23_march/deugenio-pdfpdf/_EN_1.0_&a=d

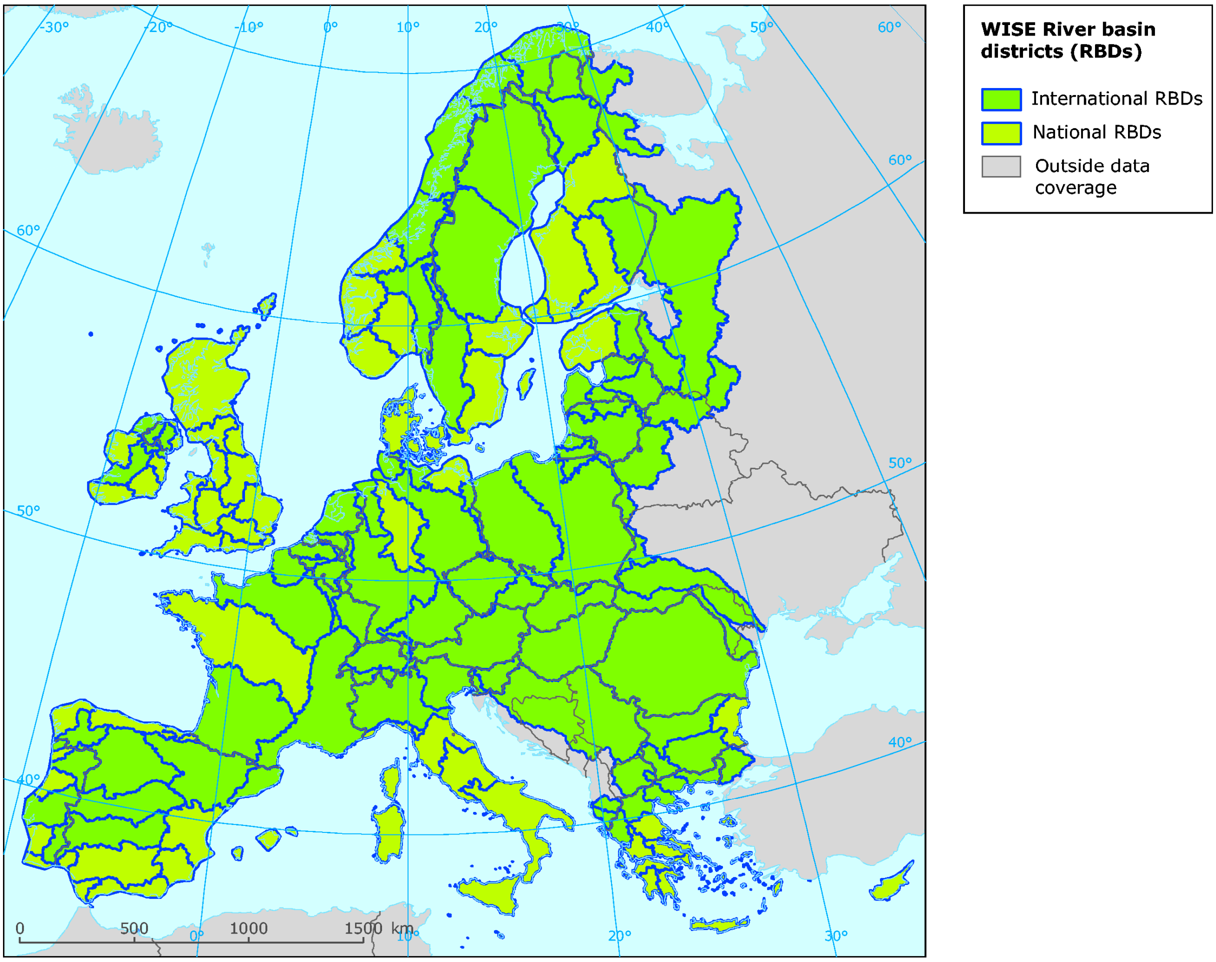

Figure 6.3.1c River Basin Districts[59] of the EU

6.3.2 Issues associated with WISE reference features

The main criterion for the use of reference features will be that they **should be built from Member States submitted data** to be able to visualise reported data correctly. Furthermore the positional accuracy and level of detail of the reference dataset should be in line with the required visualisation scale (for more details see Chapter 5.1.3).

If data provided by Member States are generalised to build reference features, the outcome of the generalisation must be validated by the data provider. This needs to be done to ensure the correct linkage between Member States data and reference features.

The guidelines for the development and use of reference features for visualisation are:

- **Definition of data use;**
  - Specification of the required visualisation of the data;
  - Specification of the required data analysis and/or indicator development.
- Specification of the **relationships between reference features and Member States reported datasets and objects**, needed to fulfill the intended use of data.

[59] http://dataservice.eea.europa.eu/atlas/viewdata/viewpub.asp?id=3687

To define correct relationships, data specifications, especially data capturing rules (see Chapter 5.1), of provided data must be analysed. Relationships defined will also depend on the intended use of data (data analysis, indicator development).

For Example:

- All WFD reported information or datasets are linked to River Basin Districts/Sub-units;
- River monitoring stations are linked to river water bodies;
- River water bodies are linked to rivers.

  The above given relationship must be specified further before it can be transferred to a data model. In most cases, the relationship will be n:m (a river water body can be located at several rivers; a river will be composed of several water bodies). But this will only be true if river water bodies have been defined as river stretches (reaching from river km A to river km B). If they have been defined as polygons (catchments) the relationship could be different.

  Thus data capturing rules of river water bodies within Member States need to be analysed to be able to define the correct relationship between rivers and river water bodies.

- Development of **data models** supporting the specified relationships:
  - WFD objects reported should carry the WISE RBD code as foreign key;
  - River monitoring stations should carry the WISE river water body code as foreign key;
  - River monitoring stations located at Main Rivers should carry the hydrological code of the main river and the hydrological code of the river segment as foreign key;
  - **Unique identifier must be available for all relevant objects** (Member States data and reference features) and requirements given in Chapter 4.4 for identifier management must be taken into account (uniqueness, persistence). Furthermore to allow a persistent reference over time, rules for historic data management should be specified.

A description of the relevant WISE reference features and reference datasets (data specification, metadata) including the necessary details as mentioned above will be available in WISE.

6.3.3 Examples of WISE reference features for visualisation

Proposed WISE reference GIS datasets related to WFD reporting are described in Chapter 3.1 and an overview of the GIS layers in WISE is given in Chapter 5.2. In the following, text, some examples of reference features and their use will be provided. In future, further WISE Reference GIS datasets and reference features might be identified.

Main Rivers & Main Lakes:

The WISE Reference GIS dataset Main Rivers and Main Lakes contains rivers that have a catchment area > 500 km^2 and lakes that have a surface area ≥ 10 km^2. They are based on WFD Article 3, Article 5 submissions and when needed ERM (EuroRegionalMap) will been used to complement the layer. For more details about the datasets see Chapter 6.2. ERM data will be replaced by Member State data as soon as they become available.

Main Rivers and Main Lakes will be reference features for objects related to surface waters such as monitoring stations, bathing waters, waste water treatment plants. If desired, statistical analysis such as "number of river monitoring stations on a certain river" can be carried out.

The datasets will be related to the reference datasets on Surface Water Bodies on Main Rivers and Main Lakes (see below). Only surface water bodies located on Main Rivers will be visualised as river network in WISE.

Surface Water Bodies on Main Rivers & Main Lakes:

Surface water bodies on Main Rivers and Main Lakes will be the reference features to visualise surface water bodies reported by Member States as a connected river network (line feature) and lakes (polygon feature). They will be based on WFD Article 5 submissions of surface water bodies. A precondition to build this dataset will be that Member States report surface water bodies in future as line and polygon features and not as centroids (points) for this reference dataset. Furthermore the selection of the surface water bodies should be based on the rivers and lakes available in the WISE Reference GIS dataset "Main Rivers & Main Lakes".

The reference features will be used to visualise information related to water bodies that are located at Main Rivers and Main Lakes like status information or heavily modified and artificial water bodies.

Furthermore, objects related to surface water bodies on Main Rivers and Main Lakes such as monitoring stations, bathing waters, waste water treatment plants can be visualised and analysed.

Groundwater Bodies:

The reference features Groundwater bodies will be based on WFD Article 5 submissions of Groundwater bodies. Groundwater bodies are transnational features and can also cross borders of River Basin Districts. Thus a harmonised European dataset will be developed including a unique European identifier.

River Basin Districts:

The reference feature River Basin Districts is based on the Member State submission under WFD Article 3. The data have been merged and harmonised to a European wide dataset. RBDs can be transnational features (international RBDs), thus a European unique identifier will be developed (see Chapter 5.4).

All data and information reported under the WFD is related to RBD. Thus RBD will be the main unit to analyse and visualise WFD data at the European scale. However, the issue of Sub-units needs to be considered.

Sub-units:

River Basin Districts are quite different in size. A few RBDs are much larger than the rest. Therefore it was agreed between EC and Member States to subdivide the larger RBDs to provide Europe-wide Sub-units of more comparable size which would be better suited for comparative analysis. It was agreed that the Sub-units should fall within national boundaries and be of a size between 5,000 and 50,000 km^2. This lower size limit does not mean that declared RBDs that are of a size less than 5,000 km^2 need to be redefined. Where RBDs exceed the threshold, the sub-basins or other suitable hydrological areas within the RBD could be defined as Sub-units.

In future, all data and information reported under the WFD should be related to Sub-units and/or RBDs . Thus in addition to RBDs, Sub-units will be the main units for analysis and visualisation of WFD data at the European scale.

Monitoring stations:

Monitoring stations will not be a WISE Reference GIS dataset as defined in Chapter 3.1. However, the monitoring stations of the WISE Reference GIS dataset reported under WFD Article 8 will be the reference feature to visualise various data related to monitoring stations. This should comprise all water-related monitoring stations (e.g. WISE-SoE monitoring stations or monitoring stations relevant for Nitrates Directive reporting should be subsets of the WISE Reference GIS dataset Monitoring stations). Thus data linked to monitoring stations can be reported in tabular form and linked to the information already available in WISE.

A precondition will be that monitoring stations must carry unique identifiers and, irrespective of the use of the station (SoE, WFD, BWD, NID, …), they will always be reported with the same unique identifier.

Note: *Monitoring stations or any other point information, for example agglomerations, urban waste water treatment plants, discharge points from urban waste water treatment, bathing water monitoring stations, etc. are the thematic layers that can be interlinked with the WISE Reference GIS datasets.*

Other WISE Reference GIS layers for other EU water policies, e.g. Sensitive Areas and their catchments for UWWTD, Nitrate Vulnerable Zones for NiD, etc. may be developed in the near future.

7 Coordination

7.1 Development phases of reporting cycle

The process on *what* to report is based on the legal requirements of EU water policy areas, and on the information needs of the European Parliament, other EU services and the European Commission's obligation to provide information for European Citizens.

The development of specific guidelines for the content and transmission of information of a particular reporting obligation follows a defined process under the Common Implementation Strategy (CIS) as seen in Figure 7.1.

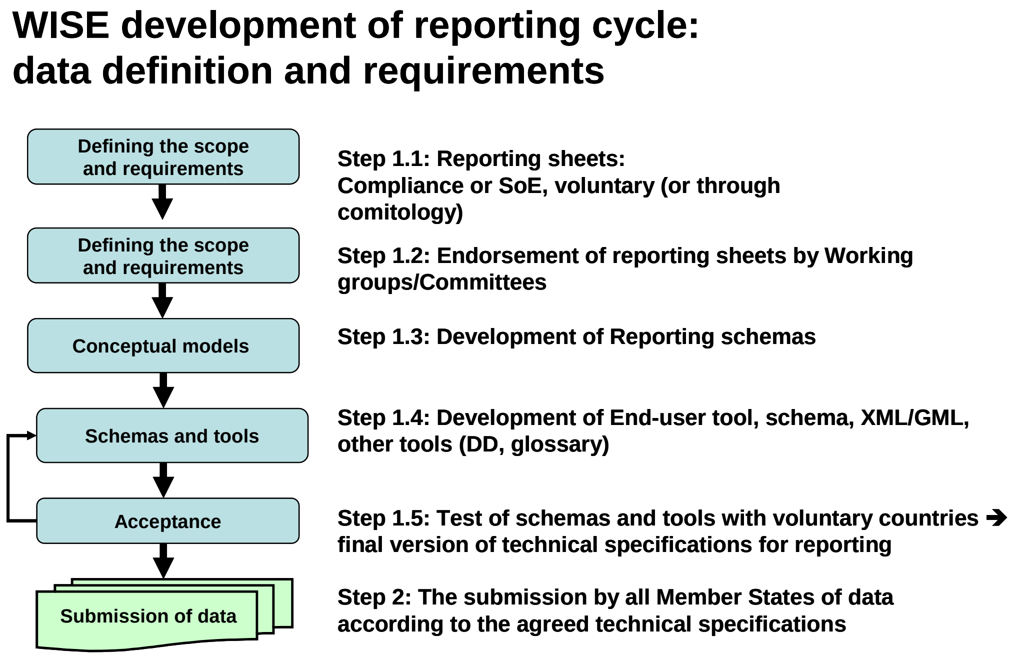

Figure 7.1 The development of specifications for a specific reporting obligation

In some cases, a Concept Paper on Reporting for a particular directive or an Article of a directive may be produced as a precursor to the Reporting sheets to allow the stakeholders to see and discuss the broader, strategic context of reporting before focussing on the more specific aspects of the Reporting Sheets.

Having the agreement on the contents and the form of reporting under each reporting exercise, technical implementation of reporting takes part.

Further steps of work flow and data flow via WISE is already presented in Chapter 1.2. The development cycle ideally starts 2-3 years in advance of the reporting deadline to allow Member States a timely implementation followed by the reporting.

7.2 Main coordinating groups

The central role of WISE development belongs to the WISE Steering group (WISE SG).

7.2.1 WISE Steering group

The WISE Steering group (WISE SG) is the main coordination body established at the EU level. It consists of representatives of four EU services (Group of 4: DG ENV, JRC, ESTAT and EEA) who guide the development of WISE. It ensures proper linkages with European Commission processes such as INSPIRE, SEIS and GMES. DG Environment chairs the WISE SG, holding meetings 2-3 times per year and external experts are invited as needed. The WISE SG reviews progress and plans upcoming work. It is also the forum to make connections to new and related work areas of WISE. WISE SG work is based on the WISE Implementation Plan agreed among the Group of 4 partners. On technical/IT matters, the WISE SG is supported by the WISE Technical group.

WISE Technical group

The WISE Technical group (WISE TG) assists on the development of the WISE system. It is chaired by EEA with representatives from DGs Environment , Eurostat and JRC, ETC-Water and a number of invited experts from Member States and external experts under support contracts. The WISE TG holds meetings 2-3 times per year and reports to and advises the WISE SG.

7.2.2 Water Directors, Committees, Strategic Coordination group and associated Working groups

Water Directors, Committees, Strategic Coordination Group (SCG) and associated working groups of relevant EU water policy areas[60] and other reporting activities at EU level[61] are the main consultation bodies involving Member States for issues related to the status of implementation of each water directive and other reporting exercises at EU level.

The Water Directors

Water Directors and the European Commission are steering the processes of the Common Implementation Strategy for the WFD which started in 2001. The group of Water Directors is an informal forum meeting twice a year under the auspices of the rotating EU Presidency. The main aim of the group is to ensure a coherent and harmonious implementation of EU water policy based on common understandings of the technical and scientific implications.

From the beginning it was realised that "*Most of the challenges and difficulties arising will inevitably be common to all Member States and many of the European river basins are shared, crossing administrative and territorial borders, where a* ***common understanding and approach*** *is crucial to successful and effective implementation. A Common Strategy could limit the risks of bad application of the Directive and subsequent dispute*".

[60] WG D on reporting and GIS for WFD, working groups on reporting for BWD, DWD, NiD, UWWTD, etc.
[61] Groups of national contact points for Eionet and water statistics under OECD/Eurostat Joint Questionnaire on Inland Waters.

The current progress and work programme[62], the 4th since the start of the CIS process, bears the main title "Improving the comparability and quality of the Water Framework Directive implementation."

Public documents on the implementation of WFD can be found at the EC document server[63].

The CIS model has recently been used when implementing the WISE Implementation Plan via streamlining reporting exercises and integrating all EU water policies and other reporting activities (such as SoE reporting, reporting on water statistics under the OECD/ESTAT joint questionnaire) into WISE.

Committees

The formal side of WISE development, as for example, endorsement of WISE reporting arrangements, reporting sheets/guidance documents, technical formats on reporting by each thematic area of water may be dealt with via Committees created for relevant EU water directives[64]. The Committees, based on the requirements of each water directive, are chaired by the Commission and have delegates from each Member State. The task of the Committee is to assist the Commission in guiding the implementation of water directives, primarily in an informal way, by endorsing documents produced jointly with Member States and relevant working groups through a common understanding.

Strategic Coordination group and Working group on Reporting

The Strategic Coordination Group (SCG) is an informal group mandated by the Water Directors. The SCG is chaired by the Commission and consists of delegates from Member State representatives and also includes NGO participation to ensure transparency and involvement of relevant stakeholders. The Working group on Reporting (WG D – Reporting) includes consideration of WISE and GIS and is one of 7 Working groups which function in the frame of the SCG and the Common Implementation Strategy.

As a basic principle of the CIS is to reach common understanding on reporting requirements, the relevant Working groups/expert forums on reporting for all water directives are actively involved in the WISE development process in the sense of discussing Reporting sheets and endorsing the process as such. The Working Groups are chaired by representatives from the Commission. The mandate and/or work programme is established and agreed by SCG (and endorsed by the Water Directors) for each Working group.

WISE GIS expert network

This network consists of experts in Information Systems and GIS nominated by the Member States. The network was formerly known as the "WFD GIS expert group" under the auspices of WG D. The network is invited, on an ad-hoc basis, to discuss

technical elements, in particular GIS and electronic reporting issues, regarding the development of WISE. In recent years in the frame of this initiative at least one workshop/seminar on WISE development has been held involving the water community concerned with reporting at EU level.

7.3 Involved organisations

7.3.1 Directorate-General Environment (DG ENV)

The main role of the European Commission's Environment Directorate-General (DG ENV) is to initiate and define new environmental legislation and to ensure that agreed measures are put into practice in the EU Member States. Its mission is protecting, preserving and improving the environment for present and future generations, and promoting sustainable development. DG ENV has overall responsibility for the WFD including the evaluation of Member State compliance with the directive. The responsibilities also include a number of proposals for specific measures and standards in various areas. DG ENV is responsible (under Article 18 of the WFD) for reporting the progress of implementation to the European Parliament and Council. DG ENV steers the process of integrating other EU water directives into WISE.

7.3.2 European Environment Agency (EEA)

The European Environment Agency (EEA) is an agency of the European Union. Its task is to provide sound, independent information on the environment and is a major information source for those involved in developing, adopting, implementing and evaluating environmental policy, and also the general public. Currently, the EEA has 32 member countries. The EEA's mandate is to help the Community and member countries make informed decisions about improving the environment, integrating environmental considerations into economic policies and moving towards sustainability, and to coordinate the European Environment Information and Observation Network (Eionet).

As a part of the “Technical Arrangement between DGs Environment, ESTAT and JRC and EEA on Environmental Data Centres” EEA has the role of the Data Centre for Water. EEA is responsible for the development of the WISE system and processing of data reported under WISE. EEA’s own thematic State of the Environment (SoE) reporting is incorporated into WISE.

7.3.3 DG Eurostat (ESTAT)

DG Eurostat is the Statistical Office of the European Communities. Its mission is to gather and analyse figures from the different European statistics offices in order to provide comparable and harmonised data to the European Institutions so they can define, implement and analyse Community policies. With regard to WISE, ESTAT is mainly involved regarding two roles. With the Eurostat/OECD joint questionnaire, ESTAT is taking an active part in European water data reporting which is intending to be streamlined with WISE. This also strengthens the cooperation on water quantity and emissions. GISCO, the Geographic Information System of the European Commission, is a service of Eurostat which promotes and stimulates the use of GIS within the European Statistical System and the Commission. It manages and disseminates the Geographical reference database of the Commission, acts as a reference centre concerning GIS, promotes geo-referencing of statistics and collaboration between national statistical institutes and mapping agencies, pursues and ensures standardisation and harmonisation in the exchange of Geographic Information, and co-leads the INSPIRE initiative on the introduction of a European Spatial Data Infrastructure.

7.3.4 DG Joint Research Centre (JRC)

The European Commission's Joint Research Centre (JRC) is a department (Directorate-General, DG) of the European Commission providing independent scientific and technological support for EU policy-making. It works closely on the development of EU legislation with the relevant Commission services. The Joint Research Centre has many roles related to WISE. JRC developed the WISE reporting prototype during the initial years of the WFD reporting and is now a user of the system in the frame of its environmental assessment and scenario modelling work. JRC also chaired the first WFD GIS Working Group and played a leading role in the preparation of the first WFD GIS Guidance document and contributes to the ongoing activities with expertise in the INSPIRE process. JRC is also active in several areas (e.g., flooding and drought) which could provide specific information to WISE. With the OECD/Eurostat Joint Questionnaire on Inland Waters, ESTAT is taking an active part in European water data reporting which will be streamlined with WISE. This also strengthens the cooperation on water quantity and emissions. GISCO as part of ESTAT is contributing with its experiences and services around GIS metadata and data.

Appendices

Technical Report - 2009 - 030

COMMON IMPLEMENTATION STRATEGY FOR THE WATER FRAMEWORK DIRECTIVE (2000/60/EC)

Guidance Document No. 23

GUIDANCE DOCUMENT ON EUTROPHICATION ASSESSMENT IN THE CONTEXT OF EUROPEAN WATER POLICIES

EUROPEAN COMMISSION

environment

Disclaimer:
This technical document has been developed through a collaborative programme involving the European Commission, all the Member States, the Accession Countries, Norway and other stakeholders and Non-Governmental Organisations. The document should be regarded as presenting an informal consensus position on best practice agreed by all partners. However, the document does not necessarily represent the official, formal position of any of the partners. Hence, the views expressed in the document do not necessarily represent the views of the European Commission.

A great deal of additional information on the European Union is available on the Internet.
It can be accessed through the Europa server (http://ec.europa.eu).

FOREWORD

Eutrophication is one of the most important and long lasting water quality problems in the EU. Since at least two decades, several policies have been adopted to tackle nutrient pollution and its consequences. The Water Directors, conscious of the challenge and the complexity of the subject, agreed in 2004 to start an activity to develop guidance on harmonisation of eutrophication assessment. The guidance should cover all water categories (inland waters, coastal and marine) and all existing European policies, and should be firmly based on the methodological concepts of the Water Framework Directive.

The activity delivered a first Interim Guidance Document in November 2005 that was endorsed by Water Directors at their meeting in London. Although the document provided useful guidance both on technical and on policy relevant concepts, it was recognised that any attempt to harmonise eutrophication classification criteria should be informed by a number of important projects on-going at the time, notably intercalibration exercise and some of the projects lead by the Marine Conventions.

The Water Directors agreed at their meeting in Dresden in June 2007 to revise and update the Interim Guidance Document on Eutrophication. The present Guidance reflects the outcome of this process, led by a Steering Group chaired by the European Commission and with participation of experts from Finland, Germany, the Netherlands, Spain and the UK. Consultations were held with the CIS Working Group on Ecological Status and with the Strategic Co-ordination Group.

The main issues addressed in the guidance document are a unified conceptual framework to understand eutrophication in all water categories, a conceptual read across EU directives (mainly Water Framework, Urban Wastewater and Nitrates Directives) and international policies (e.g. OSPAR and HELCOM) addressing eutrophication and an in-depth understanding of eutrophication in the context of WFD ecological status assessment. The guidance also includes an overview of current assessment methods and recommendations for harmonisation of classification criteria.

This document is the result of several years of work by many experts across Europe and it will contribute to a better understanding of the policies involved in tackling eutrophication and their interactions, improving harmonisation of assessment methods. In the coming years the guidance should be used and tested and those experiences should be considered in future developments.

The Water Directors recognise that eutrophication is a complex phenomenon and it may be necessary to work further on its assessment in the future. However, the publication of the WFD river basin management plans in 2009 and recent policy developments like the Marine Strategy Framework Directive (2008) and the Baltic Sea Action Plan (2007) will inevitably move the focus of the attention in the coming years towards measures to combat eutrophication and its effectiveness. The Water Directors, in close collaboration with the Marine Directors, stay committed to continue to lead on tackling this important environmental problem.

May 2009

TABLE OF CONTENTS

1. INTRODUCTION

1.1. Scope of the activity

1. European policy has consistently identified eutrophication as a priority issue for water protection. Substantial progress has been made in combating eutrophication but there remain several areas where co-ordination is necessary to achieve a harmonised result for different policy areas, in particular:

- the harmonisation of assessment methodologies and criteria for agreed eutrophication elements/ parameters/ indicators for rivers, lakes, transitional, coastal and marine waters;
- the use of water type-specific objectives for biological and general physico-chemical elements;
- the co-ordination of monitoring and reporting;
- the harmonisation of models for assessing or predicting anthropogenic or natural nutrient loading into inland and marine waters based on nutrient sources information or nutrient sources scenarios (e.g. EUROHARP models);
- the systematic identification of sources of nutrients and possible restoration measures for water bodies.

2. Thus an activity was initiated under the Common Implementation Strategy of the Water Framework Directive and the European Marine Strategy to provide guidance on the first three points. Therefore it serves as a guidance document for the common assessment and monitoring of eutrophication across different European policies.

3. On the other issues, work may be started subsequently following the finalisation of this guidance. This may also include work related to:

- developing and harmonising cause-effect models linking nutrient loading to ecological impact in different water body types and categories.
- identifying the most cost-effective measures to tackle problems induced by nutrient enrichment.

4. There is a general agreement that this activity has to be firmly based on the methodological concept of the WFD and to explore thereafter to what extent this methodology can be used in the context of other directives and policies. The final outcome of this activity should be guidance for the purpose of the implementation of the above-mentioned policies. It should also be useful for the preparation of the River Basin Management Plans at the national and international level.

1.2. Understanding eutrophication in its policy context

5. Nutrients in the appropriate amounts (i.e. background levels) are essential to maintain an adequate primary production, which in turn is essential to support all the other trophic levels in the ecosystem, i.e. to maintain a healthy structure and functioning. In general, excessive nutrients of anthropogenic origin cause an increase in plant growth, which in still waters causes increased phytoplankton biomass, which can be dominated by harmful or toxic species. In rivers, eutrophication may be seen as increased algal growth or even excessive growth of higher plants, resulting in an imbalance between the processes of plant/algal production and consumption. The decay of organic matter will lead to a stimulation of microbial decomposition and oxygen consumption depleting bottom-water oxygen concentrations particularly in stratified water bodies[1]. Eutrophication can cause severe increases in plant and algal growth but can also have adverse effects on species diversity and lead to reduced suitability of the water for human use, e.g. consumption, recreation and industrial needs.

6. In 1995, the report of the European Environment Agency (EEA) "*Europe's Environment: The Dobris Assessment*", identified eutrophication of inland and marine waters as a European wide problem of major concern. The EEA report (2003) "*Europe's water: An indicator-based assessment*" reported that progress was achieved in improving water quality and quantity particularly in the European Union but that many of Europe's rivers, lakes, estuaries and coastal waters were still impacted by human activities leading to eutrophication. The "*Fourth Assessment of Europe's Environment*"[2] (2007) by EEA indicates that concentrations of phosphorus have generally decreased in rivers and to a lesser extent in lakes in Western and Central Europe since the 1990s, reflecting the general improvement in wastewater treatment. Eutrophication remains a problem in all enclosed seas and sheltered marine waters across the pan-European region. There have been some improvements in the West-European seas, as well as in the North-Western shelf of the Black Sea, as a result of large cuts in point sources of nutrient pollution from industry and wastewater by EU15 Member States. However, diffuse nutrient sources, particularly from agriculture, remain a major obstacle for recovery and need increased control throughout Europe. Eastern European countries need to both reduce point sources and prevent the export of nutrients to marine waters from further agricultural expansion and intensification. Furthermore, the recent eutrophication assessment undertaken by OSPAR has identified eutrophication related problems in certain areas mainly covering estuaries, fjords, coastal and some offshore areas. The current HELCOM eutrophication assessment comes to comparable results.

7. It should be emphasised that aquatic systems can show different natural background concentrations of nutrients, depending on the geology and other characteristics of the catchment, giving rise to different natural trophic conditions described as oligotrophic (low), mesotrophic (medium) to eutrophic (significant primary

[1] Deep water anoxia/hypoxia can also be a purely natural phenomenon in permanently stratified water bodies.

[2] http://www.eea.europa.eu/publications/state_of_environment_report_2007_1/

production). However, in the policy context, eutrophication is widely used to refer to the undesirable effects of anthropogenic increases in nutrient loads to aquatic ecosystems. The guidance only considers anthropogenic eutrophication, i.e., resulting from nutrient enrichment caused by human activities. Further details on concept and definitions are provided in Chapter 3.

8. In case of dealing with artificial or heavily modified water bodies, all references made in the document to ecological status should be construed as references to ecological potential.

1.3. Structure of the document

9. This document compares how eutrophication is understood, defined and assessed in different EC directives and other international policies. It develops a generic conceptual framework for the assessment of eutrophication which includes existing cause-effect relationships in both marine and freshwater ecosystems.

10. The document is structured in two parts (Chapters 2-4 and Chapters 5-8). The first part deals with the development of a common understanding of the processes involved in eutrophication a) from a technical and scientific point of view (Chapter 2), b) in the context of different policies (Chapter 3), and c) in the WFD concept of ecological status with respect to impacts caused by nutrient enrichment (Chapter 4).

11. The second part of the guidance gives an overview of current assessment methods and criteria for assessing eutrophication in different kinds of waters (Chapter 5), gives guidance on the harmonisation of classification criteria (Chapter 6), addresses the co-ordination of monitoring requirements stemming from different policies and obligations (Chapter 7) and discusses the links of eutrophication assessment with the pressure and impact analysis and the programme of measures (Chapter 8).

2. OVERALL CONCEPTUAL FRAMEWORK FOR THE ASSESSMENT OF EUTROPHICATION

2.1. The need, requirements and principles of a common conceptual framework

12. A fundamental aspect of defining a common monitoring and assessment guideline for the eutrophication process is identifying a common conceptual framework that can be adapted for specific water categories. Such a common starting point should capture the commonalities in the process and manifestations of eutrophication in different water categories, and should also provide the means of linking the "process" of eutrophication (i.e. a rate process) to the requirements of the WFD for assessing the ecological status of all surface water bodies.

13. In addition, a common generic conceptual framework valid across all surface water categories would provide a suitable means for developing category-specific checklists as a basis for the classification assessment and for specifying monitoring requirements (see Figure 1).

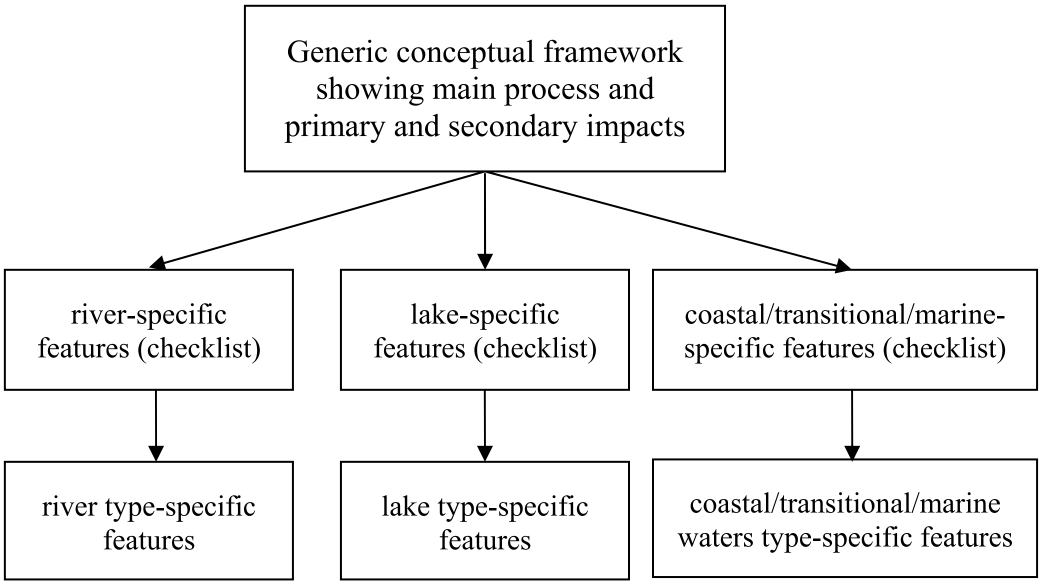

Figure 1. Schematic diagram for using a conceptual framework to assess eutrophication across different aquatic environments.

14. Assessing eutrophication in specific water categories and types will require water category-specific and perhaps type-specific monitoring. Several CIS Guidance documents have already addressed some of the specific monitoring needs (e.g. Monitoring guidance[3], COAST guidance document[4]); however the spatial and temporal monitoring requirements strongly depend on the seasonality of nutrients, chlorophyll and oxygen concentrations in different water categories. Specific monitoring requirements to assess eutrophication are addressed in Chapter 7.

15. A common "all encompassing" conceptual framework should be able to represent generic aspects of eutrophication which are common in different aquatic environments, but also be detailed enough to be useful for deriving the aspects which are specific to individual water categories and regions. Aspects of the process that may be common to all aquatic environments include:

- Nutrient enrichment;
- Enhanced primary production/biomass;
- Algal blooms;
- Changes to taxonomic composition of algae/ plants;
- Effects on light climate and hence on biota;
- Increased fixation of carbon;
- Decreased/increased oxygen levels, possible anoxia and consequent effects on biota;
- Reduced diversity of benthic fauna.

[3] Guidance Document No. 7: Monitoring under the Water Framework Directive

[4] Guidance Document No. 5: Transitional and Coastal waters – Typology, Reference Conditions and Classification Systems

2.2. Description of the conceptual eutrophication framework

16. There are numerous models of the eutrophication process: both in the scientific literature and in policy implementation documentation. All the different models link the cause (i.e. nutrients) and effect (e.g. excessive algal growth) of the eutrophication process. This overarching link has been long implemented in classification activities using regression models based on water body mass balance and algae element ratios, particularly in freshwaters (e.g. OECD, 1982; Vollenweider, 1976)[5]. However, it is now well known that manifestations of eutrophication may be much more subtle and non-linear in their occurrence (for a review see Cloern, 2001). Regression between nutrients and biomass for example may not be applicable in all aquatic environments. Regression models therefore may not always be expected to be used for classification of water bodies showing non-linear response patterns along the eutrophication gradient. In this perspective a more comprehensive approach to classification is required, that accounts for the different non-linear relationships and the different intrinsic manifestations of eutrophication.

17. An example of such an approach is the OSPAR Common Procedure[6], described in Annex 1, section 2.1.2. This procedure was developed based on a common conceptual framework of eutrophication.

18. Based upon the OSPAR conceptual framework, and taking into account discussions at the

- Joint Workshop on Marine Assessment and Monitoring with emphasis on eutrophication. JRC, Black Sea Commission and Helsinki Commission (Istanbul, Turkey, 21-22 April 2004); and the
- Eutrophication Workshop on a Common Assessment Methodology. JRC (Ispra, 14-15 September 2004)

the common conceptual framework of eutrophication presented in **Figure 2** was developed. This diagram describes the eutrophication process, the different elements and partial processes involved, and the ecological impacts which may arise. The effects of hydrological and morphological changes and their potential influence on eutrophication which play an important role in WFD ecological status assessment and can be an important factor for eutrophication are not detailed in the diagram, but summarised under "environmental factors". It is important to understand the complexity of the eutrophication process, not only for the assessment of ecological status of a water body, but also for planning appropriate mitigation measures; e.g. it is well known that top-down effects on eutrophication, e.g. through predatory fish, can be quite significant. This known from freshwater systems, but has recently also been shown for coastal and marine waters.

19. The figure does not cover (use-related) impacts on man, either directly or indirectly, which is part of what constitutes an undesirable disturbance.

---

5 The statistical variability in such models may be too large to obtain a precise classification of single water bodies, because they are not sufficiently type-specific. The REBECCA-project has investigated the potential for improving such models by restricting the datasets used for a regression to data from single water body types. For more information see: http://www.rbm-toolbox.net/rebecca/index.php .

6 Common Procedure for the Identification of the Eutrophication Status of the OSPAR Maritime Area

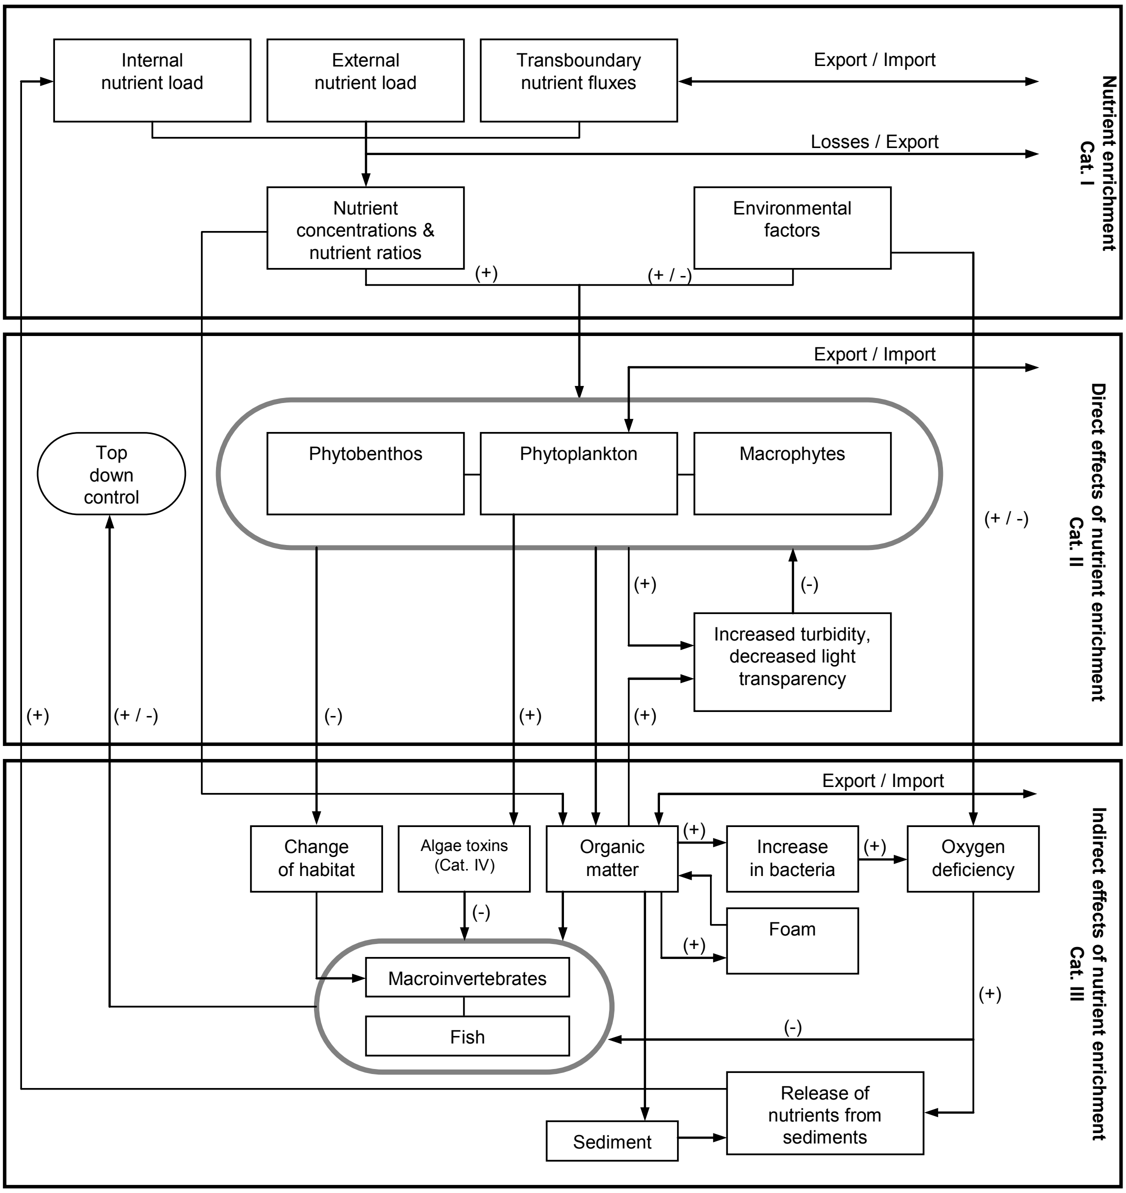

Figure 2. General conceptual framework to assess eutrophication in all categories of surface waters. (+) indicates increase; (-) indicates decrease; round boxes indicate biological quality elements of WFD.

20. To understand environmental policy and related evaluation and assessment, a framework has been developed in the past which distinguishes driving forces (D), pressures (P), state (S), impact (I) and responses (R) – this became known as the DPSIR framework. In the WFD context, P is addressed in the Article 5 reports when assessing pressures and presenting typology/characteristics of a water body. S and I are addressed by the work on classification, intercalibration and monitoring. R is addressed in the WFD programmes and measures. The conceptual framework for eutrophication assessment can be linked to the general DPSIR assessment framework as follows (Figure 3). Category I in the conceptual framework corresponds to pressures and state whereas Categories II and III refer to impacts. The focus of this guidance document is on state and impact assessment. Responses are not covered by the mandate to develop this guidance document although Chapter 8 outlines possible future work in this area.

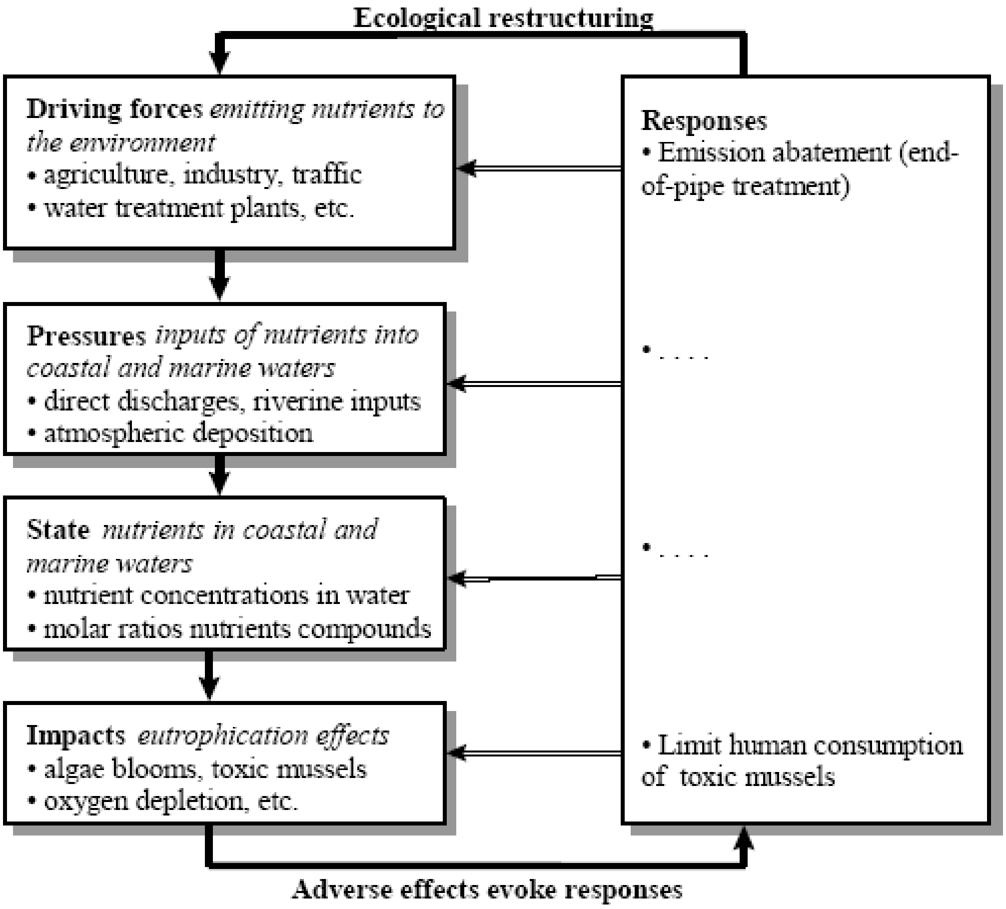

Figure 3. DPSIR assessment framework in the context of eutrophication (EEA, 2001).

21. The eutrophication conceptual framework provides an effective means of identifying the critical processes that can be adapted to processes specific to different water body categories. However, in order to provide a link to the subsequent steps of the assessment process (i.e. establishing reference conditions and classification), holistic checklists have been derived for the different water categories highlighting the critical processes and variables under the headings of: causative factors, primary or direct effects and secondary or indirect effects. The level of detail included in the checklist (presented in Table 1) reflects the specificity of the eutrophication process in rivers, lakes, transitional, coastal and marine waters. The complete checklists for each water category can be found in Annex 2.

Table 1. Indicative checklist for general and category-specific features of the impact of eutrophication in rivers, lakes, transitional, coastal and marine waters.

General assessment factors for all water categories	Additional river-specific factors	Additional lake-specific factors	Additional transitional/coastal [and marine] waters-specific factors
a. Causative factors:			
The degree of nutrient enrichment: With regard to inorganic/organic nitrogen With regard to inorganic/organic phosphorus With regard to silicon Taking account of: Sources (differentiating between anthropogenic and natural sources) Increased/upward trends in concentration Elevated concentrations Changed N/P, N/Si, P/Si ratios Changes in nutrient fluxes and nutrient cycles		Riverine, direct and atmospheric inputs internal nutrient loading	Across boundary fluxes, recycling within environmental compartments, riverine, direct and atmospheric inputs and internal loading
b. Supporting environmental factors:			
Light availability (irradiance, turbidity, suspended load) Hydrodynamic conditions () Climatic/weather conditions (wind, temperature) Typology factors Other pressures (toxic substances, hydromorphological pressures)	Hydromorphological conditions (current velocity, water flow, substrate type and mobility, water depth, flood frequency,) Typology factors: alkalinity, colour, size of catchment	Stratification, flushing, retention time, Zooplankton grazing (top-down control) (which may be influenced by other anthropogenic activities) Typology factors: alkalinity, colour, size, depth, share of area shallower than the stratification layer	Upwelling, salinity gradients, Typology factors: e.g. salinity, wave exposure

General assessment factors for all water categories	Additional river-specific factors	Additional lake-specific factors	Additional transitional/coastal [and marine] waters-specific factors
c. Direct effects of nutrient enrichment:			
i. Phytoplankton; Increased biomass (e.g. chlorophyll a, organic carbon and cell numbers) Increased frequency and duration of blooms Increased annual primary production Shifts in species composition to higher proportion of potentially harmful or toxic species ii. Macrophytes including macroalgae (such as Characeans); Increased biomass Shifts in species composition Reduced depth distribution until disappearance of macrophytes iii. Phytobenthos	i. Phytoplankton in parts of rivers with low flow or lake-like structure due to damming iii. Microphytobenthos; Increased biomass and primary production, increased areal cover on substrate Shifts in species composition from diatoms to chlorophytes and cyanobacteria	i. Phytoplankton; from chrysophytes and diatoms to cyanobacteria and chlorophytes ii. Macrophytes In very shallow lakes switches occur from macrophytes dominance and phytoplankton dominance Reduction in depth distribution, consequent shift in balance of species	i. Phytoplankton indicator species cells/L (blooms and duration) Shift from diatoms to flagellates ii. Macrophytes including macroalgae: shift from long-lived species to short-lived species, some of which are nuisance species (Ulva, Enteromorpha) Coverage of areas
d. Indirect effects of nutrient enrichment			
i. Organic carbon/organic matter; Increased organic carbon concentrations in water and sediment ii. Oxygen; Decreased concentrations and saturation percentage Increased frequency of low oxygen concentrations Increased consumption rate iii. Fish; Changes in abundance	ii. Oxygen; More extreme diurnal variation iii. Fish; Disruption of migration or movement iv. Benthic heterotrophic organisms: Increased biomass and areal cover of fungi and bacteria	ii. Oxygen More extreme diurnal variation in surface waters (oversaturation at day and undersaturation at night) Reduction in hypolimnion during stratification periods Occurrence of anoxic zones at the sediment surface ("black spots") iii. Fish Mortalities resulting from low oxygen concentrations	i. Organic carbon/organic matter; Occurrence of foam and/or slime ii. Oxygen; Occurrence of anoxic zones at the sediment surface ("black spots") iii. Fish Mortalities resulting from low oxygen concentrations iv. Macrozoobenthos Mortalities resulting from low oxygen concentrations

General assessment factors for all water categories	Additional river-specific factors	Additional lake-specific factors	Additional transitional/coastal [and marine] waters-specific factors
Changes in species composition iv. Benthic invertebrates; Changes in abundance and biomass Changes in species composition v. pH vi. Nutrients		iv. Macrozoobenthos Mortalities resulting from low oxygen concentrations v. pH increase in surface waters vi. Internal loading of phosphorus vii. Increased ammonia concentration in bottom waters viii. Often changed top-down control due to changed predation on zooplankton Often reduced top-down control due to loss of habitat structure provided by macrophytes leading to heavy fish Release of soluble Fe, Mn from sediments	vi. Release of nutrients and sulphide from sediment Occurrence of algal toxins
e. Other possible effects of nutrient enrichment			
• Amenity values compromised: • Bad smell, turbid waters,	Clogging of pipes and filters, build up of iron deposits due to low DO	Incidence of toxic algal blooms increases Loss visual amenity due to colour in water	

3. Overview and common understanding of eutrophication in EC and international policies

3.1. Introduction

22. Eutrophication is addressed in several EU policies. Nutrient levels to describe the water quality were introduced in several early pieces of EU water legislation (e.g. Freshwater Fish Directive 78/659/EEC). The main anthropogenic sources of nutrient loadings were addressed in two directives in 1991: 1) The Urban Wastewater Treatment Directive (91/271/EEC) addresses the major point sources, in particular the municipal waste water discharges. 2) The Nitrates Directive (91/676/EEC) deals with diffuse pollution of nitrogen from agriculture. Both directives define the term "eutrophication". In addition, through the identification of sensitive areas and compliance with treatment requirements (UWWTD) as well as designation of nitrate vulnerable zones and application of action programmes (Nitrates Directive), both Directives, respectively, provide for measures to combat eutrophication. Starting from the 1980s and 1990s, a number of international conventions addressed eutrophication in marine waters including OSPAR (for the North-East Atlantic), HELCOM (for the Baltic Sea), the Barcelona Convention (for the Mediterranean Sea) and the Bucharest Convention (for the Black Sea).

23. In 2000 the Water Framework Directive (2000/60/EC) introduced – amongst other requirements – a comprehensive ecological status assessment of all surface waters, based on a number of biological, hydromorphological, chemical and physico-chemical quality elements (cf. Annex V 1.1 and V 1.2). The WFD provides a basis for a clear and detailed assessment of eutrophication, and provides the potential for a more consistent and integrated approach to managing nutrient inputs to water taking fully into account the requirements of previous EU legislation.

24. In addition to these directives, the EU Marine Strategy Framework Directive (2008/56/EC) aims at achieving or maintaining 'good environmental status' including the minimisation of eutrophication in Member States' marine waters. Member States are required to develop their marine strategies and identify measures based upon the initial assessment and their determination of 'good environmental status' for their water within a harmonised methodological framework.

25. A workshop on eutrophication criteria was hosted by DG Environment, in, Brussels in May 2002. This considered eutrophication in the context of the WFD, UWWT Directive, the Nitrates Directive and the future Marine Strategy of the Commission. It launched a process to harmonise existing definitions and criteria for the assessment of eutrophication. One conclusion of this workshop was a recognised need to move from definitions to a common understanding of eutrophication, acceptable levels of deviation from reference conditions and the extent of adverse indirect effects on ecosystems and water use (European Commission 2002b). Since then, the intercalibration has addressed the harmonisation of ecological classification, also

related to eutrophication. Further workshops have dealt with harmonisation of assessment methods and the use of nutrient standards in assessing eutrophication:

1) 1st Workshop on Eutrophication, held in Ispra in September 2004,

2) 2nd Workshop on Eutrophication, held in Brussels in September 2005,

3) Nutrient Standards Workshop, held in Zandvoort in October 2007,

4) ECOSTAT Classification Workshop, held in Brussels in March 2008.

26. This chapter considers and compares how eutrophication is understood, defined and assessed in European Community directives, policies and guidance documents. In addition, the understanding and the assessment of eutrophication in other regional bodies are presented, in particular in the international marine conventions OSPAR and HELCOM.

27. An overview of the understanding of eutrophication in EU legislation and policies as well as in a number of international organisations is provided in Annex 1. This annex was the basis for the following overview of approaches.

3.2. Overview of policy instruments

28. A number of EC Directives require Member States to monitor parameters relevant to eutrophication and set ecologically relevant guideline values, however only the UWWT Directive and the Nitrates Directive have an explicit requirement to assess eutrophication (the former through the exercise to identify "sensitive areas", i.e. sensitive water bodies, and the latter through identification of "polluted waters" [7] and subsequent designation of nitrate vulnerable zones). The Water Framework Directive supports both these Directives in its provisions for protected areas, and, in addition, has an implicit requirement to assess eutrophication when classifying the Ecological Status of surface water bodies. Unlike the UWWT Directive and the Nitrates Directive, the WFD stipulates a specific framework for assessing water quality. Eutrophication assessment criteria and methods have also been developed by several European conventions, including OSPAR and HELCOM and recently by UNEP/MAP.

29. The requirements of EC directives and other relevant international policies to assess or monitor eutrophication are summarised in general in Table 2.

---

[7] For the purposes of this guidance the term “polluted waters” is taken, for the sake of brevity, to mean “waters affected by pollution and waters which could be affected by pollution if action is not taken” in line with Article 3 of the Nitrates Directive. Specifically, it refers to waters that are eutrophic or in the near future may become eutrophic if action is not taken, as per the criteria in Annex IA3 of the Directive.

Table 2. General overview of requirements of EC directives and regional conventions regarding eutrophication

Directive /Policy	Requirement to assess eutrophication	Minimum monitoring requirements relevant to eutrophication
WFD	Included in classification of Ecological Status where nutrient enrichment affects biological and physico-chemical quality elements Protected Area's support and upholds requirements of UWWTD and Nitrates Directive	Phytoplankton (6 months), aquatic flora (3 yrs), macroinvertebrates (3 yrs), fish (3 yrs) Hydromorphological quality elements (Hydrology continuous - 1 month; others 6 years) Physicochemical quality elements (3 months)
UWWT Directive	In order to identify sensitive areas under Annex IIA(a) criteria (i.e. water bodies that are eutrophic or may become eutrophic in the near future if protective action is not taken)	Review of the existing sensitive areas and designation of new ones at least every 4 years (Article 5(6))
Nitrates Directive	In order to identify "polluted waters" [7] and to designate their catchment area as nitrate vulnerable zones.	For the purpose of designating the nitrate concentrations in freshwaters (surface water and groundwater) should initially be monitored over a period of one year. This monitoring programme should be repeated at least every four years. A review of the eutrophic state of their fresh surface waters, estuaries and coastal waters should be made every four years.
Freshwater Fish Directive	No specific requirements to assess eutrophication, but guideline values for phosphorus are explicitly to reduce the effects of eutrophication	Ammonia, pH and dissolved oxygen (monthly)
Shellfish Water Directive	No specific requirement to assess eutrophication	Dissolved oxygen (monthly) & algal toxins
Dangerous Substance Directive	No specific requirement to assess eutrophication, but requirement on setting quality objectives for phosphorus and for substances which have an adverse effect on the oxygen balance, particularly ammonia and nitrates	No specific requirements
Groundwater Directive	No explicit mention of eutrophication but quality standards are established for nitrates and pesticides and in some cases more stringent threshold values have to be set. A minimum list of pollutants is set up for which MS have to consider establishing threshold values including e.g. ammonium and conductivity	Details of groundwater chemical monitoring are included in WFD Annex V point 2.4, core parameters are: oxygen content, pH value, conductivity, nitrate, ammonium
Bathing Water Directive	As a part of the obligations of the new Bathing Water Directive bathing water profiles have to be established. When the bathing water profile indicates a tendency for proliferation of macro-algae and/or marine phytoplankton, investigations shall be undertaken to determine their acceptability and health risks and adequate management measures shall be taken, including information to the public.	Old Directive: Transparency (fortnightly), pH, dissolved oxygen (when water quality has deteriorated). Nitrates and phosphates, ammonia and nitrogen (Kjeldahl) when there is a tendency towards eutrophication. New Directive: When establishing, reviewing and updating bathing water profiles, adequate use shall be made of data obtained from monitoring and assessments carried out pursuant to Directive 2000/60/EC.

Directive /Policy	Requirement to assess eutrophication	Minimum monitoring requirements relevant to eutrophication
Marine Strategy Framework Directive	Included in assessment of environmental status based on 'good' environmental status concept Complementarity with WFD in 'coastal waters' (following definition of 'marine waters' in MSFD Art. 3(1)), hence no MSFD specific issues in those waters as regards assessment of eutrophication	A monitoring programme will be established by each Member State under Art. 11 by July 2014, taking account of the information needs derived from their development of the earlier elements of their marine strategies (initial assessment, determination of good environmental status, identification of environmental targets and indicators, in 2012).
Habitat Directive	If threatening protected habitats or species	None
Emission Ceilings, LRTAP	No requirement to assess eutrophication but specific national emission ceilings for ammonia and NOx emissions to reduce nitrogen atmospheric deposition and ecosystem eutrophication	No requirement to monitor water quality under the Directive, but monitoring of nitrogen deposition and critical loads for ecosystems eutrophication under the Convention
OSPAR Eutrophication Strategy	Explicit requirements for assessing the eutrophication status of waters in OSPAR maritime area using the OSPAR Common Procedure (in particular its Comprehensive procedure)	Monitoring of selected parameters for nutrient enrichment, direct effects, indirect effects and other possible effects according to the mandatory Eutrophication Monitoring Programme (OSPAR 2005-4)
HELCOM	Explicit in quantifying and assessing emissions/discharges/losses and inputs to as well as concentrations and effects in the Baltic Sea [HELCOM Periodic Assessments of the Status of the Baltic Sea and PLCs (Air and Water)]	MONAS: Pollution Load Compilation (PLC Air and Water) Monitoring Programme (total nitrogen, nitrates, ammonia, orthophosphate and total phosphorus) and COMBINE (including total nitrogen, total phosphorus, DIN, DIP, Si, phytoplankton and zoobenthos species composition, abundance and biomass, Chl a, dissolved oxygen and Secchi depth)
Barcelona Convention - Strategic Action Programme (SAP) to address LBS	The SAP states eutrophication as the result of input of nutrients from rivers and sewage into inshore waters such as lagoons, harbours, estuaries and coastal area which are adjacent to river mouths, so actions should be taken to reduce inputs of nutrients from Land Based Sources (LBS).	MED POL: Eutrophication monitoring strategy (2003) – DIN, DIP, TP, Si, Chl a, phytoplankton (total abundance, abundance of major groups, bloom dominance), transparency, dissolved oxygen, T, S, pH
Black Sea Strategic Action Plan (SAP)	Eutrophication is still a challenge at regional and national levels even though there are substantial improvements in the North Western shelf of the Black Sea. For these reason the SAP has provisions to monitor and reduce the inputs of nutrients.	Black Sea Integrated Monitoring and Assessment Programme: nutrients are monitored in water, sediment and biota

3.3. Concepts and definitions of eutrophication

30. It is recognised that different geochemical and hydromorphological conditions are reflected in different characteristics of water bodies such as different trophic and biological conditions. Thus, the assessment of eutrophication should consider these issues and assess the deviation from the type-specific condition. This concept is directly or indirectly addressed in all the relevant policies that aim at controlling the pressures stemming from human activities with an impact on the natural condition of the ecosystem. For the purpose of this guidance, the term "eutrophic" is used to refer to this situation, when the natural trophic status (including the biology) is out of balance because of anthropogenic pressures.

31. This understanding of "anthropogenic" eutrophication corresponds with how the WFD classifies surface water ecological status in relation to type-specific reference conditions. A pressure (in this case nutrient inputs) causes an adverse change in biological quality elements (e.g. 'composition, abundance and biomass of phytoplankton'). This in turn might cause indirect effects on physicochemical quality elements (e.g. transparency, oxygenation conditions), and other biota (e.g. macroinvertebrates). Water bodies that fail to achieve Good Ecological Status due to the effects of human induced nutrient enrichment can be considered to be adversely affected by eutrophication.

32. In the context of this guidance, eutrophication involves adverse ecological changes (an "undesirable disturbance") and it can apply to waters from anywhere within the trophic spectrum. It should not be confused with the same term when used in relation to limnological trophic classification, where its meaning is more limited and not necessarily linked to assessing the extent of ecological change. In that sense, an oligotrophic water body (e.g. a lake) which deteriorates to mesotrophic would require UWWTD/ND/WFD designation/action despite the fact that it would not have become "eutrophic" in terms of OECD trophic status. In contrast a naturally "eutrophic" water body, as measured through OECD classification, would require no designation or action under the UWWTD/Nitrates Directive/WFD unless its ecological status had deteriorated, or was at risk of doing so due to nutrient enrichment.

33. These deliberations concur with conclusions from the May 2002 Eutrophication Workshop (European Commission 2002b) that the definition of eutrophication in the UWWT Directive is adequate as a starting point for further development of a guidance on the issue of eutrophication assessment, which is as follows:

Definition of eutrophication (cf. Art. 2(11) of the UWWT Directive 91/271/EEC):

Eutrophication is "the enrichment of water by nutrients, especially compounds of nitrogen and/or phosphorus, causing an accelerated growth of algae and higher forms of plant life to produce an undesirable disturbance to the balance of organisms present in the water and to the quality of the water concerned".

3.4. Key terms used in different European policies

34. Table 3 compares different terms used in the WFD, UWWT and Nitrates Directives, as well as the OSPAR and HELCOM Conventions.

Table 3: Comparison of key terms used in relevant European policies in relation to eutrophication

	Water Framework Directive	UWWT Directive	Nitrates Directive	OSPAR	HELCOM
Assessment result (not fulfilling the objective and requiring measures)	Water body at less than good status based on eutrophication-related biological quality elements or judged at risk of deterioration	Sensitive area (=sensitive water body) due to eutrophication	"Polluted waters" [7]	Problem area and potential problem area	Areas affected by eutrophication
Location of pressures (other than those directly on the water body)	River basin or sub-basin	Catchment area of sensitive area	Nitrate vulnerable zone (areas which drain into identified waters and which contribute to pollution)	Any location that is relevant, directly or indirectly influenced by nutrient pressures	Coastal waters relevant to WFD and open sea

35. Although different terms are used the underlying concepts are similar, e.g. there is a quality problem in a (part of a) particular river, lake or coastal area (called water body, sensitive area, polluted water or problem area) that is caused by an activity or pressure located at the water body having less than good status, or upstream of this water body in the catchment area, river basin, sub-basin or vulnerable zone.

36. In OSPAR there is no explicit reference to river basins, because in the marine area the pressures causing eutrophication may be located somewhere else. However, one of the main pillars of the OSPAR approach to combat eutrophication is the source-oriented action which should be taken in "areas from which nutrient inputs are likely, directly or indirectly, to contribute to inputs into problem areas with regard to eutrophication"[8]. This definition is broader and includes anthropogenic nutrient inputs into the river basins of transitional, coastal and marine areas affected by eutrophication. In addition, OSPAR is also considering transboundary nutrient transport of anthropogenic origin from other parts of the maritime area.

3.5. Overview of classification of water bodies with regard to eutrophication

37. The way in which different EC Directives and OSPAR classify eutrophic water bodies with regard to human induced eutrophication is summarised in Table 4. The comments in the table describe the focus and extent of each classification.

---

8 The same wording is used in several OSPAR normative and technical documents, for instance in OSPAR Eutrophication Strategy.

Table 4. The classification of water bodies not achieving the objective with regard to eutrophication under different directives and policies (overview).

Directive/ Policy	Classification	Comments
WFD	Worse than good Ecological Status (deterioration in Ecological Status)	Good ecological status for the algal and plant quality elements includes an absence of undesirable disturbances due to accelerated growth. Nutrient conditions must support the biology. Being worse than good ecological status for these quality elements due to nutrient enrichment implies a eutrophication issue. Covers all freshwaters and transitional waters, and all coastal water that is on the landward side of a line that is 1 nautical mile seaward of the baseline from which the breadth of territorial waters is measured.
UWWT Directive	Sensitive area	Sensitive areas include water bodies (including freshwater bodies, estuaries and coastal waters) that are eutrophic or in the near future may become eutrophic if protective actions are not taken. Designation of sensitive areas results in action regarding waste water treatment independent of the origin of the pollution (i.e. independent whether pollution comes from urban waste water discharges or originates from agricultural-based sources, since both of them contribute to eutrophication)[9].
Nitrates Directive	"Polluted waters" [7] whose catchments require designation as nitrate vulnerable zones.	Nitrate vulnerable zones must be established over the catchment of "polluted waters" [7] which include water bodies that are eutrophic or in the near future may become eutrophic if protective action is not taken. Only applies to pollution by nitrogen from agricultural sources.
Habitats Directive	Non-favourable condition	If affecting protected habitats or species.
Shellfish Water Directive	No direct link	Might result in a shellfish water site failing water quality criteria.
Marine Strategy Framework Directive	Worse than good environ-mental status	Areas where human induced eutrophication is not minimised; in particular where it entails adverse effects.
OSPAR Common Procedure	Problem area	Applies to the OSPAR Convention Waters (estuaries and marine waters). All anthropogenic nutrient sources and inputs are taken into account in assessing the eutrophication status.
HELCOM	Areas affected by eutrophication	Applies to the Helsinki Convention (HELCOM) area (coastal and open waters). All anthropogenic nutrient sources and inputs are taken into account in assessing the eutrophication status.

38. For the purpose of this guidance, it is assumed that the process of eutrophication may occur in water bodies regardless of their natural status (in line with the concept of anthropogenic eutrophication referred to in the previous section). However, water bodies are not considered to be "eutrophic" or to fall in the "may become eutrophic" category unless the nutrient enrichment causes (or could cause in the near future) the ecological status to be (or to become) moderate or worse. This ensures the same level of protection in all EC directives as far as nutrient enrichment is concerned.

[9] According to the Judgement of the Court in the case C-280/02 (for more details, see Annex 1, Section 1.2.4)

39. From the legal point of view the terms "eutrophic" and "may become eutrophic in the near future" as used in Nitrates and UWWT directives are similar and require similar consequence, i.e. the designation of those areas as nitrate vulnerable zones (Nitrates Directive) or identification as "sensitive areas" (UWWT Directive). However, technically speaking, they reflect different situations. These concepts will be further addressed in the following sections.

3.6. Assessment results under various policies

40. The analysis and comparison of assessment results is an important starting point for the development of a harmonised assessment framework. Ultimately, the assessment should lead to a comparable and consistent conclusion under different policies. In general, the outcome of the assessment is used to determine whether or not certain measures need to be taken under different policies. At this stage, it is important to recall two basic principles when interpreting the content of this document:

a. in case that the assessment under different policies leads to a different level of protection the most stringent requirement shall apply.

b. it is ultimately up to the European Court of Justice (ECJ) to interpret legal requirements of EC Directives. Recently, the ECJ has interpreted the designation of sensitive areas under the UWWT Directive in a broad sense (see EJC judgement C-280/02 in section 1.2.4 of Annex 1). In consequence, the application of this guidance must lead, at least, to the same level of protection provided by this ruling independent of which EC Directive is applied insofar as the judgement is relevant to other policies.

41. In Table 5 the WFD ecological status classes are compared with (i) sensitive areas and not sensitive areas (so called 'normal' areas) (cf. the UWWT Directive), (ii) "polluted waters" [7] requiring designation of nitrate vulnerable zones (cf. Nitrates Directive), (iii) problem and non-problem areas or potential problem areas (cf. OSPAR Comprehensive Procedure), and (iv) the terms used in HELCOM. The comparison considers when action is required to address eutrophication under each directive/policy. As regards the obligation to identify sensitive areas under UWWT Directive or designate nitrate vulnerable zones under the Nitrates Directive Table 5 is not applicable to Member States that have chosen to implement the "whole territory approach" (see paragraphs 52-54 for more information on the whole territory approach).

WFD moderate, poor and bad status, compared with the eutrophication categories

42. As stated in the previous section, the use of the terms "eutrophic" and "in the near future may become eutrophic" in the Nitrates and UWWT Directives are interchangeable from the legal point of view and both have similar consequences (identification/designation of nitrate vulnerable zones or of sensitive areas). However, in order to establish a consistent link with the WFD status classes, they can be interpreted as the result of different degrees of ecological deviation from reference conditions. The term "eutrophic" can be identified with a situation where undesirable disturbances are common, whereas the term "in the near future

may become eutrophic" corresponds with a situation where undesirable disturbances[10] are not necessarily present, but the degree of ecological change is such that they are likely. Therefore, based on the text of normative definitions for the algal/plant quality elements, moderate status under the WFD corresponds broadly with the "in the near future may become eutrophic" situation, particularly if there is increasing nutrient pressure.

43. As the degradation of water quality increases, so does the likelihood of undesirable disturbances, and from a certain point in the moderate class and beyond into poor and bad, the conditions would correspond with "eutrophic". The moderate class is interpreted as a transition class between good status, where no undesirable disturbances are present, and poor or bad, where they are increasingly common and severe. See Chapter 4.4 (including paragraph 73 and Table 8 on undesirable disturbances) for a more detailed interpretation of eutrophication in the context of WFD ecological status assessment.

44. In deciding on whether and with what certainty to report a water body as being at less than Good Ecological Status (in terms of eutrophication) and in determining the appropriate follow-up actions, the issues covered and guidance given in Chapter 6.2, on (a) dealing with mismatches between nutrients and biology (paragraphs 188-190) and (b) accounting for uncertainty in eutrophication assessment (paragraphs 198-200), should be considered. These issues are important not only in relation to classification but also in a policy context in terms of decisions on priorities for control measures (under the WFD and, where relevant, via identification of waters as sensitive/polluted under UWWT and/or Nitrates Directives) and further monitoring or other investigations.

WFD good and high status compared with the eutrophication categories

45. Table 5 and paragraphs 41-43 above address the assessment of current status. However, the WFD also requires Member States to assess the risk of future deterioration of status, linked to the WFD objective of preventing such deterioration. This means water bodies that are currently in good or even high status and that may deteriorate in the future due to increasing pressures will need to be part of the Programme of Measures under the WFD. This forecasting of future breaching of the prevent deterioration principle equates well with the forecast/estimation of "may become eutrophic in the near future" of the UWWT and Nitrates Directives, at least if the deterioration may result in a moderate or worse status due to eutrophication. However, at least until the first WFD River Basin Management Plans are in place in 2009, the time scales of the WFD objectives and 'the near future' estimation may not necessarily coincide. In order to assess whether undesirable disturbances are likely to occur, nutrient pressures/concentrations, data on the effects of eutrophication (e.g. large phytoplankton blooms, mats of green algae, oxygen deficiency) and other environmental factors that influence eutrophication should be taken into account, for example light

[10] On the definition of undesirable disturbances see Annex 1, section 1.2.4 Relevant Case Law. Some examples of significant undesirable disturbances can be found in Chapter 4, Table 8.

availability/turbidity, hydrodynamic conditions, temperature, etc. (see category-specific checklist in Annex 2). The following WFD activities should be considered:

i. ecological status assessment – whether there is a trend/development in the recent past from high to good status or in values for individual quality elements that determine eutrophication, indicating movement towards moderate/poor/bad and thus "eutrophic";

ii. risk assessment to estimate future status and prevent deterioration – using information on expected change in pressures that are likely to result in a water body becoming eutrophic in the near future (predictive analysis).

46. The initial results of the Article 5 analysis under WFD will be further refined with the information from the monitoring networks, and by further characterisation and classification. The status assessment of water bodies is part of the River Basin Management Plans (RBMP) which are due by December 2009. Along this process from the Article 5 analysis to the RBMP, increasing certainty will be attained on the evaluation of future status of water bodies. At any point, designation under UWWT and/or Nitrates Directives must take place if sufficient certainty is attained that a water body may become eutrophic in the near future.

Summary of links between WFD status and eutrophication categories

47. In summary, it is proposed that in terms of WFD status classification and environmental objectives, the term "eutrophic" relates to situations where undesirable disturbances are common or severe and equates primarily to poor or bad status, whereas "in the near future may become eutrophic" of the UWWT and Nitrates Directives can be interpreted in two complementary ways:

- in the context of **current status** assessment, as corresponding to moderate status (undesirable disturbances are not necessarily present, but the degree of ecological change is such that they are likely, particularly if there is increasing nutrient pressure) or,
- in the context of **future status** evaluation especially for waters of high or good status as corresponding to a risk of breaching the Water Framework Directive prevent-deterioration principle.

48. It is noted that moderate is a transition class between good and poor and that where there is a read across to UWWT or Nitrates Directives, water bodies can be either in the "may become eutrophic" or "eutrophic" categories depending on the extent of ecological impacts.

49. As discussed in Chapter 3.6 (paragraph 44) and Chapter 6.2, information on confidence/uncertainty in classification is important for informing decisions on the appropriate follow-up actions.

50. The interpretation set out in the preceding paragraphs ensures a coherent action against eutrophication across the various policies. Action requirements under the various Directives should be considered together in order to produce the final outcome of the RBMP in December 2009. Therefore, whenever pressures

addressed by UWWT and Nitrates Directives are present, the list of water bodies subject to WFD Programme of Measures should be coherent with the designation of sensitive areas and polluted waters under UWWT and Nitrates Directives. It should be recalled that measures under these Directives are part of the Programme of Measures foreseen in Article 11.3 and Annex VI part A of the WFD.

51. It is worth noting that both sensitive areas under the Urban Waste Water Treatment Directive 91/271/EEC and nitrate vulnerable zones under Directive 91/676/EEC become Protected Areas under Article 6 and Annex IV of the WFD.

52. As regards concrete measures foreseen in the various Directives to combat eutrophication, according to Art. 5(2) of Directive 91/271/EEC, Member States shall ensure that urban waste water entering collecting systems shall before discharge into sensitive areas be subject to a more stringent treatment to reduce the nutrient load, for agglomerations of more than 10,000 p.e.. In addition, in accordance with Art. 5(5), discharges which are located in the relevant catchment areas of sensitive areas and which contribute to the pollution of these areas shall also be subject to a more stringent treatment[11]. Similarly, Art. 5(1) of Directive 91/676/EEC requires Member States to establish action programmes consisting of mandatory measures in respect to designated nitrate vulnerable zones (Art. 5(4)), as well as additional measures or reinforced actions if necessary to achieve the objectives (Art. 5(5)).

53. Nevertheless, following Article 5.8 of Directive 91/271/EEC, Member States do not have an obligation to identify sensitive areas (i.e. sensitive water bodies) if they implement, on their whole territory, more stringent treatment (Art. 5.2 and 5.3) or apply 75 % reduction of the overall load of total nitrogen and of total phosphorus entering all urban waste water treatment plants (Art. 5.4).

54. In the same way, following Article 3.5 of Directive 91/676/EEC, Member States shall be exempt from the obligation to designate specific vulnerable zones, if they establish and apply action programmes referred to in Article 5 throughout their national territory.

55. Member States may decide to apply the whole territory approach without taking into consideration the status of water bodies. Therefore, the fact that Member States have chosen to apply in their whole territory the control measures mentioned in the previous two paragraphs does not prejudge the result of the status assessment under WFD.

[11] See ECJ judgement in §§18 to §§ 20 of the case C-396/00, of 25 April 2002 (Milano case)

Table 5. Comparison of assessment results under various policies for waters responding to nutrient enrichment (based on the assumption that the WFD classification is the starting point and that the different sources of pollution are relevant).

ASSESSMENT OF CURRENT STATUS						
Ecological status	**WFD normative definition**	**UWWT Directive[12]**	**Nitrates Directive[12]**	**OSPAR**	**HELCOM**	**MSF Directive**
High	Nearly undisturbed conditions	Non-eutrophic, designation of sensitive area is **not required[13]**	Non-eutrophic, not a polluted water [7], designation of nitrate vulnerable zone is **not required**	Non-problem area	Area not affected by eutrophication	-
Good	Slight change in composition, biomass	Non-eutrophic, designation of sensitive area is **not required**	Non-eutrophic, not a polluted water [7], designation of nitrate vulnerable zone is **not required**	Non-problem area[14]	Area not affected by eutrophication	Human induced eutrophication is minimised[15]
Moderate	Moderate change in composition, biomass	Eutrophic or may become eutrophic in the near future, designation of sensitive area is **required**	Eutrophic or may become eutrophic in the near future, polluted water [7], designation of nitrate vulnerable zone is **required**	Problem area[14]	Area affected by eutrophication	Human induced eutrophication is not minimised[16]
Poor[17]	Major change in biological communities	Eutrophic, designation of sensitive area is **required**	Eutrophic, polluted water [7], designation of nitrate vulnerable zone is **required**	Problem area	Area affected by eutrophication	Human induced eutrophication is not minimised[16]
Bad	Severe change in biological communities	Eutrophic, designation of sensitive area is **required**	Eutrophic, polluted water [7], designation of nitrate vulnerable zone is **required**	Problem area	Area affected by eutrophication	Human induced eutrophication is not minimised[16]

12 If Member States have chosen to apply the whole territory approach, there is no obligation to designate sensitive areas under the UWWT Directive or nitrate vulnerable zones under the Nitrates Directive.

13 In coastal zones, with good water exchange and other conditions described in the Directive 91/271/EEC, Annex II.B, even less sensitive areas can be designated.

14 If insufficient data is available, ‘good’ or ‘moderate’ Ecological Status could correspond to a potential problem area. Nevertheless, in the case of potential problem areas with regard to eutrophication, preventive measures should be taken in accordance with the Precautionary Principle. Furthermore, there should be urgent implementation of monitoring and research in order to enable a full assessment of the eutrophication status of each area concerned within five years of its being characterised as a potential problem area (see OSPAR Strategy to Combat Eutrophication § 3.2b.).

15 Human induced eutrophication is minimised, especially effects thereof, such as losses in biodiversity, ecosystem degradation, harmful algal blooms and oxygen deficiency in bottom waters (MFSD Annex 1 (5))

16 Work on the development of the respective descriptor is under way.

17 Indirect effects of eutrophication (e.g. decline in dissolved oxygen) will be evident at poor Ecological Status.

56. Table 5 provides a general comparison but has to be interpreted with care. The following aspects should be considered in more detail, in particular:

a. In general, the designation of many sensitive areas (under the UWWTD), the identification of "polluted waters"[7] requiring designation of nitrate vulnerable zones (under the Nitrates Directive), and the first designation of "problem areas" (2003) under the OSPAR Common Procedure has taken place before the WFD entered into force. All existing designations will be unchanged by the WFD independent of the ecological status of the water bodies concerned, although that status will be important in determining what nutrient control measures will be required. Sensitive areas and nitrate vulnerable zones will become protected areas under Article 6 and Annex IV of the WFD. After 2006, any classification of the status of these water bodies under the WFD will not change this designation, but will affect decisions on the range and extent of control measures required to achieve WFD objectives[18].

b. After 2006, however, when the monitoring programmes under the WFD will have become operational, the results of the ecological status assessment should be considered in reviews of the identification of "sensitive areas" and the designation of nitrate vulnerable zones in accordance with the UWWT and Nitrates Directives, respectively. Where these directives apply, a complementary approach to eutrophication assessment under the WFD is desirable as these two directives are basic measures under the WFD. In considering any read across from WFD classes to identification of waters as "sensitive" or "polluted" under the UWWT or Nitrates Directives, the advice on checking procedures (paragraph 43 and Chapter 6.2) and accounting for uncertainty in eutrophication assessment (paragraphs 44 and 46 and Chapter 6.2), should be taken into account.

c. Designation of sensitive areas or nitrate vulnerable zones is only necessary when pressures covered by the UWWT or Nitrates Directives are significant (regarding the latter see paragraph 35 of Judgement Case C-293/97). Recent ruling by the Court of Justice helps to interpret this concept of significant contribution (see paragraphs 40, 52, 77 and 87 of Judgement Case C-280/02 and paragraphs 81 to 88 of the Case C-221/03).

d. Water bodies may still be in moderate-bad status for a long time after pressures have been reduced, due to delayed soil leaching/run-off response, internal loading and/or time-lagged response in the biological quality elements. In such cases, the clause on "natural processes" in the exemption of the WFD (Article 4.4 WFD) may be checked to see whether it is applicable. Alternatively, other internal restoration measures (e.g. bio-manipulation or sediment dredging) may be required to speed up the recovery back to good status.

e. Finally, also other criteria (independent from eutrophication of surface water) may lead to designation of nitrate vulnerable zones and identification of sensitive areas (for example high nitrate concentrations in surface and groundwater)[19]. However, these are not part of the deliberations in this guidance.

---

18 The requirements on review of sensitive areas and designation of vulnerable zones every four years remains unchanged according to Art. 5(6) of 91/271/EEC and Art. 3(4) of 91/676/EEC.

19 See section A of Annex II of Urban Waste Water Treatment Directive 91/271/EEC, and Section A of Annex I of Nitrate Directive 91/676/EEC.

57. The pressures causing eutrophication may originate a long way from the water body being affected. In accordance to UWWT and Nitrates Directives, measures have to be taken in the relevant catchment areas of sensitive areas and which contribute to the pollution of these areas (Art. 5(5) of Directive 91/271/EEC), or in all known areas of land which drain into "polluted waters" [7] and which contribute to pollution (Art. 3(1), 3(2) and 5(1) of Directive 91/676/EEC). However, from the WFD perspective, this does not mean that all the water bodies upstream will need to be classified as less than good status.

58. Moreover, there may be situations where the nutrient pressures on affected water bodies may be located in another river basin (district) or adjacent areas of the marine waters (e.g. different parts of the Baltic Sea). This situation mainly occurs in transitional and coastal waters, where nutrient loads and/or eutrophication effects may be transported from one coast to another (e.g. North Adriatic Sea or German Bight, parts of the Baltic Sea, etc.) or from estuaries to coastal waters[20]. The assessments needed in this type of situation can be complex.

59. In comparing class boundaries used by the WFD and OSPAR it is helpful to describe the criteria for assessing Ecological Status in terms of primary and secondary impacts of eutrophication; this is done in Table 6. Environmentally significant undesirable impacts are expected to start at moderate Ecological Status (see Chapter 4 for more detail). It is proposed that the probability and severity of adverse effects increases from moderate to bad status.

Table 6. Examples of qualitative criteria for assessing WFD Ecological Status in terms of primary and secondary eutrophication impacts

Ecological Status	**WFD normative definition**	**Primary impacts (e.g. phytoplankton biomass)**	**Secondary impacts (e.g. O_2 deficiency)**
High	Nearly undisturbed conditions	None	None
Good	Slight change in abundance, composition or biomass for relevant biological quality elements	Slight	None or only slight
Moderate	Moderate change in composition or biomass for relevant biological quality elements	Change in biomass, abundance and composition begins to be environmentally significant, i.e. pollution tolerant species more common.	Occasional impacts from increased biomass
Poor	Major change in biological communities	Pollution sensitive species no longer common. Persistent blooms of pollution tolerant species	Secondary impacts common and occasionally severe
Bad	Severe change in biological comm.	Totally dominated by pollution tolerant species	Severe impacts common

20 Recent European Court of Justice ruling is relevant to interpret this concept. See Annex I, Section 1.2.4.

3.7. Examples of class comparisons

60. In this section some examples are given to clarify the relationships between different policies and, in particular, the differentiation between current status and the evaluation of status in the future, as set out in the preceding section. Table 7 summarises those examples. In all cases, it is assumed that pollution from urban waste water and agriculture sources are significant.

Table 7: Examples illustrating the relationship between WFD assessment classes, the result of the assessment of status in the future and the need for action under UWWT Directive, Nitrates Directive (ND) and WFD Programme of Measures

	Example A		Example B		Example C		Example D		Example E	
	Today	Future	Today	Future	Today	Future	Today	Future	Today	Future
High	●				●	►		►		
Good	●				●	►		►		
Moderate		►	●	► (1)			●		●	►►
Poor		►	●	►			●		●	►
Bad		►	●	►			●		●	
Action under UWWTD or Nitrates Directive needed?	Yes, in this case status may become eutrophic in the near future, action is needed		Yes, current status is eutrophic or may become eutrophic in the near future (case 1), action is needed		No		No. This can reflect the case in which measures under UWWTD or ND have already been taken and it is predicted that they will be effective to achieve the WFD objectives		Yes. This can reflect the case in which measures under UWWTD or ND have already been taken but it is predicted that they will NOT be effective to achieve the WFD objectives	
Action under WFD Programme of Measures needed?	Yes, status is predicted to deteriorate if no action is taken, therefore this case is at risk of not achieving WFD objectives		Yes, status less than good, this case does not achieve the WFD objectives		No		No additional measures than that already taken are necessary		Yes, additional measures under WFD Programme of measures are needed	

61. Some comments on the examples:

EXAMPLE A: In this case it is predicted that the status of the water body will deteriorate in the future. Action is needed under UWWT and Nitrates Directive because the water body "may become eutrophic in the near future". This water body would also be included in the WFD Programme of Measures because it is at risk of breaching the prevent deterioration principle.

EXAMPLE B: The water body is eutrophic or it may become eutrophic in the near future (case 1 corresponding to current moderate status). Therefore action is needed under UWWT and Nitrates Directives and it will also be included in the WFD Programme of Measures as this water body will not achieve the WFD objective of good status unless action is taken.

EXAMPLE C: This is the case where no eutrophication problem exists today and none is envisaged for the future. It should be noted that if it is predicted that the water body will deteriorate from high to good status, action should be taken under WFD Programme of Measures as this water body would be at risk of breaching the prevent deterioration principle.

EXAMPLE D: In this case it is predicted that the status of the water body will improve and it will reach good or high status. This can reflect the case in which measures under UWWT and Nitrates Directives have already been taken and are predicted to be sufficient to achieve WFD objectives. No further action under WFD is thus necessary.

EXAMPLE E: The last case has also the same starting point as D, but it is not expected that the measures taken according to the requirement of the Nitrates and UWWT Directives will give sufficient improvement in order to achieve a non-eutrophic status. This means that this water body has been identified as a polluted water and/or a sensitive area. WFD assessment would not change this designation. The WFD assessment results in a "less than good" status in the future as concerns nutrient enrichment. Additional measures to achieve WFD objectives are necessary under WFD Programme of Measures.

62. Linked with Example E, it is important to recall that under Article 5.5 of the Nitrates Directive "Member States shall take, in the framework of the action programmes, such additional measures or reinforced actions as they consider necessary if, […] it becomes apparent that the measures referred to in paragraph 4 will not be sufficient for achieving the objectives specified in Article 1". Therefore, in case of pollution from agricultural sources, the obligation to take additional measures and to review their effectiveness every four years (Art 5(7)), is already in force. In case of UWWT Directive, according to the Annex IB.4, more stringent measures must be applied where required to ensure that the receiving waters satisfy any other relevant Directives, for example the WFD.

63. It is important to note also that measures under UWWT and Nitrates Directives are considered basic measures in the WFD Programme of Measures, and therefore are minimum requirements to be complied with (Article 11.3 and Annex VI, Part A of the WFD).

64. The comparison of assessment results under various policies introduced in the preceding section and illustrated with the examples in Table 7 ensure a coherent and reinforced action against eutrophication across different policies.

65. In the examples, a generic "future" scenario is used, deliberately omitting any deadline for implementation of different directives. Measures under Nitrates and UWWT directives should have already been taken to combat eutrophication as appropriate. Nevertheless, as stated previously, from 2006 onwards and for new developments and newly identified problems, the WFD assessment framework may help in the implementation of these other directives.

4. THE WFD CONCEPT OF ECOLOGICAL STATUS IN THE CONTEXT OF EUTROPHICATION

66. This section summarises the main outcomes of a paper drafted by the Working Group on Ecological Status (ECOSTAT) under the WFD Common Implementation Strategy, on the interpretation of the WFD concept of ecological status in the context of eutrophication (the full paper is available as a background document)[21]. This paper is based on and further develops the Classification Guidance Document which was adopted by the Water Directors in November 2003 (see Annex 1, section 1.1.6 for a summary of this document).

67. The objective of this chapter is to set out a proposed common understanding of the Water Framework Directive's normative definitions in the context of nutrient enrichment and eutrophication. Such an understanding is necessary to underpin the ecological status classification in the context of eutrophication and thus the intercalibration exercise and the design of monitoring programmes. The proposed understanding focuses on those key principles of the normative definitions that are relevant across the water categories.

4.1. Most sensitive biological quality elements

68. As a general rule, the aquatic flora will have an earlier response to changes in nutrient conditions than benthic invertebrates or fish. The relative 'sensitivity' of different quality elements of the aquatic flora (e.g. macrophytes, phytobenthos or phytoplankton) to nutrient enrichment may vary, depending on the water category, surface water body type, the quality, amount and transport of nutrient loading as well as the specific environmental conditions such as flow conditions, salinity or turbidity. Furthermore, the most sensitive quality element or parameter to changes in eutrophication status, be it either in a deterioration or a recovery situation, will depend on the state of the water body's biological community's development towards 'equilibrium' with the altered pressure status.

---

21 http://circa.europa.eu/Public/irc/env/wfd/library?l=/framework_directive/thematic_documents/13_eutrophication&vm=detailed&sb=Title

69. For instance phytoplankton, phytobenthos and macroalgae derive their nutrients from the water column and, under the right conditions, can colonise, grow and reproduce quickly. As a consequence, they tend to respond rapidly to changes in nutrient concentrations. However, these quality elements can also be characteristically highly variable. This may make reliable assessments of their condition difficult.

70. Rooted macrophytes and angiosperms derive their nutrients from sediments or from a combination of sediments and the water column. Their response to nutrient enrichment tends to be slower than that of phytoplankton, phytobenthos and macroalgae, and therefore may enable reliable assessments to be achieved more easily. On the other hand, this relative ‘stability’ means that assessments based solely on macrophytes and angiosperms may in some situations fail to detect the early onset of eutrophication or the effects of restoration measures.

4.2. Role of the normative definitions in the development of ecological assessment methods

71. The normative definitions are the basis for identifying suitable boundary values for each of the indicator parameters. After selecting the metric or metrics to be used to assess the condition of the quality element, the common interpretation of the normative definition will drive the setting of the boundaries for each metric. Once a boundary has been set up, the monitoring results can be used to classify the condition of the quality element.

4.3. Shared principles in the normative definitions for the different water categories

72. The type-specific conditions defined for good and for moderate ecological status in rivers, lakes, transitional and coastal waters represent equivalent stages in the process of eutrophication in the different water categories, even if the conditions are sometimes expressed in the Annex V normative definitions using different wording.

4.4. Description given for abundance and taxonomic composition of aquatic flora

73. The condition of phytoplankton, phytobenthos, and macroalgae would not be consistent with good status unless there was a negligible probability (i.e. risk) that accelerated algal growth would result in a significant undesirable disturbance to the aquatic ecosystem (see Figure 4). The condition of macrophytes and angiosperms would not be consistent with good status unless there was a negligible probability that accelerated growth of higher forms of plant life would result in a significant undesirable disturbance to the aquatic ecosystem.

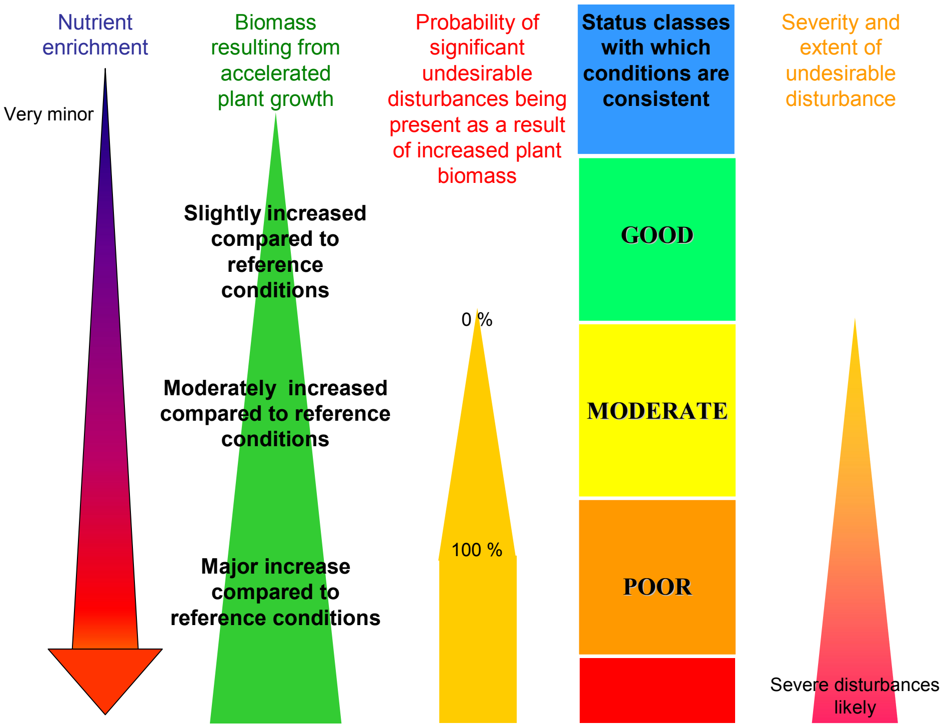

Figure 4. The condition of the water body would not be consistent with good status, once phytoplankton biomass, macroalgal cover, average phytobenthic abundance, average macrophytic abundance or angiosperm abundance has reached levels at which the probability of a significant undesirable disturbance to the aquatic ecosystem is no longer negligible.

74. A significant undesirable disturbance is a direct or indirect anthropogenic impact on an aquatic ecosystem that appreciably degrades the health or threatens the sustainable human use of that ecosystem (see Table 8). For a water body to be at good status there must be a negligible probability of such disturbances being present as a result of human activity.

75. Nutrients can sometimes cause changes in the taxonomic composition of plants or algae, without causing the biomass to increase to a level where it shows secondary impacts on flora, fauna or water quality in general. These rather subtle effects of eutrophication may occur in oligotrophic lakes in particular (see Figure 5).

76. The condition of phytoplankton, phytobenthos, macrophytes, macroalgae or angiosperms would not be consistent with good ecological status where, as a result of anthropogenic nutrient enrichment, changes in the balance of taxa are likely to adversely affect the functioning or structure of the ecosystem (see Table 9). For a water body to be at good status there must be a negligible probability of such disturbances to the balance of organisms being present.

Table 8. Significant undesirable disturbances that may result from accelerated growth of phytoplankton, macroalgae, phytobenthos, macrophytes or angiosperms (Source: ECOSTAT Paper on classification related to eutrophication[22])[23]

a.	Causes the condition of other elements of aquatic flora in the ecosystem to be moderate or worse (e.g. as a result of decreased light availability due to increased turbidity and shading caused by increased phytoplankton growth)
b.	Causes the condition of benthic invertebrate fauna to be moderate or worse (e.g. as a result of increased sedimentation of organic matter; oxygen deficiency; release of hydrogen sulphide; changes in habitat availability)
c.	Causes the condition of fish fauna to be moderate or worse (e.g. as a result of oxygen deficiency; release of hydrogen sulphide; changes in habitat availability)
d.	Compromises the achievement of the objectives of a Protected Area for economically significant species (e.g. as a result of accumulation of toxins in shellfish)
e.	Compromises the achievement of objectives for a Natura 2000 Protected Area
f.	Compromises the achievement of objectives for a Drinking Water Protected Area (e.g. as a result of disturbances to the quality of water)
g.	Compromises the achievement of objectives for other protected areas, e.g. bathing water.
h.	Causes a change that is harmful to human health (e.g. shellfish poisoning; toxins from algal blooms in water bodies used for recreation or drinking water)
i.	Causes a significant impairment of, or interference with, amenities and other legitimate uses of the environment (e.g. impairment of fisheries)
j.	Causes significant damage to material property

77. It is relevant here to introduce the interpretation of the European Court of Justice of the concept of "undesirable disturbances of the balance of organisms present". A recent Court ruling states that this concept means species changes involving loss of ecosystem biodiversity, nuisances due to proliferation of opportunistic macroalgae and severe outbreaks of toxic and harmful phytoplankton (see Annex 1, section 1.2.4).

---

22 http://circa.europa.eu/Public/irc/env/wfd/library?l=/framework_directive/thematic_documents/13_eutrophication&vm=detailed&sb=Title

23 See also §§18 and 22 of the ECJ judgement for the case C-280/02.

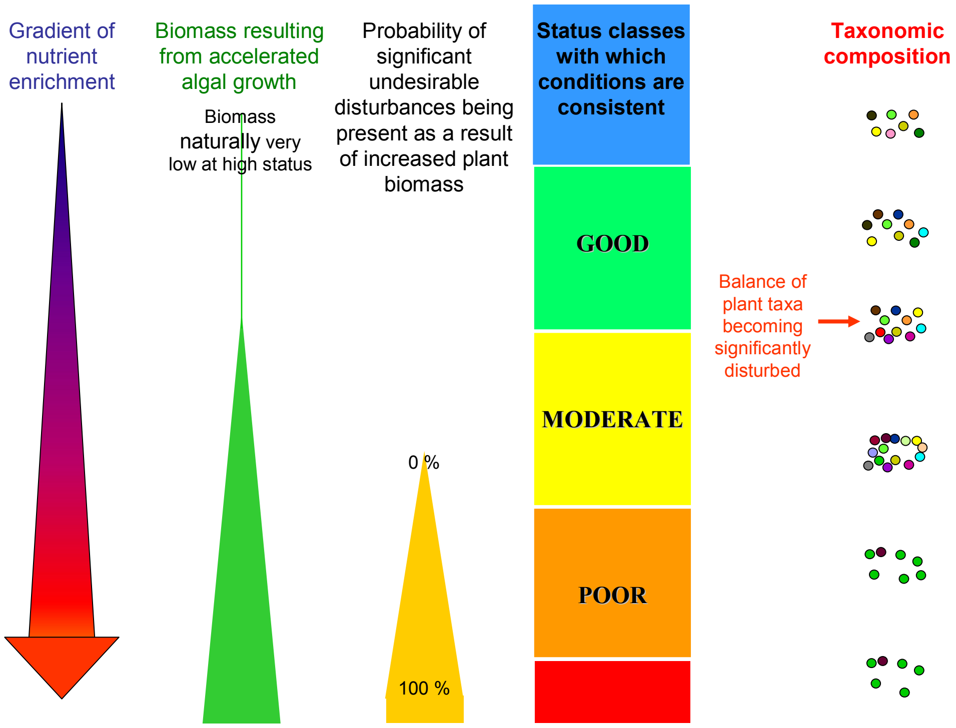

Figure 5. Ecologically undesirable changes in the composition of aquatic flora taxa may occur earlier along an increasing nutrient enrichment gradient than ecologically undesirable disturbances resulting from changes in the biomass of that flora (e.g. in some lakes that at reference conditions are low in nutrients and plant biomass)

Table 9. Examples of ecologically significant, undesirable changes to the composition of taxa.

Moderate conditions	**Poor or bad conditions**
The composition of taxa differs moderately from type-specific reference conditions such that:	
• nutrient-tolerant taxa or a functional group[24] of taxa that are absent or rare at reference conditions is no longer rare	• communities are dominated by nutrient-tolerant functional groups normally absent or rare under reference conditions
• moderate number of taxa are absent or rare compared to reference conditions such that a functional group of taxa is in significant decline; or • The condition of the functional group of taxa is exhibiting clear signs of stress such that there is a significant risk of localised extinctions at the limits of its normal distributional range	• one or more functional groups of taxa normally present at reference conditions has become rare or absent • the distribution of a functional group of plant taxa is so restricted compared to reference conditions that a significant loss of function has occurred (e.g. invertebrates or fish are in significant decline because of the loss of habitats normally provided by functional groups of macrophyte; macroalgal or angiosperm taxa)
• a group of taxa normally present at reference conditions is in significant decline	• a group of taxa normally present at reference conditions has become rare or absent

[24] Functional groups of taxa are different groups of taxa within a biological quality element that serve particular ecological roles

4.5. The role of general physico-chemical quality elements

78. The relative significance of the two most critical eutrophying nutrients, nitrogen and phosphorus, will vary in different surface water categories and types of surface waters. In transitional and coastal waters anthropogenic nitrogen enrichment is generally the most important cause of eutrophication, although there are cases where both nutrients may be limiting, but during different seasons. In freshwaters, generally phosphorus enrichment is the main cause of eutrophication.

79. If the monitoring results for (a) the biological quality element or elements most sensitive to nutrient enrichment and (b) the nutrient or nutrients being discharged in significant quantities meet the relevant type-specific conditions required for good ecological status, the level of nutrient enrichment in the water body will be consistent with good ecological status.

80. However, if either (a) one of the most sensitive biological quality elements to nutrient enrichment; or (b) one of the nutrients being discharged in significant quantities do not meet the conditions required for good ecological status, the ecological status of the water body will be moderate or worse.

81. Further guidance on classification and, in particular, on the role of general physico-chemical quality elements is provided in CIS Guidance on the Classification of Ecological Status. The guidance describes a checking procedure aimed at helping to ensure that the good status type-specific levels for nutrient concentrations are neither more stringent nor less stringent than required to support the achievement of good status for the type-specific conditions for the biological quality elements and the functioning of the ecosystem (see also Chapter 6.2 and Annex 1, section 1.1.6).

5. Overview of current eutrophication assessment methodologies and criteria in European countries

5.1. Introduction

82. Eutrophication assessment methodologies and criteria for classification of water quality status have been used by Member States in particular in the implementation of the Urban Waste Water Treatment and Nitrates Directives, and in relation to the commitments taken within the marine conventions OSPAR and HELCOM. Member States have completed the WFD Article 5 risk assessments for which existing eutrophication assessment criteria were used or newly derived criteria to determine whether surface water bodies are at risk of failing their environmental objectives in 2015 from eutrophication related pressures. Since then, new eutrophication-related assessment methodologies and criteria, or some degree of modification of already existing methods, were developed in the Member States in relation to the implementation of the requirements of the WFD for the classification of ecological status in lakes, rivers, coastal and to a lesser extent in transitional waters. These requirements included the choice of the appropriate indicators, typology of water bodies, reference conditions, and agreement on common principles for setting

quality class boundaries (see Heiskanen et al., 2004). In addition, some of the methods developed were subjected to an intercalibration process during the years 2004 to 2007. This process, to a large extent focused on methods sensitive to eutrophication, has established the value for the boundary between the quality classes of high and good status, and the value for the boundary between good and moderate status for the Member State's biological classification systems ensuring their consistency with the normative definitions (WFD annex V, section 1.2) and the comparability between Member States.

83. The results of the intercalibration exercise were adopted in Commission Decision 2008/915/EC on 30 October 2008[25]. Technical reports on the Water Framework Directive intercalibration exercise (Carletti and Heiskanen, *in press*; Poikane, *in press*; Van de Bund, *in press*), one for each water category (i.e. lakes, rivers and coastal and transitional waters), describe in detail how the intercalibration exercise has been carried out in each Geographical Intercalibration Group (GIG), including the procedures and criteria that were agreed for setting reference conditions, to ensure consistency with the normative definitions, and to ensure comparability of class boundaries between Member States.

84. In several cases, the results of European collaborative research projects were used in the development of new indicators and/or classification schemes (e.g. Charm, AQEM, STAR, REBECCA, FAME; see Heiskanen et al., 2005; Hering et al., 2006; Solimini et al., 2006; Pont et al., 2006). In this sense, one of most supportive projects was REBECCA (2003-2007) which has contributed to development of methodologies and criteria with a timetable for the project deliverables synchronised to some extent with the timetable for the intercalibration process.

85. This overview of current eutrophication assessment methodologies and criteria gathers information provided by Member States during the development of this guidance document and new methodologies and criteria from the intercalibration exercise and REBECCA project.

86. Sections 5.2 to 5.4 summarise the information available from these sources for lakes, rivers, transitional, coastal and marine waters, respectively.

5.2. Lakes

5.2.1. Assessment methodologies and criteria used for water quality status classification

87. Many Member States had water quality assessment systems prior to the adoption of the WFD which already included assessment methods and criteria for eutrophication related parameters. Information collated in previous syntheses (i.e. Cardoso *et al*., 2001) and as part of this activity[26] indicates that the assessment of the degree of eutrophication in lakes has been, until the adoption of the WFD, primarily determined through

[25] http://eur-lex.europa.eu/LexUriServ/LexUriServ.do?uri=CELEX:32008D0915:EN:NOT

[26] see Eutrophication Workshop held in Brussels on the 7-9 September 2005

the application of nutrient (phosphorus and nitrogen) concentration criteria supplemented with the use of criteria for indicators of eutrophication direct effects. The most commonly included were the criteria for chlorophyll a and Secchi depth but occasionally other indicators, such as changes to phytoplankton composition were also used. A number of other parameters (indicators) were used in some Member States, although indicators of indirect eutrophication effects (dissolved oxygen concentrations and responses in benthic invertebrate and fish communities) were not generally used.

88. Some of these water quality assessment schemes recognised the existence of different lake types in broad terms but many schemes were applied indiscriminately to all lakes in a Member State. However, for management purposes the assessment was done in relation to a rough estimation of the lake's natural trophic status. Thus, with few exceptions these assessment systems are not type-specific in terms of WFD typology and do not relate to reference conditions.

89. Information of the assessment systems for which information has been shared at the Eutrophication Workshop (Brussels, 2005) for Norway, Sweden, Finland, Austria, Italy and Hungary showed that the most commonly used assessment parameters, i.e. chlorophyll a, total phosphorus (TP) and Secchi depth, of most of these countries' systems (with exception of the Hungarian) showed relatively good agreement in the criteria for the best quality classes. For chlorophyll a (summer mean values) the best quality class varies from < 2 μgl^{-1} in Norway and Sweden to < 4 μgl^{-1} in Finland and Austria. For total phosphorus (summer mean values) the best quality class varied from < 7 μgl^{-1} in Norway to < 13 μgl^{-1} in several other countries. For Secchi depth the best quality class varies from > 6 m to > 3 m between countries. For all these three basic eutrophication assessment parameters, the between country variation for the best class is roughly a factor of 2. For the other classes the differences between countries are larger, probably due to both different class definitions, as well as to real regional differences.

90. The Hungarian system has considerably higher boundary criteria between the quality classes for total phosphorus and chlorophyll a, which is probably mainly explained by different lake types in Hungary (very shallow, calcareous) compared to the Northern and Alpine countries (deeper, more siliceous geology). The Hungarian class I includes values comparable to class III (moderate) of the other countries compiled, whereas the Hungarian class II compares to class IV or V (poor or bad) in the other countries.

91. For the indirect effect criterion oxygen saturation, the two systems compiled (Hungary and Finland) show relatively good agreement, with class I having 80-110 % O_2 saturation, whereas class V has < 20 % or < 40 % O_2 saturation for the Hungarian and Finnish systems respectively.

92. The two countries, Sweden and Austria that have developed classification systems for phytoplankton biomass (mgl^{-1}) show remarkably good agreement: Class 2 is <1 mgl^{-1} and class 5 is > 5 mgl^{-1}.

93. For other assessment criteria the data provided is not sufficient to enable comparisons between countries.

94. For additional information on national criteria for eutrophication assessment in the context of the UWWT and Nitrates Directives see Cardoso *et al*. (2001).

5.2.2. Impact and pressure criteria used in WFD Article 5 risk assessment

95. In completing the WFD Article 5 risk assessments for eutrophication related pressures, some Member States have derived pressure and impact criteria to determine whether a lake water body was at risk of not achieving its environmental objective in 2015. Where used, the pressure criteria have been based on the presence of point sources of nutrients and/or a proportion of a particular land use (most commonly agricultural and urban land uses) in the catchment of the lake. One country (Spain) assesses a water body to be probably at risk if the application of fertilizer is > 25 kg N ha^{-1} year or if major point sources are present, such as urban waste water > 2000 PE, unless no impact is documented.

96. For the most part, the impacts were measured based on nutrient concentrations (phosphorus and nitrogen) with occasional examples of the use of direct effects (chlorophyll a) to supplement them. For the latter the existing classification systems are used in a way in which lakes in the high or good classes are assessed as being not at risk, whereas lakes in the poor or bad classes are assessed as being at risk of failing the WFD objective. One Member State (UK) use the EQR< 0.5 for current phosphorus concentrations relative to type or site-specific background concentrations to assess water bodies at risk, whereas other (NL) use, among others, the existing management target value to assess water bodies at risk. The actual cut-off for TP between at risk and not at risk is comprised within a wide band of concentrations from < 10 µg l^{-1} to > 100 µg l^{-1} for the different countries, which is probably related to type differences. For chlorophyll a the only two Member States who have reported cut-off values (Norway and Spain) both use 8 µg l^{-1} to say that a water body is clearly at risk (Norway) or probably at risk (Spain)[27]. Other impact parameters are too scarcely used to allow comparisons between countries. Many Member States also evaluate future trends in nutrient pressures from the catchment as part of their risk assessment. Further details on the parameters used are provided in the reports provided by the Member States under Article 5 WFD.

5.2.3. New WFD-compliant assessment systems

97. Many Members States have been engaged in the development of new, or refinement of existing, assessment methods for the eutrophication related biological quality elements required for the assessment of ecological status under the WFD. The work under the Intercalibration process for lakes has focussed on the calibration and harmonisation of the national assessments based on phytoplankton and macrophyte responses to nutrients. Intercalibration metrics (Poikane, *in press*) used for lakes are: phytoplankton parameters indicative of biomass - chlorophyll a and total biovolume; phytoplankton parameters indicative of taxonomic

[27]http://circa.europa.eu/Public/irc/env/wfd/library?l=/framework_directive/thematic_documents/13_eutrophication&vm=detailed&sb=Title

composition and abundance - Brettum Index, PTSI - Phytoplankton Taxa Lake Index, PTI_{ot} - Phytoplankton Taxa Index, $PTI_{species}$ - Phytoplankton Taxa Index, Catalan Index, Med PTI Index, % bluegreens, % chrysophytes, % diatoms; macrophyte composition (% isoetids, % characeans) and reduction in depth distribution of macrophytes (Austrian Index Macrophytes for lakes, German Macrophytes Assessment System, Free Macrophyte Index, Swedish Macrophyte Trophic Index (Ecke), Norwegian Macrophyte Trophic Index (Mjelde), UK Macrophyte Assessment System: LEAFPACS).

98. The development of these methods and their intercalibration (included the definition and agreement on reference conditions and collation of data illustrating the metric (=indicator) response to a pressure gradient) also supported the development of criteria for the eutrophication related supporting physico-chemical elements such as Secchi depth and nutrients, primarily total phosphorus concentrations.

99. The intercalibration process partially included methods sensitive to the indirect effects of eutrophication, such as oxygen depletion in bottom waters and fish kills. In several GIGs secondary effects were used for setting chlorophyll a boundaries, such as oxygen depletion and fish kills.

100. The REBECCA project Work Package 3 (WP3 Lakes) has supported the intercalibration process by establishing the relationships between nutrient concentrations or an indicator of the trophic condition (e.g. trophic score) and response variables (= effects indicators, metrics) relating to phytoplankton, macrophytes, macroinvertebrates and fish (see report on dose-response relationships between biological and chemical elements in different lake types; Lyche-Solheim, 2007). These results have already, because of the close collaboration between the REBECCA project and the intercalibration expert groups, where appropriated, been considered in the intercalibration process. Further details of the REBECCA results can be found in a review of the literature on these relationships in European lakes based on the knowledge until 2005 (Solimini *et al.* 2006), as well as a report on Reference conditions of European Lakes (Lyche-Solheim *et al.* 2005).

101. The work carried out in recent years within Member States and at the EU level, in research projects and as part of the intercalibration process, has provided scientifically based and intercalibrated assessment systems and further understanding of the relationships between biological and supporting physico-chemical elements of lakes. The results of the intercalibration process, the Ecological Quality Ratios for the high/good and good/moderate class boundaries (for phytoplankton also the absolute metric values, i.e. chlorophyll a concentration and biovolume), per Geographic Intercalibration Group (GIG) and lake type, for the phytoplankton and macrophyte metrics listed above, have now been agreed and included in Annex to the Commission Decision (Commission Decision 2008/915/EC). The Member States will now need to translate the values published in the Decision into their national systems with the help of guidelines prepared for this purpose and available online at:

http://circa.europa.eu/Members/irc/jrc/jrc_eewai/library?l=/intercalibration&vm=compact&sb=Title.

102. The application of these assessment systems as part of the WFD implementation, including the collation and analysis of data from WFD monitoring and from research projects, may lead to a review of the intercalibration results and thus also to changes to the national assessment systems.

103. Another important issue that may lead to a need for revision of the intercalibration results is related to lack of standardisation of methods for collection of the data used in this first round of the process. Thus, with maybe the exception of the Northern GIG, where there was already some degree of harmonisation of the methods, the noise in the data associated to the method is probably an important component of all variance in the data.

104. Through the intercalibration, all GIGs have now agreed on the good/moderate quality class boundary for the metrics list above (see paragraph 87), and all but the Mediterranean GIG have agreed on the high/good quality class boundary for chlorophyll a for a small number of broadly defined lake types, which are applicable in all the countries sharing the type.

105. The national lake phytoplankton metrics can be roughly divided into taxonomic based and non-taxonomic based metrics. The use of phytoplankton taxonomic metrics for water quality assessment has a long tradition, with the first indicators developed in the 40's and since then numerous indicators were developed, some of which have been included in the WFD assessment schemes. Yet, a number of new indicators were developed tailored to address the WFD requirements. Three new phytoplankton trophic indices (PTI-s) where elaborated for deep subalpine lakes (Salmaso et al., 2006). Another development is the method adopted in the WFD monitoring scheme in Hungary based on functional groups, i.e. groups with species frequently found to co-exist and to increase or decrease in number simultaneously are thus given association identities. The method was first developed by Reynolds et al. (2002) and further developed Padisák et al. (2003, 2006).

106. Phytoplankton abundance and occurrence of blooms are the parameters for which a taxonomic determination is not necessarily required. The abundance is measured as the total count of cells and/or colonies in a unit volume of water or recalculated further into biovolume or biomass. The WFD allows using chlorophyll a as a surrogate for phytoplankton biomass, and in fact chlorophyll a is still the most frequently measured phytoplankton metric in lakes. Not all countries have included the bloom occurrence in routine monitoring as in some areas (e.g. countries belonging to the Alpine GIG) they occur too rarely and irregularly (if at all). Other non-taxonomy based metrics, like size composition and primary production, are not considered in lake monitoring schemes.

107. Classification schemes for macrophytes were developed by many Member States. One approach being followed in Germany (Schaumburg et al., 2004) and England (Willby et al., 2006) is to designate macrophytes as reference, impacted, or indifferent for specific lake types. The classification of a lake is then based on the proportions of macrophytes that are indicative of reference and impacted conditions. The method used in Northern Belgium also incorporates aspects of this approach together with metrics describing

the diversity of growth forms and changes in abundance (Leyssen et al., 2005). The Dutch method incorporates information on the percentage cover of submerged macrophytes (for a depth range of 0-3 m), shoreline emergent vegetation cover and species composition (divided into three indicative groups weighted by their abundance) (Van der Molen, 2004; Coops et al., 2007). In Sweden assessment is based on taxa richness and the assignment of a trophic ranking score for different lake types (Swedish EPA, 2007). In Ireland a multimetric approach is followed incorporating several of the aforementioned parameters as well as the depth of colonization of macrophytes (Free et al., 2007).

108. Although there appears to be some concordance of assessment approaches across Europe, the methods used to collect such data are diverse and may in some cases not be fully representative of the pressure impact (e.g. strong biased towards sampling the shallower areas and not the full representative of macrophyte depth distribution). Future work needed includes the gathering of an extensive standardized dataset matched with important environmental parameters, including sediment characteristics, and to further understand the role of macrophytes in lake ecosystem functioning.

109. Several GIGs have attempted to relate environmental factors like TP and Secchi depth with chlorophyll a. Such relationships may be used for setting criteria of quality classes for those environmental factors which is of fundamental importance in lake management. The main approaches followed, with the support of data and their analysis from the REBECCA project (Table 10), were either based on a percentile of the reference lakes data set (mostly the 75 %ile for reference sites) or based on regressions between chlorophyll a and TP compiled for a large number of lakes, or based on both methods. The use of this type of relationships can be, however, limited. For shallow lakes discontinuous relationships may be present e.g. between TP and chlorophyll a, and therefore linear regression is not very appropriate. In addition, the TP is providing generally the best prediction for the maximum chlorophyll a values, because there can be many biological reasons why not all TP is transferred into phytoplankton biomass.

Table 10. **Regression equations for relationships between mean growing season chlorophyll a and TP for lakes categorised by grouped typology factors (Phillips et al, 2008).**

Type group	Equation	R^2	p
Low and moderate alkalinity shallow and very shallow lakes	Log10 Chl = -0.528(±0.03) + 1.108(±0.02)Log10 TP	**0.81**	<0.001
High alkalinity shallow and very shallow lakes	Log10 Chl = -0.306(±0.10) + 0.868(±0.07) Log10 TP	**0.52**	<0.001
All deep lakes	Log10 Chl = -0.286(±0.04) + 0.776(±0.041) Log TP	**0.65**	<0.001

5.3. Rivers

5.3.1. Assessment methodologies and criteria used for water quality status classification

110. As for lakes, in most cases Member States water quality assessment systems for rivers, prior to the adoption of the WFD, included assessment methods and criteria for eutrophication related parameters. Information collated in previous syntheses (i.e. Cardoso *et al*., 2001) and as part of this activity (see Eutrophication Workshop, Brussels 2005) indicates that the assessment of the degree of eutrophication in rivers to date has been primarily determined through the application of nutrient (phosphorus and nitrogen) concentration criteria with the occasional supplementary use of metrics indicative of direct effects (chlorophyll a and changes to phytobenthos and macrophyte communities) and metrics indicative of indirect effects (e.g. dissolved oxygen concentration and changes to benthic invertebrate communities) criteria. The most commonly used parameter for rivers is TP concentration and the criteria for excellent water quality are broadly comparable (0.01 to 0.07 mgl^{-1} TP; though these include summer mean, annual mean and 90 and 75 %ile values). Criteria for orthophosphate are used in one Member State. Criteria for total nitrogen (TN) and nitrate are used in 2 Member States and also show good agreement. In all cases existing classification schemes are river type-specific but were applied to all types of river.

111. For additional information on national criteria for eutrophication assessment in the context of the UWWT and Nitrates Directives see Cardoso *et al*. (2001). The most commonly used criterion for designation of nitrate vulnerable zones is the 50 mgl^{-1} NO_3 value. However, for UWWT sensitive area designation, phosphorus criteria are used along with further information from metrics indicative of direct effects (chlorophyll a concentration and phytobenthos and macrophytes community metrics) and from metrics indicative of indirect effect (changes to the dissolved oxygen regime) in a weight of evidence approach to determine the case for designation.

5.3.2. Impact and pressure criteria used in WFD Article 5 risk assessment

112. In completing the WFD Article 5 risk assessments for eutrophication related pressures, some Member States have derived pressure and impact criteria to determine whether a river water body was at risk of not achieving its environmental objective in 2015. Where used, the pressure criteria have been based on the presence of point sources of nutrients and/or a proportion of a particular land use (most commonly agriculture, forestry and untreated wastewater from settlements) in the upstream catchment of the river water body. For the most part, the impact criteria were based on nutrient concentrations (phosphorus and nitrogen). The most commonly used impact criteria were TP and orthophosphate. Values for the estimated good/moderate class boundary used in the Article 5 risk assessments were comparable for similar river types (i.e. lowland rivers) (0.15 mgl^{-1} TP and 0.1mgl^{-1} orthophosphate-P). Criteria for TN and for nitrate were used in some Member States supplemented with criteria for metrics indicative of indirect effects (dissolved

oxygen concentrations, benthic invertebrate and phytobenthos metrics). Further details on the criteria used are provided in the reports provided by the Member States under Article 5 WFD.

5.3.3. New WFD-compliant assessment systems

113. Many Member States have been engaged in the development of new, or refinement of existing, assessment methods for the eutrophication related biological quality elements required for the assessment of ecological status under the WFD. For rivers, the eutrophication related biological quality elements are principally phytobenthos, macrophytes and, where appropriate, phytoplankton and macrozoobenthos. The development of assessment methods for these elements will necessarily result in the definition of type-specific reference conditions and class boundary criteria for the classification of ecological status with respect to these biological quality elements. Also, the development of assessment methods for these biological quality elements and their intercalibration (as explained above this process included the definition and agreement on reference conditions and collation of data illustrating the metric response to a pressure gradient) have resulted, in some cases, in the development of criteria for the eutrophication related supporting physico-chemical determinands such as nutrients and dissolved oxygen concentrations. Information collated under this activity on the development of new methods (compare overview of nutrient standards)[28] indicates that preliminary criteria for nutrients (TP, orthophosphate, TN and nitrate) have been proposed for reference conditions and the good/moderate boundary in a number of Member States. Additional criteria for chlorophyll a and dissolved oxygen have also been suggested.

114. The REBECCA project Work Package 4 (WP4 Rivers) has supported the intercalibration process by exploring new tools for assessing eutrophication through the response of phytobenthos metrics to nutrients, i.e. diatom based techniques, making use of diatoms morphological-functional attributes and biotypes, but also revaluating existing indexes in a WFD perspective (see report on suitable single and integrated biological indicators for different pressures in rivers; Friberg, 2007). Further details of the REBECCA WP4 results can be found in a review of the literature on these relationships in European rivers based on the knowledge until 2004 (Andersen *et al.* 2004), as well as a report on relations linking pressures, chemistry and biology in rivers and tools for assessing these linkages (Friberg, 2007).These results have already, because of a close collaboration between REBECCA researchers and the intercalibration expert groups, where appropriated, been considered in the intercalibration process.

115. The work under the Intercalibration process has for rivers focussed on benthic invertebrates as indicators of organic contamination or general degradation. However, four of the five river GIGs, the Alpine, Central/Baltic, Mediterranean and Northern GIG have successfully intercalibrated phytobenthos metrics which are primarily eutrophication indicators, thus have also provided criteria for eutrophication related

[28] http://circa.europa.eu/Public/irc/env/wfd/library?l=/framework_directive/thematic_documents/13_eutrophication&vm=detailed&sb=Title

supporting physico-chemical elements. The results of the intercalibration process, the Ecological Quality Ratios for the high/good and good/moderate quality class boundaries, and for the phytobenthos national classification systems, per GIG and river type have now been agreed and included in Annex to the Commission Decision (Commission Decision 2008/915/EC). The Member States will now have to translate the values published in the Decision into their national systems with the help of guidelines prepared for the purpose.

116. The application of these assessment systems to data to be collected as part of the WFD monitoring requirements, the analysis of this data and other data collected through research projects may eventually lead to a review of the intercalibration results in order to improve their quality. Unlike the problems found with phytoplankton metrics in lakes related to the noise (i.e. highly variable due to different national sampling procedures) in the data available, the existence and common use of standard methods for sampling of phytobenthos was responsible for the good quality of the data available which greatly facilitated the intercalibration exercise.

117. All but the Eastern Continental GIG have agreed on the high/good and good/moderate quality class boundary for phytobenthos national assessment metrics for a small number of broad river types.

The biological monitoring of water quality in rivers has a long tradition in Europe (see Ziglio et al., 2006 for a recent review). However, the fulfilment of the WFD's requirements imposed a revision of many old assessment methods which were either adapted to meet WFD specifications or resulted in the setup of new classification systems.

118. Annex V of the WFD refers to ‘macrophytes and phytobenthos’ as a single biological element and identifies four characteristics (taxonomic composition, abundance, likelihood of undesirable disturbances and presence of bacterial tufts) that need to be considered for the purpose of ecological status assessment. Most countries decided to develop separate methods for macrophytes and phytobenthos. Some MS included larger algae such as Cladophora in their macrophyte methods while others included the latter as part of the phytobenthos. However, most of the countries decided to use diatoms as a representative group for the whole phytobenthos.

119. The term “phytobenthos” refers to a highly diverse group of organisms (diatoms, filamentous algae, blue-green, etc.) with heterogeneous growth forms on many different river substrates. For the assessment of ecological status, diatoms are the most frequently used indicators included in monitoring programs. Almost all metrics rely on the taxonomic composition of the assemblages, often relating the metric value to the pressure gradient with weighted averaging like in the Trophic Diatom Index (TDI; Kelly, 2001) or in the Indice de Polluosensibilité (IPS; Coste in Cemagref, 1981). For example, the TDI relies on the fact that (in theory) at least the diatom assemblages characteristic of low, moderate and high phosphorus concentrations can be defined (Kelly, 2001). In practice, there are many other factors that can also influence the composition of the diatom assemblage, making assessment difficult. The phytobenthos abundance is also

highly temporally and spatially variable and its assessment, also in relative terms, is problematic. Few Member States have developed new methods based on the relative abundance of positive and negative indicator species.

120. Phytoplankton is an important component of riverine food webs in large rivers (Prygiel and Haury, 2006). The short generation time makes this group of organisms highly reactive to changes in flow conditions, light and nutrients. However, phytoplanktonic biomass is strongly linked to the water residence time and significant amount of biomass may be reached only in low gradient tracts of large rivers and canals when the residence time is long enough for algal development (e.g. more than 6 days). Routine monitoring using phytoplankton is foreseen by those countries where such river types are present in a relevant number but may be often limited to the measure of chlorophyll a as an indicator of phytoplanktonic biomass.

5.4. Transitional waters

5.4.1. Assessment methodologies and criteria used for water quality status classification

121. Eutrophication is a recognised threat to the ecological status of transitional water bodies as these accumulate nutrients transported from river systems, from direct inputs from their surrounding catchments and, in some cases, from coastal waters. The expression of the direct and indirect effects of eutrophication in response to increasing nutrient inputs is more complicated in many transitional water types due to the confounding influences of other natural and anthropogenically induced processes. Transitional waters can support a high degree of anthropogenic activity. Zaldívar et al. (2008) identified this phenomenon and termed it the 'transitional water quality paradox', based on the 'estuarine water quality paradox' suggested by Elliott and Quintino (2007 in Zaldívar et al. 2008) for estuaries, to describe the difficulties in identifying a pressure-specific signal (such as eutrophication) against a highly variable natural background compounded by the competing effects of the impacts arising from other pressures.

122. Nevertheless, approaches to eutrophication assessment have been developed for transitional water bodies. Zaldívar et al. (2008) reviewed these approaches and categorised them into screening methods, model-based assessments and mixed approaches.

123. Screening methods typically include the consideration of a number of diagnostic physico-chemical and biological determinands to assign an eutrophication status class. Methods specific to transitional water body types include those for estuaries, fjords and coastal lagoons. The OSPAR Common Procedure (see Section 2.1.2) is the screening type method most commonly used for transitional waters within the OSPAR Convention area. The NOAA ASSETS (Assessment of Estuarine Trophic Status) method (see Zaldívar et al. 2008) has been modified for use in Portugal. This method combines measures of pressure (an estimate of net nutrient load to the water body), state (an assessment of eutrophication status based on indicators of direct and indirect effects) and response (an assessment of the susceptibility of the estuary to eutrophication) into an integrated assessment of trophic status. The measure of state comprises metrics for physico-chemical

(dissolved oxygen) and direct biological response determinands. Methods appropriate for coastal lagoons are less well developed. The Trophic Index (TRIX) (Vollenweider et al. 1998 in Zaldívar et al. 2008) integrates measures of chlorophyll a, oxygen saturation, total nitrogen and total phosphorus to provide a value indicative of trophic status. Zaldívar et al. (2008) indicate that this method is commonly used for coastal lagoons but is poorly suited to shallow water systems where phytoplankton are not the only component of the primary producer community responding to increasing nutrient concentrations. The importance of sedimentary processes in shallow water systems is important with respect both to the mobilisation of nutrient deposits and the detection of secondary effects of eutrophication. Two indices that exploit sedimentary responses to oxygen production and respiration include the Benthic Trophic Status Index (BSTI) (Rizzo et al. 1996 in Zaldívar et al. 2008) and the Trophic Oxygen Status Index (TOSI) (Viaroli and Christian 2003 in Zaldívar et al. 2008). Coastal lagoons dominated by macroalgae as a response to eutrophication demonstrate different responses to those unimpacted lagoons dominated by seagrasses on the basis of these indices. Both sediment and water quality variables have been integrated into the lagoon water quality index (LWQI) (Giordani et al. 2008 in Zaldívar et al. 2008). This index includes metrics for macroalgal and seagrass cover along with water column metrics for nutrients (DIP, DIN), oxygen saturation and phytoplankton chlorophyll a.

124. Model-based assessments identified by Zaldívar et al. (2008) tended to be restricted to site-specific applications that sought to link inputs of nutrients with hydrodynamic and biogeochemical models to provide predictions of nutrient regimes for transitional water bodies from which the likelihood of eutrophication effects could be estimated.

125. Mixed or hybrid approaches that combine the use of screening methods with simplified model-based approaches have the potential to deliver the advantages of a wider degree of applicability and predictive power (Zaldívar et al. 2008). Two examples of this include the use of the ASSETS tool with an ecological model in water body definition in estuaries (Ferreira et al., 2008 in Zaldívar et al. 2008) and the combination of the LWQI with a biogeochemical model and interfaced with a Decision Support System (Mocenni et al. 2008 in Zaldívar et al. 2008).

5.4.2. Impact and pressure criteria used in WFD Article 5 risk assessment

126. The available information for Article 5 related criteria indicates that whenever pressure criteria were reported these were based mainly on the presence of surface point sources (sewage) of nutrients loads and surface water run-off. The impact criteria were based mainly on nutrient concentrations and chlorophyll a (direct effect) and occasionally on dissolved oxygen, macrovegetation, etc (indirect effects).

5.4.3. Examples of development of new WFD-compliant assessment systems

127. The implementation of the Water Framework Directive has stimulated the development of assessment methodologies addressing the appropriate eutrophication-related, direct and indirect physico-chemical and biological determinands.

128. A workshop on Classification of Ecological Status[29] held under the auspices of ECOSTAT included a questionnaire on the quality elements most likely to be used in the classification of status for the common pressures. For transitional and coastal waters, Member States indicated the phytoplankton, macroalgae and angiosperm biological quality elements were most likely to be used for the assessment of ecological status in relation to nutrient pressure and that macroinvertebrates and fish (in transitional waters only) were most likely to be used in relation to oxygen depletion.

129. Zaldívar et al. 2008 reviewed the methodologies under development for the purposes of WFD status assessment and intercalibration for each of the biological and supporting physico-chemical quality elements.

130. The assessment of the phytoplankton quality element requires tools to address all aspects of the normative condition, namely: phytoplankton biomass, composition and bloom frequency. Estimation of phytoplankton biomass is most commonly undertaken using chlorophyll a concentration as a surrogate. Methods and class boundary values have been intercalibrated for chlorophyll a for most coastal water body types but have yet to be developed for transitional water types. Similarly, some work has been undertaken to develop tools for phytoplankton composition and bloom (*Phaeocystis*) frequency for coastal water body types but these have yet to be intercalibrated. These tools are likely to be adapted for use in some transitional water types in the second phase of intercalibration due for completion in 2011.

131. The assessment of the macroalgae quality elements requires consideration of the composition of macroalgal communities and the extent of macroalgal cover.

132. A proposed classification tool for macroalgal cover has been developed by Scanlan et al. (2007 in Zaldívar et al. 2008) based on the relationship between percentage cover and biomass of opportunistic species of macroalgae such as *Ulva* and *Entermorpha*.

133. The angiosperm quality element comprises a requirement for the assessment of taxonomic composition and abundance. A classification tool called the Ecological Evaluation Index (EEI) based on the abundance of macroalgae and angiosperms has been proposed by Orfanidis et al. (2001, 2003 in Zaldívar et al. 2008). This utilises the known shift in community status from one dominated by angiosperms to one dominated by macroalgae in response to increasing nutrients as a measure of ecological quality.

134. The benthic macroinvertebrate quality element can be useful in the assessment of the indirect effects of eutrophication. The normative definition requires the assessment of the diversity and abundance of benthic

[29] Report on Workshop Setting Nutrient Standards (2007).

invertebrates and the presence of disturbance sensitive taxa. Zaldívar et al. (2008) identify three indices that are under consideration for use in the assessment of transitional water benthic invertebrate status.

135. The AMBI index (Borja et al. 2000 in Zaldívar et al. 2008) utilises the known response of benthic invertebrates inhabiting soft sediments to pollution gradients and the classification of polluted conditions has been adapted to reflect the status classification of the Water Framework Directive. The BENTIX index (Simboura and Zenetos 2002 in Zaldívar et al. 2008) has been developed specifically to meet the requirements of the Water Framework Directive in the Eastern Mediterranean. The approach is similar to that used for the AMBI index. These tools have been developed for use in coastal water body types but have the potential to be adapted and used in transitional water body types. The Benthic Ecosystem Quality Index (BEQI) (Hoey et al. 2007) has been developed and applied in both coastal and transitional water body types in the Netherlands and Belgium. This index uses the relationship between the density of the number of species or individuals and increasing sampling area to determine impacts on soft sediment benthic communities. The ISD index (Reizopoulou and Nicolaidou 2007 in Zaldívar et al. 2008) is a taxonomy free approach developed specifically for use in coastal lagoons based on the distribution of individual benthic invertebrate species among biomass classes.

136. The fish quality element can also be useful in the assessment of the indirect effects of eutrophication. Preliminary work has been undertaken in the North-East Atlantic GIG to develop a tool for fish in transitional waters and this is due for completion in 2011.

137. The key supporting physico-chemical determinands in relation to eutrophication assessment are those related to nutrients and to dissolved oxygen.

138. The approach to the development and use of nutrient standards in ecological status classification was addressed in a workshop organised by the Netherlands in 2007[30], in a workshop on ecological status classification in 2008[31] and through the responses to a questionnaire issued to Member States by the Eutrophication Steering Group in November 2007.

139. While the workshops did not deal specifically with the issues of setting nutrient standards in transitional waters, it is clear that all Member States are deriving type-specific nutrient standards for use in ecological status classification in all water categories. In setting the value of the standard, Member States are faced with a choice of selecting values anywhere on the spectrum between close to the Good/Moderate boundary for either most sensitive or the least sensitive water body in the type. The former more precautionary option has an associated low confidence in the status classification with a high risk of misclassification. However, the use of such values in practice will allow water managers to control the risk

[30] Report on Workshop Setting Nutrient Standards (2007)

[31] http://circa.europa.eu/Public/irc/env/wfd/library?l=/framework_directive/implementation_conventio/ecological_classificatio/classification_2008-05pd/_EN_1.0_&a=d

of deterioration and deliver restoration of the water body. The latter less precautionary option, while providing a status classification with higher associated confidence, is less useful in the control of the risk of deterioration. Exceedances of nutrient standards will not in themselves determine the ecological status of the water body. The role of the supporting physico-chemical determinands and the approach to combining these results with those from the biological quality elements is addressed in the checking procedure detailed in the CIS Guidance on classification.

140. Based on the responses to the questionnaire on nutrient standards, Member States are in the process of setting values for forms of nitrogen (DIN and Total-N) and for phosphorus (DIP and Total-P) for transitional water types as seasonal averages (see compilation of existing nutrient standards, March 2009[32]). The degree of precaution in the derivation of these standards is not yet clear.

141. While some Member States reported values for dissolved oxygen standards in relation to nutrient standards in the response to the nutrient standards questionnaire, none were reported for transitional waters.

5.5. Coastal waters

5.5.1. Assessment methodologies and criteria used for water quality status classification

142. Coastal ecosystems receive nutrients either directly from the sources on the coastal line or from rivers that bring nutrients from their catchments, via sea current transport from distant coastal and marine waters, and from the atmosphere. The increased nutrient loading from anthropogenic sources has caused eutrophication of coastal ecosystems, the symptoms of which are excessive accumulation of phytoplankton biomass, depletion of oxygen in bottom waters, increased frequency of noxious algal blooms, increased turbidity, deterioration of coastal food webs and reduction of biodiversity.

143. Where coastal eutrophication is an international problem it needs to be tackled by co-ordinated national and international efforts. This reality is at the origin of the Regional Seas Conventions, which have started strategies to combat eutrophication already in the late eighties recognising the need for a harmonised way of assessing the eutrophication status of the nations ‘common’ waters. For more detailed information on the work on eutrophication by the regional sea conventions see Annex I Section 2 of this guidance.

144. Yet, procedures for assessing eutrophication are different in the different Conventions but in the last years, in specific after the adoption of the WFD, there has been an effort by all of them to converge their assessments into WFD compatible assessment systems.

145. Differences in the eutrophication assessment are at least partially explained by the characteristics of the coastal ecosystems. The extent to which nutrient loads have an affect on coastal ecosystems depend largely on their physical characteristics: regions of vertical stratification, restricted water exchange and long

[32] http://circa.europa.eu/Public/irc/env/wfd/library?l=/framework_directive/thematic_documents/13_eutrophication&vm

residence time, with low tide and low mixing accumulate more nutrients and thus have a higher risk to eutrophication, while nutrients received in upwelling areas, open coastal areas with high tide or currents are rapidly diluted and transported to the open sea.

146. The Regional Seas Conventions procedures for the assessment of eutrophication typically include the measurement of nutrient enrichment, some measurement of direct effects of nutrient enrichment (phytoplankton chlorophyll a, macrophyte vegetation, and other biological elements) and indirect effects of nutrient enrichment (dissolved oxygen, algal toxins, macrozoobenthos kills, etc.).

147. Phytoplankton growth is generally considered to be limited by light or one of the major nutrients, (N or P), in addition to diatoms which are dependent of silica (Si). The optimal DIN:DIP ratio (N/P-ratio) for phytoplankton growth is 16:1 (based on molar concentrations) and is called the Redfield ratio. Significant deviations from 16 indicate potential nitrogen or phosphorus limitations to phytoplankton primary production, which might affect the biological state of the ecosystem, in particular the phytoplankton biomass, species composition and eventually food web dynamics.

148. While phosphorus is regarded as the main limiting nutrient in freshwaters, marine open waters are primarily nitrogen-limited. However, as nutrients concentrations increase due to anthropogenic loading, on average higher N:P ratios, but also lower Si:N ratios are observed in coastal areas which are likely to have either or both P and Si limitation (e.g. Black Sea (Shtereva et al. 1999); Northern Europe (Jickells 1998, Turner et al. 2003); some Danish coastal areas (Jørgensen 1996), and Dutch coastal waters (de Jonge et al. 2002)). Thus, the eutrophication phenomena in coastal areas are not only determined by the single nutrients concentrations but also and even more relevant are the nutrient ratios. The ratio of dissolved inorganic nitrogen and phosphorus, DIN:DIP is thus a an indicative number for potential nutrient limitations.

149. In coastal waters with many fjords and inlets the level of nutrient concentrations shows the same pattern as in some transitional waters with reference and actual status concentrations increasing going from the open coastal part towards the closed bays. National methods for assessing eutrophication in such sheltered parts of coastal water bodies have been developed based on the assessment of both biological and physico-chemical quality elements.

150. Transparency of the water column in coastal waters can indirectly reflect the nutrient loading/ nutrient status. Transparency can be easily measured, directly by measuring the light attenuation through the water column using light meters or alternatively using a Secchi Disc. Most often Secchi depth is measured as a proxy of transparency. Increased nutrient loading often lead to increases in phytoplankton biomass in the water column, which in turn decreases the transparency. In its turn, changes in transparency will affect the depth of the euphotic zone and thus the depth limits of macrophytes, e.g. sea grasses and macroalgae. Also,

=detailed&sb=Title

because different species have different light requirements changed transparency therefore also affects dominance patterns of the vegetation.

151. Phytoplanktonic primary producers are the first organisms to respond to elevated nutrient concentrations in their environment. Most phytoplankton species respond positively and predictably to nutrient enrichment in all European coastal areas (Olsen et al. 2001). High phytoplankton biomass results in increased amount of organic matter to be degraded after sedimentation by bacteria, meso- and macrofauna, which may lead to hypoxia or anoxia of bottom waters. Long-lasting eutrophication causes recurrent or even permanent oxygen deficit on bottom layers, leading to self-fertilization in coastal areas that may delay recovery of the ecological status when external nutrient inputs are reduced. High biomass of phytoplankton also increases the turbidity.

152. Also, it is generally believed that the frequencies of harmful algal blooms have increased worldwide due to the increased nutrient input and algal toxins are included in some cases in the eutrophication assessments. Although a strong causal relationship has not been established, there are indications that excessive blooms of nuisance algae, such as Phaeocystis spp in at least the southern North Sea, are related to nutrient loads.

153. Planktonic and opportunistic algae (mostly filamentous species) are generally favoured by high nutrient concentrations and tend to cast out seagrasses and perennial algae in eutrophic areas. Their increased biomass shades the perennial vegetation and limits its depth distribution, thereby further accelerating the decline of the perennial vegetation.

154. Changed dominance patterns of the coastal primary producers from benthic macrophytes to planktonic algae or from long-lived seagrasses and macroalgae towards opportunistic algae, as a consequence of increased nutrient concentrations and reduced water transparency, may affect the macrophyte community functional attributes. Moreover, opportunistic algae grow and decompose faster than perennial species and may thereby generate a temporal imbalance between oxygen production and consumption increasing the likelihood of anoxia having negative effects on the ecosystem (benthic invertebrates and fish kills).

155. Marine benthic macrofaunal communities often respond to decreasing oxygen concentrations and different species show different tolerance against hypoxic conditions. Adverse effects of oxygen deficiency may occur through different mechanisms. One is direct suffocation of aerobic organisms. Another mechanism is because oxygen deficiency may alter sediment chemistry, the poisonous element H2S may be released from the sediments and kill the organisms. From this it is to be expected a progressive change in diversity and structure of the benthic community in response to decreasing oxygen levels in the critical range.

5.5.2. Assessment methodologies and criteria used for UWWT and Nitrates Directive designations

156. There is limited information available from Member States regarding the criteria used for the UWWT and Nitrates Directive designations. The information available regarding designating sensitive areas under the UWWTD shows that the designation was based principally on nutrient (DIN and orthophosphate) concentrations and chlorophyll a concentrations.

5.5.3. Impact and pressure criteria used in WFD Article 5 risk assessment

157. The available information for Article 5 related criteria indicates that whenever pressure criteria were reported these were based mainly on the presence of surface point sources (sewage) of nutrients loads and surface water run-off. The impact criteria were based mainly on nutrient concentrations and chlorophyll a (direct effect) and occasionally on dissolved oxygen, macrovegetation, etc (indirect effects).

5.5.4. Examples of development of new WFD-compliant assessment systems

158. New eutrophication assessment methodologies and criteria have been developed in relation to the implementation of the WFD and the intercalibration exercise. The boundaries are set based on definitions of reference criteria and the application of the Boundary Setting Protocol (BSP) to set the high-good and good-moderate boundaries in line with the normative definitions for status class boundaries for each quality specified in the WFD.

159. The Coastal intercalibration exercise was carried out within four Geographical Intercalibration Groups (GIGs): the Baltic Sea, the Black Sea, the Mediterranean Sea and the North-East Atlantic. Common intercalibration types shared by Member States within each GIG were defined for the intercalibration exercise. The eutrophication related biological metrics that were subject to intercalibration in at least some MS coastal types are: benthic invertebrate fauna quality element (all GIGs), metrics and boundaries representing the phytoplankton quality element (chlorophyll a in all GIGs), metrics representing the macroalgae and angiosperms quality elements (Baltic, Mediterranean and NE Atlantic GIGs). There is also work on eutrophication related to supporting physico-chemical determinands including nutrient concentrations, transparency and dissolved oxygen concentrations.

5.6. Marine waters

5.6.1. Existing assessment methodologies and criteria used for water quality status classification

160. Regarding marine waters, several Member States use water quality assessment methodologies and criteria related to eutrophication that have been established in the frame of the Marine Conventions. The existing information on eutrophication assessment (Conventions and national methodologies) shows that, as in the case of rivers and lakes, eutrophication is determined according to criteria including nutrient concentration together with direct effects (chlorophyll and other biological parameters) and indirect effects (dissolved oxygen, organic matter, algal toxins, etc).

161. The Marine Strategy Framework Directive 2008/56/EC[33] is in force since 15 July 2008 and will now require monitoring and assessment tools in relation to the eutrophication-related components of 'good environmental status' (which is defined in Art. 3 (4) and (5) of the Directive, and for which further qualitative descriptors are in Annex I of the Directive) (see below Chapter 5.6.5).

5.6.2. Assessment methodologies and criteria used for UWWT and Nitrates Directive designations

162. There is limited information available from Member States regarding the criteria used for the UWWT and Nitrates Directive designations. The information available regarding designating sensitive areas under the UWWTD shows that the designation was based principally on nutrient (DIN and orthophosphate) concentrations and chlorophyll concentrations.

5.6.3. Impact and pressure criteria used in WFD Article 5 risk assessment

163. The available information for Article 5 related criteria indicates that whenever pressure criteria were reported these were based mainly on the presence of surface point sources (sewage) of nutrients loads and surface water run-off. The impact criteria were based mainly on nutrient concentrations and chlorophyll a (direct effect) and occasionally on dissolved oxygen, macrovegetation, etc (indirect effects).

5.6.4. Examples of development of new WFD-compliant assessment systems

164. Eutrophication related assessment methodologies and criteria are subject to intercalibration for marine waters. The eutrophication related biological metrics that are subject to intercalibration in at least some marine water GIGs are: chlorophyll a, phytoplankton, macroalgae, angiosperms and benthic invertebrates. There is also related work on eutrophication related supporting physico-chemical determinands including nutrient concentrations, transparency and dissolved oxygen concentrations.

165. At present there is limited information available on progress with these developments.

5.6.5. Criteria and standards under the Marine Strategy Framework Directive

166. Criteria and methodological standards are now (in 2009) under development in fulfilment of MSFD Art. 9(3) with a view to achieving a common methodological framework for the determination of 'good environmental status'. This work takes into account the existing methodologies. It starts, as regards eutrophication, with an examination by the JRC of the applicability of environmental quality elements used in the assessment of the quality status of coastal waters under the Water Framework Directive to waters on the seaward side of the limit of those coastal waters, and where applicability might extend, the formulation of the precise boundary conditions for that applicability (e.g. water depth, light conditions, habitat types). The eutrophication-related quality elements of the MSFD are mainly Annex I descriptor (5): "*Human-induced*

---

[33] OJ L 164 of 25 June 2008, p. 19

eutrophication is minimised, especially adverse effects thereof, such as losses in biodiversity, ecosystem degradation, harmful algae blooms and oxygen deficiency in bottom waters", but as work on the criteria and methodological standards develops for all descriptors, the lateral relations with those other descriptors (e.g. "*all elements of marine food webs, (...) occur at normal abundance and diversity (...)*") will have to be evaluated as some of them may also include elements that are strongly influenced by eutrophication.

6. HARMONISATION OF CLASSIFICATION CRITERIA

6.1. Use of nutrient standards and best practice in deriving them

167. Nutrients are supporting physico-chemical quality elements in the assessment of ecological status. According to the normative definitions in Annex V WFD "nutrient concentrations do not exceed the levels established so as to ensure the functioning of the ecosystem and the achievement of the values specified […] for the biological quality elements". Figure 6 (as well as the explanations in Annex 1.1.6) provides an interpretation of how to apply supporting physico-chemical quality elements in ecological status assessment. Nutrient standards – as will be explained later – play an important role in the assessment.

168. In the context of preparing this guidance document a questionnaire had been sent to the Member States to collect information on the definition of nutrient standards, the methodologies used to derive them, as well as information on the legal status of these standards. At the time of compilation some of the standards were still under development and did not have a formal status yet. The compilation provides an overview on nutrient standards in the Member States in March 2009[34].

169. In the assessment of eutrophication, nutrients particularly support the biological quality assessments of phytoplankton, macrophytes, macroalgae and phytobenthos. At the boundary between good and moderate status and below nutrients will provide important information on the status of eutrophication, which is one of the pieces of basic information needed for setting up the programme of measures.

170. Different water categories have different sensitivities to nutrients: the same nutrient concentration does not necessarily have the same effect e.g. in small rivers versus lakes, or in freshwaters versus coastal and/or marine waters. Therefore, when setting nutrient standards it is important to consider the water category and where necessary the surface water type.

171. In setting nutrient standards one should always consider the objectives and keep in mind that the nutrient parameters are part of a supporting quality element and consequently that standards for this parameter are targets to strive for. In general, the primary objective of the WFD is good ecological status and

http://eur-lex.europa.eu/LexUriServ/LexUriServ.do?uri=OJ:L:2008:164:0019:0040:EN:PDF

[34] http://circa.europa.eu/Public/irc/env/wfd/library?l=/framework_directive/thematic_documents/13_eutrophication&vm=detailed&sb=Title

thus can not do without an assessment of the biological quality elements. The process of deriving appropriate nutrient standards should ideally involve:

(a) having a clear view of what good status for biology/ecology looks like;
(b) having an understanding of the relationship between nutrients and the biology/ecology (and the variability in this);
(c) deciding on the best available techniques for deriving the standards and on the appropriate level of precaution and summary statistic to be used in defining the standard;
(d) having sufficient and reliable monitoring data for deriving and determining compliance with the standards.

Methodologies for setting nutrient standards

172. Discussions at a 2007 workshop on nutrient standards in Zandvoort (NL)[35] indicated that many differences exist in the standards derived and the methodologies/assumptions to derive those standards. As many countries share river basins districts and marine areas, there is a need for harmonisation of methods and assumptions at the European level, possibly in the same way as is done for ecological standards within the context of the WFD. Standards will not necessarily be the same in the different Member States, because they depend on the functioning of the ecosystems and differences across ecoregions and types.

173. In any case, setting of nutrient standards has to be linked with setting of biological boundaries for ecological status assessment. This can be an iterative process (see also Figure 8 in Annex 1.1.6). It should be kept in mind that a clear relation between biology and nutrients is less obvious when the status becomes less than good.

Toolbox to derive nutrient standards

174. **Use of empirical data:** If monitoring data from the past are available for both biological quality and nutrient concentrations, standards for nutrients can be set using these data. The most straight forward way is using a certain percentile of a distribution of nutrient concentrations of sites classified as Good Status for one or more biological quality element or parameters. This method is very simple and defendable if a sufficient low percentile is selected in order to ensure the achievement of the biological values. Exclusion of sites where other environmental factors than nutrients may hamper the biological quality is recommended. A disadvantage is that the relationship between biology and nutrient concentrations is not tested. Such a test can show the reliability and the type of the relationship.

[35] Final report available at:
http://circa.europa.eu/Public/irc/env/wfd/library?l=/framework_directive/implementation_conventio/standards_zandvoort&vm=detailed&sb=Title

175. A more complex method is the **application of regression analysis**. In its most simple form, a linear and one factor relationship between biology and nutrients is assumed. By proper regression analysis and by plotting, the assumptions on the relationship between nutrients and biology, and the goodness of fit can be investigated. An appropriate statistical value derived from the regression analysis can be used for setting the nutrient standards. When the predicted nutrient concentration at G/M boundary value derived from a best fit relationship, the G/M nutrients concentration will result in about 50 % achievement of the biological value. By using the percentile distribution of the errors of the linear regression, the level of confidence of achievement of the biological value can be enhanced to another desired level (reference).

176. The most advanced method is **using statistical techniques** which relate nutrient concentrations to more than one environmental factor or may allow different types of relationships, e.g. non-linear. This method can be recommended in cases where it is clear that nutrients are not the only factor determining the biological quality, or where relationships are clearly non-linear. The disadvantage is that the development of standards is more difficult to understand.

177. The **level of misclassification** between biological quality elements and nutrients can also be used for setting the G/M boundary for nutrients. This method is more or less iterative and gives direct insight in the consequences of the defined nutrient standard for classification of sites. The procedure starts with making a set of potential nutrient standards in small discrete steps, which can be used for making a set of classifications for each potential nutrient standard for both biological quality elements and nutrients. For each site the classification results have four possible combinations:

1) biological quality elements are good and nutrients are not good,
2) biological quality elements are good and nutrients are good,
3) biological quality elements are not good and nutrients are good, and
4) biological quality elements are not good and nutrients are not good.

178. If nutrients are related with the biological quality elements, then the fraction of these four classification combinations are shifting over the potential nutrient standard gradient. If the discrete steps are small enough, the potential standard can be plotted against the distribution of the four types of classification results. The standard can now be defined as a contribution of one of these four types of classification combinations. For example, the nutrient concentration where e.g. 10 % of the classification results of the biological quality elements are not good and nutrients are not good may be defined as the standard. By using this definition the tested biological good status value is in about 90 % of the cases ensured by achievement of the nutrient standard.

179. The methods based on empirical data will not always be applicable for the River Basin Management Plan 2009 for all types of water, because monitoring data are not available or knowledge about ecological

relationships is not sufficient or reliable. This can be a reason to use other means of setting nutrient standards, e.g. using historical data or non-empirical models in combination with expert judgement**.**

Expert judgement methods:

180. **Hindcasting** is one means of estimating background levels. Natural background values for rivers can be deduced from models, assuming pristine conditions (e.g. forested catchments) and not a certain time period, because the latter reflects different status of eutrophication processes in different areas. Model data should be validated by comparison with values from remote areas and historical (palaeo-ecological) findings. Hindcast values are not standards but can be used with expert judgement to decide on standards.

181. Natural background concentrations in the different coastal areas have to be estimated from **modelling** or scientifically based assumptions because of the lack of pristine coastal areas. Also, in some areas there is a large exchange between coastal water and the open sea while in others it is very restricted. This has to be reflected in the decision on background levels. In setting nutrient standards (good/moderate) the natural variability should be considered and deviation from background can be used as a method of deriving standards; e.g. for coastal waters OSPAR, HELCOM and the Baltic GIG chose an acceptable deviation of 50 % above natural background, because this range reflects moderate deviation and variability (also recommended by CIS guidance documents). The deduction of natural background concentrations should be based on reproducible scientific methods allowing a harmonisation for larger areas.

Issues to consider in deriving and applying nutrient standards

182. Nutrient standards are in principle type-specific, and within the type waters will slightly differ in their sensitivity for eutrophication. These sensitivity differences are one of the sources of **potential misclassification**. The standards can be chosen to be protective for the eutrophication sensitive bodies or on the other hand for the more tolerant bodies. This delicate choice is largely an interpretation of the WFD, Annex V, where good status of nutrients is defined. In principle, the nutrient standards developed for the type should protect most water bodies from being or becoming eutrophied. However, if the standard is set to protect the most sensitive water body this will lead to most other water bodies in that type failing the standard. Furthermore, in some cases ecological knowledge or data is not sufficient to separate the effect of nutrient concentration on biological quality from those that are not related to nutrient concentration. If other factors are negatively affecting the quality of the sites involved in the analysis, automatically the standards are getting more precautionary than necessary. In addition, there may be delayed recovery effects from measures taken, because the trajectory of recovery may be different than that of deterioration – a so called hysteresis effect (Scheffer et al. 2001). Long-term trends in the maximum depth of eelgrass in Danish waters have shown an almost continuous decline, also in recent years despite strong efforts to reduce nutrient inputs from land. Examining the trajectory of eelgrass depth distribution versus the main pressure, nitrogen inputs, clearly indicates a lack of recovery. The causal explanation for this is still unclear, but the mechanisms could

be a combination of lag time in the response, a shifting baseline and a hysteresis effect where recovery can be anticipated only once the nitrogen input falls below an unknown threshold value.

183. Therefore, for an individual water body, a nutrient standard set to prevent deterioration may be ineffective at securing restoration. Consequently, choices about the purpose of the standard and the degree of precaution in setting a nutrient value will affect the likelihood of mismatches in compliance for nutrients and relevant biological elements (see chapter 6.2 and section 1.1.6 of Annex 1 on checking procedures for guidance on dealing with mismatches).

184. In conclusion, defining standards for nutrients is a real challenge where legal wordings are translated into numbers and, even more challenging, with uncertainties about dose-response relationships between biological and nutrient quality. As a minimum requirement for the first River Basin Management Plan, a transparent description of the method for deriving the standards is recommended.

185. To account for **spatial variation** within types, within water bodies or within grouped water bodies the use of water body-specific versus type-specific standards could be recommendable. This could be particularly relevant in lakes and transitional waters. In rivers, nutrient standards may be developed for different sections of the stream due to the different characteristics. Nutrient standards developed for upstream sections will not necessarily ensure that good ecological status is also achieved in the downstream section, but the measures taken in the River Basin Management Plan may need to consider reducing nutrient inputs from upstream sources. Lack of knowledge exists especially on background levels in large rivers, as there are not many good reference sites.

186. In addition, it is important to take drifting baselines into account that can be an effect of **climate change**. A Guidance Document is currently being developed under the Common Implementation Strategy on how to include effects of climate change in river basin management plans[36].

6.2. Combining information from different quality elements in the assessment of ecological status

Use of nutrient standards in classification and how to deal with mismatches between nutrients and biological quality elements

187. According to the CIS Classification Guidance, a water body may be classified as less than good ecological status under the WFD, because values for physico-chemical quality elements (in the context of eutrophication, notably nutrients) exceed levels established so as to ensure the functioning of the ecosystem and the achievement of the biological quality required for good status (compare Figure 6 and further explanations given in section 1.1.6 in Annex 1). Scientific understanding of the causal link between the levels of physico-chemical quality elements in a water body and the condition of the biological quality

elements is incomplete. Chapter 4 of the CIS Classification Guidance proposes a checking procedure designed to ensure that the type-specific values established for the general physico-chemical quality elements are no more or no less stringent than required by the WFD. The checking procedures apply only in relation to values for the good-moderate status/potential boundaries and where Member States are confident that the mismatch between the monitoring results for the biological and general physico-chemical quality elements does not occur as a result of uncertain monitoring. This will usually require evidence that there is a consistent mismatch from a significant number of water bodies in the type.[37] Accordingly it may be appropriate for Member States to relax the nutrient standards established for a type, subject to specific provisions (see Figure 8 of Annex 1.1.6), if there is evidence from a significant number of water bodies that the nutrient status is less than good but the biological status is good. The opposite situation, where the biology is not good and the supporting elements are good, may follow a similar procedure to determine whether the type-specific nutrient standard is sufficiently tight. It should be noted that adjustments to type-specific nutrient levels will reduce the extent of mismatches but will not eliminate them. This is because the characteristics of water bodies within a type are never identical.

188. In some cases it may be more appropriate to revise the status of an individual water body to good if (a) the nutrients are less than good, (b) the biology complies and the biological assessment is confident and precise, and (c) delayed impacts are unlikely, rather than revising the type-specific nutrient level.

189. Before revising the status of a water body and/or the nutrient standards, it is considered important to undertake checks to confirm the absence of biological impacts (including delayed impacts) and of upward trends in nutrient concentrations. As regards the absence of biological impacts, such checks should be done using biological assessment methods that are fully WFD-compliant[38].

Selection of biological quality elements

190. Chapter 4.1 to 4.3 explain the general concept of using the "most sensitive quality element(s)". For assessing eutrophication, quite often several biological quality elements may be suitable for this assessment. Whilst it is inappropriate to take into account elements that are not sensitive to nutrients, there may be a number of quality elements which are and there is value in a rounded assessment of ecological data. The indicative checklists in Annex 2 suggest that more than a minimalist approach is needed, and as recognised in Chapter 4.1, it is not easy to interpret the meaning of “most sensitive” as there are pros and cons of different plant/algal indicators.

---

[36] Interim title: How to adapt to climate change with regard to water issues and EU water legislation

[37] CIS Guidance Doc. No. 13 Overall approach to the classification of ecological status and ecological potential, p. 14

[38] The ECOSTAT Classification Workshop (March 2008) recommended to understand the Checking Procedure in this way.

191. The relevant sub-sections of Chapter 5 on the development of WFD-compliant assessment systems provide further information on available classification methods. Further information is also provided in the report of the ECOSTAT Classification Workshop[39].

Effects of variability in space and in time relevant to classification

192. According to the CIS Guidance Document[40] on delineation of water bodies "a discrete element of surface water should not contain significant elements of different status. A water body must be capable of being assigned to a single ecological status class with sufficient confidence and precision through the Directive's monitoring programmes."

193. Nonetheless, spatial variability can be found within types, within water bodies and within grouped water bodies. A range of different approaches is currently being considered by Member States on how to deal with such variability. These include taking the average status or the worst status, considering the extension of the variability, e.g. as a percentage of the water body that is affected. Spatial criteria need to be developed for classification. A combination of criteria based on lateral extension, water depth and residence time of a water body and an even distribution of sampling sites have been suggested as a useful approach, reflecting the fact that water body sizes are variable depending on the way water bodies have been delineated. Sampling in the surrounding of specified types is often recommended for detection of exchanges with adjacent areas by currents. Sampling sites should be adequately distributed over the water body if no steep gradients are observed. In such areas, a certain percentage (e.g. 10 % of the maximum length of the water body) could be used as the distance between stations. Water bodies should be delineated such that they are more or less homogeneous, thereby reducing variability within the water body as much as possible. If it is not possible to further downsize a water body, e.g. in marine areas where there are steep gradients at frontal systems[63], a higher resolution of sampling sites is required. These must be appropriately placed considerating the relevant physical parameters, such as salinity, temperature and current speed.

194. Grouping of water bodies is important to make best use of available monitoring data and consider exchange of water masses between adjacent areas. The majority of Member States are using grouping of water bodies for classification purposes. The same principles mentioned above apply for grouped water bodies. Grouping may increase variability. This needs to be balanced with the confidence in the monitoring results. Grouping of water bodies of the same type and the same pressure does not automatically mean that all water bodies have the same ecological status. Grouping of water bodies is generally quite useful for assessing ecological status due to diffuse pressures.

[40] CIS Guidance Document No. 2: Identification of Water Bodies, p. 9

195. In coastal waters, spatial gradients of standards, recent concentrations and their difference may also be related to salinity gradients or upwelling, reflecting dominant mixing and by this distance from main river sources, river plume extensions and dilution by open sea water. Furthermore, mixing diagrams can be used for comparisons/assessments, smoothing regional variability caused by hydrodynamics and identifying outliers for re-investigations. Nutrient gradients from shore to offshore areas are often combined with salinity gradients if dominant nutrient sources are river freshwater discharges. If such gradients occur, they should also be reflected by respective gradients of nutrient standards, reflecting mixing (of end-members).

Accounting for uncertainty in eutrophication assessment

196. Uncertainty in classification, particularly for water bodies close to the good-moderate boundary, is an important issue for river basin management planning. Information on confidence and precision of classifications is important for informing decisions about the appropriate follow up action. To start with the acceptable level of confidence and precision should be decided beforehand, and the sampling/monitoring should be appropriately designed (sampling sites, frequency, sampling and analysis methods, etc.) to be able to reliably classify the water bodies. Depending on the level of confidence, this information can inform, as appropriate, decisions on exemptions[41], prioritising water bodies for improvement, and/or prioritising further monitoring and investigation to improve confidence. Being clear on the level of confidence achieved and on the follow up action where confidence is insufficient to justify expensive measures is considered important: Appropriate follow-up action in such cases includes (a) further targeted monitoring and assessment to try to improve confidence and to assess the risk of deterioration, and (b) action to assess the risk of, and prevent deterioration.

197. A lack of monitoring should not be an excuse for inaction although it is recognised that in the first cycle of river basin planning, when the new classification tools and monitoring plans have not been in place for long, uncertainties will be greater than in subsequent cycles. Investigative monitoring should be introduced as a priority, where needed, to improve the evidence base and inform decisions on programmes of measures.

198. In water bodies where there is insufficient confidence in the assessment of eutrophication, the appropriate action will generally be to undertake further monitoring and investigation to improve confidence, rather than to move to immediate control measures under the WFD or through "read across" to UWWT or

---

[41] See also Section 6 of the Policy Paper "Exemptions to the environmental objectives under the Water Framework Directive; Article 4.4 (extension of deadlines), 4.5 (less stringent objectives) and 4.6 (temporary deterioration)"

http://circa.europa.eu/Members/irc/env/wfd/library?l=/framework_directive/thematic_documents/environmental_objectives/final_policy_44-45-46/_EN_1.0_&a=d

Nitrates Directive designations. This may apply when, for example, the nutrients appear less than good but we are not confident that the relevant biological quality elements are less than good. Confidence should then be improved in the biological assessments and, where necessary, the nutrient thresholds should be reviewed. In any case, Member States can not wait until all symptoms of eutrophication are present before taking action. As set out in paragraph 46 in Chapter 3.6, if sufficient certainty is attained that the water body is likely to become eutrophic in the near future, then protective measures need to be undertaken (application of the precautionary principle).

6.3. The river basin perspective: linking results of inland waters with transitional and coastal waters

199. The assessment of ecological status in upstream and downstream water bodies is independent from another, but in terms of management, good ecological status in upstream water bodies does not guarantee also reaching the environmental objectives downstream. It may be necessary to undertake measures in upstream areas to reduce nutrient inputs and transport downstream.

200. The management of nutrients in upstream areas should therefore take into account problems with nutrients downstream, for example in lakes/reservoirs connected to a river, rivers flowing into coastal or marine waters. Nutrients may also be transported between different coastal waters or marine areas due to currents or upwelling, and this needs to be taken into account when developing appropriate measures to mitigate eutrophication. These measures need to be coordinated at the river basin scale as well as between coastal and marine areas if necessary.

201. The following example from the Rhine River Basin District illustrates how river basin management can appropriately address measures to mitigate eutrophication at the basin scale. Similar examples are also available from other river basins, e.g. the Elbe River.

6.4. WFD and marine conventions: coherence of current eutrophication assessment schemes

202. Marine eutrophication has been addressed by marine conventions in Europe since many years. A considerable body of expertise has been generated for the Baltic Sea (HELCOM) and the North-East Atlantic (OSPAR), but also in the Mediterranean Sea (MED POL) and the Black Sea (Bucharest Convention) activities to address eutrophication in a common way have started. The Conventions' eutrophication combating policies (OSPAR: Eutrophication Strategy, 1998, revised 2003; HELCOM: Ministerial Declaration 1988, and recently the Baltic Sea Action Plan 2007) have required them to undertake periodic assessments. In this process, the participating countries have considered a need to ensure an approach that would be consistent with their obligations under EU instruments, most notably the WFD, but also the Marine Strategy Framework Directive.

Reduction of nitrogen discharges: The Example of the Rhine River Basin District

In the process of the production of the first river basin management plan, the Co-ordinating Committee Rhine agreed on a discharge reduction target via the river Rhine into the marine environment for nitrogen of approximately 15-20 % (reference years: 2004/2005/2006). The reduction is considered to be necessary in order to achieve a good ecological status in the coastal waters and the Wadden Sea of the international river basin district of the Rhine.

Within the Co-ordinating Committee Rhine representatives of the Rhine riparian states (Austria, Liechtenstein, Germany, France, Luxembourg, Belgium and the Netherlands), the European Community, for Germany also representatives of the federal states and for Belgium representatives of the Walloon region, are responsible for the international co-ordination of the implementation of the WFD in the international river basin district Rhine. Switzerland declared to support the EC-Member States in the co-ordination of the work. Italy, that covers only a very little part of the Rhine district, agrees with the approach.

Considering the fact that the coastal waters and the Wadden Sea are part of the international Rhine district, an integrated approach respecting upstream-downstream relations is needed. Because the coastal waters (including the Wadden Sea) as part of the international river basin district Rhine are situated in the Dutch territory only, the Co-ordinating Committee Rhine asked the Netherlands to take the initiative for estimating the potential riverine discharge reduction of nitrogen in the fresh water part of the Rhine district in order to achieve the good ecological status in its coastal waters by 2015.

Building on the intercalibrated parameter bloom frequency of Phaeocystis and the partly intercalibrated parameter chlorophyll a, it became clear that especially in the Wadden Sea the good ecological status is not achieved in the present situation. For the coastal and transitional waters the Netherlands have developed objectives for nitrogen concentrations (averaged values of Dissolved Inorganic Nitrogen) that ensures the achievement of the quality element phytoplankton. This objective depends on salinity, and is calculated to a standard at a salinity of 30. Subsequently, this objective is calculated to a concentration in large fresh water rivers. Based on this objective the maximum allowed discharge of nitrogen to the coastal waters and the Wadden Sea is calculated and compared with the current riverine discharge of nitrogen.

The Co-ordinating Committee Rhine did not directly use the Dutch objectives for Nitrogen in terms of concentrations, but accepted it as an indicator of the direction for the restoration measures and as a tool for evaluation of the measures taken. The parties involved will continue to implement their programme of measures in order to reduce the nitrogen load. The ‘polluter pays principle’ and the present EC-policies are put into practice. In addition to this, it has to be kept in mind that other sources than the River Rhine contribute significantly to the nitrogen concentrations in coastal waters as well, e.g. other river basins and atmospheric deposition. It is assumed that the other North Sea riparian states also achieve a reduction of nitrogen discharges.

For the sake of completeness, it is stressed that in line with the WFD the assessment of biological status is limited to the 1 mile zone. Therefore there can be some differences with the assessments made under OSPAR, because OSPAR takes into account the whole North Sea and its delineation of "non-problem areas" and "problem areas" with regard to eutrophication is not fixed to the WFD subdivision of coastal water bodies. In the near future, the Marine Strategy Framework Directive 2008/56/EC may play a role for eutrophication sensitive parameters of coastal states' marine waters (territorial waters and exclusive economic zones, the part of the sea between the territorial water (up to 12 nautical miles) and a max. of 200 nm).

203. In the North-East Atlantic, a first application of the OSPAR eutrophication assessment procedure was undertaken by the OSPAR countries of their waters in 2003 and, with a procedure slightly revised in 2005, repeated in 2008[42]. The background levels used in 2003 had mainly been based on expert judgement. In the 2008 assessment process, a number of OSPAR countries reviewed background levels based on more recent knowledge. One important driver for the review has been the need to harmonise the assessment methods with the Water Framework Directive in transitional and coastal waters. The review of background levels has led in some cases to the update and change of assessment levels used earlier. The 2008 OSPAR assessment report demonstrates that, although the OSPAR procedure aims to result in a comparable assessment throughout the Convention area, there are significant differences in the national application of the OSPAR procedure by the OSPAR countries, in particular in the choice of assessment parameters and assessment criteria (see report Table 3.2 of the 2008 report[42]). These differences in the choice of parameters and assessment methods imply that the OSPAR and WFD assessment outcomes for coastal and transitional waters are at present not fully interchangeable, and that there is scope for further work to make them fit together better[43].

204. HELCOM has developed a common, harmonised Eutrophication Assessment Tool, called HEAT. This assessment tool is in full accordance with the requirements for ecological status assessment of WFD and the relevant guidelines under the CIS process. It is targeted to the assessment of eutrophication in transitional, coastal and open marine areas.

205. HEAT is a multi-metric indicator based assessment method which is based on the use of reference conditions and defining an acceptable deviation from them for defining the boundary between good and moderate status. The assessment results are calculated as Ecological Quality Ratio and presented as one of five classes (high, good, moderate, bad, and poor). HEAT comprises two assessment steps. The first step is an interim assessment for specific selected indicators and/or biological quality elements (such as phytoplankton, submerged aquatic flora, benthic fauna). By a second step, these individual assessment results are merged into an overall classification using the "one out, all out" principle as laid out in the WFD. HEAT will be further improved in order to meet the requirements of the Baltic Sea Action Plan and eutrophication relevant EC directives such as the WFD, Habitats Directive and the MSFD.

206. HEAT has successfully been tested for coastal and marine waters along the Baltic Sea.

[43] This issue is still on the agenda of the OSPAR Eutrophication Committee.

7. MONITORING – GUIDANCE AND INTEGRATION OF REQUIREMENTS STEMMING FROM VARIOUS OBLIGATIONS

7.1. Introduction

207. The aim of this chapter is to:

- specify further which aspects in the existing Guidance on Monitoring are relevant for eutrophication assessment;
- provide guidance on how to harmonise the monitoring in a way to satisfy the requirements in the different directives and regional conventions dealing with eutrophication.

208. As Section 1.1 of this document indicates, this guidance on monitoring has to be firmly based on the methodological concept of the Water Framework Directive and to explore thereafter to what extent this methodology can be used in the context of other directives and policies. For the Water Framework Directive monitoring networks have to be designed "so as to provide a coherent and comprehensive overview of ecological and chemical status within each river basin and shall permit classification of water bodies into five classes consistent with the normative definitions in section 1.2"[44]. Table 2 (section 3.2) gives a general overview of the requirements of EC Directives and regional conventions regarding the assessment and monitoring of eutrophication.

209. Assessing eutrophication in specific water body types may change specific monitoring requirements. The implementation activities of the Water Framework Directive have already addressed monitoring needs to a certain degree (e.g. Monitoring guidance document[45]); however the spatial and temporal monitoring requirements may differ for critical variables when eutrophication issues are specifically focused on, and the requirements of specific water types (e.g. to capture the necessary seasonality and flow dependency in nutrients and of nutrient loads, chlorophyll and oxygen) are considered.

210. Member States had to establish their monitoring programmes for the Water Framework Directive by 22 December 2006. Member States will have integrated monitoring programmes that provide the data and information which will meet the needs of all the relevant policies, in this case, all those that deal with eutrophication. For example, where possible, the same monitoring stations, quality elements and sampling frequencies should be used for Water Framework Directive assessments and also for any assessment required for other policies e.g. OSPAR.

---

[44] Article 8 WFD

[45] Guidance Document No. 7: Monitoring under the Water Framework Directive

7.2. Guidance documents

211. Monitoring guidance documents or guidelines have been developed for most of the policy drivers dealing with eutrophication. These have been used in this document and include:

- Common Implementation Strategy Guidance Document No. 7: Monitoring under the Water Framework Directive, 2003.
- Common Implementation Strategy Guidance Document No. 13: Overall approach to the classification of ecological status and ecological potential, 2003.
- Urban Waste Water Treatment Directive (91/271/EEC). There is no EU guidance on how the monitoring of water status/quality[46] should be undertaken. There may be national examples available.
- European Commission. Draft guidelines for the monitoring required under the Nitrates Directive (91/676/EEC), March 2003[47].
- HELCOM: Monitoring and Assessment Strategy[48] and Manual for Marine Monitoring in the COMBINE Programme of HELCOM[49]
- OSPAR (2005): Eutrophication Monitoring Programme, OSPAR Agreement 2005-04.
- UNEP-MAP (2003): Eutrophication monitoring strategy of MEDPOL. UNEP(DEC)/MED WG.231/14, 30 April 2003.

212. The European Marine Monitoring and Assessment (EMMA) group formed under the European Commission's *"Thematic Strategy for the Protection and Conservation of the European Marine Environment"* has worked on improving indicators related to eutrophication. The implications of the Marine Strategy Framework Directive 2008/56/EC[50] (MSFD; the Directive that is the legal instrument under this Strategy) for marine eutrophication assessment are being elaborated in the context of the preparation of 'criteria and methodological standards' that relate to the MSFD Annex I descriptor (5) that "human-induced eutrophication is minimised, especially adverse effects thereof, such as losses in biodiversity, ecosystem degradation, harmful algae blooms and oxygen deficiency in bottom waters." A clear synergy with the existing eutrophication assessment framework is necessary.

213. Also the revision of HELCOM monitoring programmes is underway (MONPRO project). The aim of the revision is to have a monitoring and assessment framework, which is in line with obligations stemming

from various regulations (e.g. WFD, UWWTD, Nitrates Directive) and which foresees the demands from the Thematic Strategy for the Protection and Conservation of the European Marine Environment

7.3. Water categories and geographic coverage

214. The Water Framework Directive covers all waters, including inland waters (surface water and groundwater) and transitional and coastal waters up to one sea mile (in terms of monitoring ecological status and hence eutrophication – and for the chemical status also territorial waters which may extend up to 12 sea miles) from the territorial baseline of a Member State, independent of the size and the characteristics[51.] These waters (water bodies) will need to be included in surveillance, operational or investigative monitoring programmes. Monitoring of surface freshwaters, estuarine, coastal and marine waters is also required for the Nitrates Directive. The geographic extent of marine waters included in the requirements of the Urban Waste Water Treatment Directive is not clear: Annex II (criteria for the identification of sensitive and less sensitive areas) includes estuaries and coastal waters in terms of sensitive areas, whereas marine water bodies are included in the criteria for less sensitive areas. Coastal waters are defined as "waters outside the low-water line or the outer limit of an estuary"[52].

215. Monitoring required for Marine Conventions is generally for assessing the state[53] of transitional, coastal and open marine waters.

216. Operational monitoring for the Water Framework Directive will be carried out for all those water bodies identified as being at risk of failing their environmental objectives (for example, achievement of good ecological status or good ecological potential, or no deterioration of status). Where this risk is due to nutrient enrichment and water bodies have been assessed as eutrophic under other policies, these water bodies will be, or be part of, a sensitive area/water body, or a polluted water or a problem area, respectively, under the Urban Waste Water Treatment Directive, Nitrates Directive and OSPAR Strategy to Combat Eutrophication (in waters of overlapping jurisdiction) (see section 3.6). For these water bodies, operational monitoring will potentially help assess the effectiveness of the measures introduced under those other polices, and help to decide what further measures may be needed. In waters/water bodies not previously identified as eutrophic under the other policies but have been identified by the Annex II risk assessments as being at risk due to nutrient enrichment, operational monitoring could be the basis for deciding a water body is "eutrophic", as part of its status assessment. Where there is a risk of future deterioration of status (due to increasing nutrient pressures), operational monitoring could also contribute to the assessments needed as to whether waters "may become eutrophic" under the other policies. In short, it is anticipated that, depending on the

---

51 Articles 2 (1), (2) and (3)

52 Article 2.13

53 Some Marine Conventions also require the monitoring of rivers for the estimation of loads entering the marine environment.

commonalities between other aspects of monitoring e.g. geographic jurisdiction, quality elements and frequency, integrated monitoring programmes could be established that will provide the data and information required for all of the relevant policies dealing with eutrophication.

217. Surveillance monitoring for the Water Framework Directive must be carried out on a sufficient number of surface water bodies to provide an assessment of the overall surface water status within each catchment or sub-catchment within the river basin district[54]. This implies that water bodies across a range of statuses will be included and in particular those identified as not being at risk of failing their environmental objectives (good and high status water bodies, no risk of deterioration of status). Where Member States have identified sensitive and less sensitive areas for the Urban Waste Water Treatment Directive and designated vulnerable zones for the Nitrates Directive, there is a requirement for Member States to review the identification of sensitive areas[55] and nitrate vulnerable zone(s)[56] of their surface waters respectively, at least every four years. Assuming that this would involve some monitoring[57] then it is likely that this would include those water bodies not previously identified as being sensitive/vulnerable or polluted. Where relevant, in terms of overlapping geographic jurisdiction of the different policies, it would be expected that the results from surveillance monitoring (which will include parameters indicative of the quality elements relevant to eutrophication) could contribute to the review and assessment of non-eutrophic, non-polluted waters and non-problem areas (the latter as identified in the OSPAR Comprehensive Procedure) (see Table 5, section 3.6). Results from surveillance monitoring might also contribute to the establishment of the extent of nitrate pollution from agricultural sources in those countries that have established and applied action programmes throughout their national territory for the Nitrates Directive[58]. In addition, investigative monitoring might need to be carried out to get a fuller picture of existing nutrient sources and their impacts on the water bodies.

---

54 Annex V.1.3.1

55 For the UWWTD, Member States do not have to identify sensitive areas if they have applied Article 5.8 of Directive 91/271/EEC.

56 For the Nitrates Directive, monitoring requirements depend on whether Member States establish and apply action programmes throughout their national territory (Article 3.5) or identify and designate specific vulnerable zones (Article 3.1 and 3.2). Monitoring for the purpose of designating and revising the designation of vulnerable zones (Article 6) does not apply to Member States who establish and apply action programmes throughout their national territory. In the latter case, Member States must monitor their surface waters and groundwater at selected monitoring points to establish the extent of nitrate pollution in their waters from agricultural sources (Article 5.6 first sentence). Those Member States who have designated vulnerable zones must monitor to assess the effectiveness of action programmes (Article 5.6 first sentence), and monitor the nitrate concentration in freshwaters over a period of a year (every 4 years or, under defined circumstances, every 8 years) and to review (every 4 years) the eutrophic state of their fresh surface waters, estuarial and coastal waters (Article 6).

57 Non statutory draft guidelines for the monitoring required under the Nitrates Directive (91/676/EEC), 2003

58 Article 3.5

7.4. Selection of monitoring sites

218. CIS Guidance No. 7 gives guidance on the selection of monitoring sites for inclusion in surveillance and operational monitoring for the Water Framework Directive. There is no EU guidance on the number of monitoring stations that might be appropriate for monitoring the quality of receiving waters under the Urban Waste Water Treatment Directive. The informal guidance for monitoring under the Nitrates Directive suggests different station densities for rivers and standing waters, with an increased density inside and at the borders of polluted waters, and waters deemed to be at risk of eutrophication, and less in areas with low nutrient pressures.

219. For the OSPAR Eutrophication Monitoring Programme, the spatial coverage of stations should be greatest in problem and potential problem areas, and least in non-problem areas. In all cases the optimum station locations are to be determined by each Contracting Party. The HELCOM Combine Manual (for monitoring) indicates that mapping stations and high-frequency stations are required. Mapping stations are used to map the winter pool of nutrients, oxygen/hydrogen sulphide in bottom waters and zoobenthos. High frequency stations are used for pelagic variables and for monitoring water exchange between the various basins in the Baltic Sea, and between the Baltic Sea and the North Sea. MEDPOL's eutrophication monitoring strategy[59] requires Contracting Parties to select representative water bodies in marine waters in order to detect changes over a selected period (e.g. 10 years), and in relation to off-shore fish farms and coastal lagoons.

7.5. Selection of quality elements/parameters to be measured

220. Annex V, Table 1.1 in the Water Framework Directive, explicitly defines the quality elements that must be used for the assessment of ecological status (e.g. composition and abundance of phytoplankton). Quality elements include biological elements and elements supporting the biological elements. These supporting elements are in two categories: 'hydromorphological' and 'chemical and physicochemical'. CIS Guidance No. 7 gives as to which quality elements and parameters indicative of the quality elements should be selected for each type of monitoring[60]. In addition the key features of each element are described with an indication of which pressures the elements respond to e.g. nutrient enrichment[61]. Further guidance on the meaning of parameters, quality elements and groups of quality elements is given in the guidance on the overall approach to the classification of ecological status and ecological potential[62]. The relevant sections in Chapter 5 give examples of the most widely used indicators.

59 UNEP(DEC)/MED WG.231/14 30 April 2003

60 Guidance document No. 7, Monitoring under the Water Framework Directive, pages 21 and 24

61 Guidance document No. 7, Monitoring under the Water Framework Directive, pages 35 to 73

62 Guidance document No. 13, Overall approach to the Classification of Ecological Status and Ecological Potential, Paragraph 3.3

221. Guidance on the selection of quality elements/parameters to be measured for the purpose of the OSPAR, HELCOM and MEDPOL is also given.

222. At the quality element level there are many similarities between the different policies, particularly for the biological and physicochemical quality elements that are considered to be indicative of eutrophication. However, there are some differences in terms of the recommended measured parameters indicative of the quality elements. More significantly, surveillance and operational monitoring for the Water Framework Directive requires the monitoring for hydromorphological quality elements: there is no such explicit requirement in the other relevant policy drivers even though some of these elements are included as supporting environmental factors in the conceptual framework for eutrophication (see Figure 2 in section 2.2). Hydromorphological quality elements can be relevant in assessing eutrophication, e.g. in impounded rivers or in lakes with large water level fluctuations.

Use of nutrient monitoring

223. Nutrients are a key factor in eutrophication and, therefore, should be included in monitoring programmes for the assessment of eutrophication, besides other key parameters such as temperature or salinity in coastal waters. Basically, two different monitoring concepts can be applied: 1) monitoring of biological quality element(s) including supporting quality elements, or 2) monitoring of nutrients (and possibly other physico-chemical quality elements) as a screening tool. Generally, monitoring of nutrients will be at a higher frequency than for biological quality elements.

224. For screening procedures it has to be considered that nutrients may be transported over long distances, disconnected to local sources and diluted but steadily enhancing local production. It can also be useful to monitor organic matter (included partly in total nitrogen and total phosphorus; but also particulate and dissolved organic carbon may cause eutrophication), because organic matter contains nutrients and is a direct cause for secondary eutrophication effects (e.g. oxygen deficiency) and may not have been produced locally, but transported from elsewhere.

225. For a detailed analysis of eutrophication processes all fractions of nutrients (dissolved and particulate, organic and inorganic forms of nitrogen and phosphorus) should be monitored to allow a better understanding of the status and the factors explaining the status. Such a detailed analysis can be part of an investigative monitoring programme. The analysis of total nitrogen and total phosphorus is the basis for budget calculations and overall assessments. However, for detailed analyses of eutrophication processes individual parameters are needed.

226. For both types of analyses the often inhomogeneous vertical distribution of particulate organic matter in the water column has to be considered during monitoring. In stratified water bodies (lakes, transitional and

coastal waters) and in frontal areas[63] (mainly in transitional and coastal waters) nutrients have to be monitored with a sufficient vertical resolution. Therefore, it is important to adapt the monitoring strategy to different hydrodynamic regimes.

7.6. Frequency of monitoring

227. Annex V of the Water Framework Directive provides tabulated guidelines in terms of the minimum monitoring frequencies for all the quality elements. The suggested minimum frequencies are applicable to both surveillance and operational monitoring and are generally lower than those currently applied in some countries. More frequent monitoring will most likely be necessary in many cases to achieve a reliable assessment of the status of the relevant quality element, but also less frequent monitoring is justified when based on technical knowledge and expert judgment[64]. Member States are also able to target their monitoring to particular times of the year to take into account variability due to seasonal factors.

228. The frequency of sampling and the distribution of sampling sites for nutrient monitoring should be set up in a way that it is possible to detect trends. For high-frequency monitoring the use of automatic measuring devices and remote sensing tools can be very useful.

229. Monitoring is required over one year, at least once every 4 years for the Nitrates Directive[65], and the sensitivity of waters in general needs to be reviewed every 4 years for the Urban Waste Water Treatment Directive. The review does not explicitly require monitoring though undoubtedly information from monitoring would be invaluable in the assessment. For the Nitrates Directive, a minimum of monthly samples for nitrates analysis is required[66]; this compares with once every 3 months (for nutrient status) for the Water Framework Directive.

230. The OSPAR Eutrophication Monitoring Programme defines the minimum requirements for monitoring and reporting. For areas, including local areas located in wider non-problem areas, identified as problem or potential problem areas, a sufficient frequency and spatial coverage of all the parameters in the programme should be monitored and reported each year. For the areas identified as non-problem areas, results relating to the monitoring of the nutrient assessment parameters (nutrient inputs, winter DIN and DIP

[63] Frontal areas are characterised by the occurrence of steep gradients of water density, mostly including salinity gradients. They are formed at the borders of river plumes, coastal water plumes or upwelling water masses with adjacent homogenous mixed water masses.

[64] Guidance document No. 7, Monitoring under the Water Framework Directive, section 2.10.2

[65] For the purpose of designating and revising the designation of vulnerable zones

[66] At stations laid down in the Surface Water for Drinking Directive (75/440/EEC) and/or other sampling stations representative of surface waters of Member States (Article 6.1.a.i). These stations are used to identify polluted waters based on exceedance or potential exceedance of 50 mg/l nitrate (Annex I.A.1). Annex 1.A.3 also gives "eutrophic" or "may become eutrophic" as other criteria for identifying polluted waters. Though not strictly relevant to the eutrophication criteria (phosphorus is often the limiting nutrient for algal growth in freshwaters), monthly sampling of nitrate at those stations described in Article 6.1.a.i would in practice be useful in the assessment of eutrophication.

and winter N/P ratio) should be reported once in 3 years. For HELCOM, there are two main monitoring frequencies recommended: frequent and highly frequent. Frequent sampling ranges from once or twice per year to 6 to 12 times per year depending on purpose and parameter. Some high frequency stations are sampled up to 26 times per year or even more often. For the MEDPOL eutrophication monitoring strategy, the optimal sampling frequency should be chosen by each country according to the parameter variability in the affected area, and with the objective of detecting a change in concentration over a selected period (e.g. 10 years).

231. A common theme between policies is the acknowledgement that monitoring/sampling may need to be targeted to particular seasons (e.g. for seas: nutrients in winter, algae in summer) and particular water bodies/areas (e.g. problem areas, water bodies at risk) and higher sampling frequencies may be needed in more variable water bodies/areas or during periods of high variability than the minimum frequencies recommended[67].

7.7. Monitoring of protected areas

232. As already described in Section 3.6 of this guidance both sensitive areas under the Urban Waste Water Treatment Directive and nitrate vulnerable zones under the Nitrates Directive are Protected Areas under Annex IV of the Water Framework Directive. This means that monitoring programmes established under the Water Framework Directive will have to take into account any monitoring requirements in the respective Directives such as the monitoring of nitrate concentrations in freshwaters over a period of a year at least every 4 years for the Nitrates Directive[68].

7.8. Harmonisation of monitoring programmes

233. Member States will wish, where possible, to have integrated and harmonised monitoring programmes that provide the data and information which will meet the needs of all the relevant policies, in this case, all those that deal with eutrophication. This section attempts to demonstrate where this should be possible based on the commonalities of policies in terms of, for example, geographic coverage of waters and the monitoring requirements as given in Directives/Conventions and any associated guidance/guidelines.

7.8.1. Rivers and lakes

234. For fresh surface water bodies there is potentially a good deal of synergy between policies in terms of the identification and inclusion of the same water bodies impacted by nutrients, and the quality elements indicative of eutrophication that are recommended to be monitored. There is also a joint need to review periodically the status of those water bodies identified as not being impacted by nutrients or at risk of

67 See, for example, for further guidance section 2.10 in CIS Guidance Document No. 7, Monitoring under the Water Framework Directive

becoming impacted by nutrients: these (or groups of these) may be included in surveillance monitoring for the Water Framework Directive and be part of the periodic review of waters for the Nitrates Directive and Urban Waste Water Treatment Directive. Eutrophication assessment is an integral part of the ecological status assessments under the Water Framework Directive. So the assessments and monitoring to be carried out for ecological status (and for the objective of preventing deterioration in status) should be a good step forward towards integration across these three policies with the Water Framework Directive monitoring (and assessment) schemes meeting the needs for future reviews of sensitive areas and polluted waters (eutrophic).

235. Water bodies impacted by, or at risk from, nutrients will be included in operational monitoring for the Water Framework Directive (though not all will necessarily be monitored as the representative monitoring of groups of water bodies is allowed), and they will also be required to be monitored for the Urban Waste Water Treatment Directive (waters subject to discharges from urban waste water treatment works and direct discharges from some industries) and for the Nitrates Directive (diffuse sources from agriculture, assessment of effectiveness of action programmes). Surveillance monitoring for the Water Framework Directive may include water bodies across the range of statuses from high to bad (where all statuses exist), and therefore some of the impacted or at risk water bodies (from nutrient enrichment) might also be included: the results from this monitoring might also contribute to the periodic reviews required for the Urban Waste Water Treatment and Nitrates Directives.

236. There are synergies between the monitoring required in all water categories for the different policies in terms of quality elements required for assessing eutrophication particularly in terms of biological quality and physicochemical quality elements but less so for the hydromorphological quality elements required for the Water Framework Directive. There are also some differences in terms of the recommended measured parameters indicative of the quality elements, e.g. HELCOM requires the monitoring of zooplankton in coastal and marine waters, an element not required by the WFD or other policies. However these difference may not be significant as long as some common disaggregated parameters such as composition and abundance of the biological element are measured (at an appropriate taxonomic level) then other related parameters could be easily derived.

237. There are potential differences in the frequency that monitoring might be undertaken in fresh surface waters. The review of sensitive areas (including eutrophic state) and less sensitive areas under the Urban Waste Water Treatment Directive is required at intervals of no more than four years. For the purpose of designating and revising the designation of vulnerable zones under the Nitrates Directive, monitoring for nitrate is required at least every four years over one year. It is not yet clear, how Member States will implement surveillance and operational monitoring programmes for the WFD. A minimum of one year in six years (or one year in 18 years in exceptional circumstances) is given in the Directive for surveillance

[68] Article 6 (a)

monitoring, with a minimum of one sample per 3 months for nutrient status[69] in the years that monitoring is undertaken for surveillance and operational monitoring. However, an additional requirement of monitoring for the WFD is the choice of frequencies that will "achieve an acceptable level of confidence and precision"[70] in the monitoring results and subsequent assessments. Monthly sampling for nutrients is currently common practice in many Member States. Therefore, Member States might in practice wish to critically assess their sampling frequencies for surveillance and operational monitoring in terms of the confidence in the estimates of status they will provide[71], and in terms of the costs of monitoring. In conclusion, it is likely that an integrated monitoring programme based on the requirements of the Water Framework Directive would be at a frequency that meets the needs of the other policies dealing with eutrophication.

7.8.2. Transitional, coastal and marine waters

238. Monitoring undertaken for the assessment of eutrophication for Marine Conventions and the Marine Strategy Framework Directive includes offshore marine waters not required under the Water Framework Directive. Additional monitoring of coastal and marine waters will, therefore, be required beyond the WFD in order to assess eutrophication for the other relevant policies. Some policies also require the designation of specific areas in relation to eutrophication (e.g. polluted water and problem areas). These areas may not always be the same geographically or in spatial extent and this will have to be borne in mind when developing a harmonised integrated monitoring programme for eutrophication.

239. HELCOM defines frequent and highly frequent monitoring stations that have recommended sampling frequencies higher than other geographically relevant policies (i.e. WFD and Nitrates Directive). A common theme that could be incorporated into a harmonised monitoring programme for transitional, coastal and marine waters is the recognition that sampling should be targeted to specific times of the year for some of the elements (e.g. nutrients and chlorophyll). There is also a common theme of ensuring that monitoring results are fit for purpose and this implies that different frequencies would be required for different elements, different water categories and different water bodies. As examples: Member States have to achieve acceptable levels of precision and confidence in the monitoring results and subsequent assessments (Water Framework Directive); Contracting Parties have to determine optimum sampling frequencies, for example, to confirm maximum winter nutrient concentrations have been determined (OSPAR) or to detect changes in concentrations over 10 years (MEDPOL).

---

69 Minimum monitoring frequencies are also given for the other quality elements in all water categories

70 Annex V.1.3.4, sentence 3.

8. NEXT STEPS – LINKS OF EUTROPHICATION ASSESSMENT WITH PRESSURE AND IMPACT ANALYSIS AND PROGRAMME OF MEASURES

8.1. Use of the DPSIR framework

240. The DPSIR framework (Figure 3 in Chapter 2) is seen as giving a structure in which the indicators are presented that are needed to enable feedback to policy makers on environmental quality and the resulting impact of the political choices made or to be made in the future.

241. Within the DPSIR framework, eutrophication assessment as described in the previous chapters belongs to the part of "state" and "impact". The outcome of the assessment might result in responses and measures. In order to be able to formulate the response, there is a need to understand the links between drivers/pressures, state/impact and the response.

242. The need for a response becomes evident if the result of eutrophication assessment is that a water body (or part of marine area) is eutrophic or may become eutrophic in the near future. In that case it has to be clear how the appropriate response/measures will be developed and decided upon to reduce/eliminate eutrophication in that water body. The objective of the measures should be to move to a situation where a water body (or part of marine area) is not eutrophic, in order to assist the achievement of the environmental objectives for a water body. The steps that are necessary to set objectives and to develop measures have been described in general in the WFD CIS Guidance document "Environmental objectives under the WFD"[72]. Below, more specific details are given for the steps to develop measures to combat eutrophication.

8.2. Steps in the development of measures for a water body (or part of marine area) that is eutrophic or may become eutrophic in the near future

Step 1

243. A first step in the development of measures to abate eutrophication in a water body is the assessment of all the sources that (may) contribute to the nutrient load to a water body. Such an assessment should not be limited to the sources near the water body itself, as sources upstream may contribute to eutrophication in downstream water bodies/marine areas (cf. paragraphs 51 and 52 in section 3.6). Also retention processes (denitrification and sedimentation), atmospheric deposition and re-suspension from sediments can be taken into account.

Step 2a

244. A further step is to consider the possible (combination of) reduction measures for these sources, including the effect of those reduction measures on the eutrophication status (= effectiveness of a measure) and the costs associated to the implementation of those measures (= selecting the most effective measure for

[72] http://circa.europa.eu/Public/irc/env/wfd/library?l=/framework_directive/guidance_documents/documentn20_mars09p

the least costs = cost-efficiency). An important question to be answered in this step is the scale at which measures need to be considered – in other words: what is the expected extent in a catchment of the impact/effect of the various measures at source.

245. The implementation of existing measures needs to be considered as well in this context – relevant existing measures in EU context are the Nitrates Directive, the Urban Waste Water Treatment Directive, the IPPC Directive, the Groundwater Directive, the National Emission Ceilings Directive and the Thematic Strategy on Air Pollution. Furthermore, the Marine Strategy Framework Directive needs to be considered.

Step 2b

246. Besides measures at source, also measures in (or nearby) the affected water body should be considered that can result in a reduction of eutrophication. Examples of such measures are alterations of the morphological characteristics of the water body, e.g. restoration of banks or floodplains, changes to the flow conditions, other changes to the infrastructure. Also for these types of measures, the extent of achievable reduction and related costs should be considered and assessed.

Step 3

247. Finally, it has to be decided which (combination of) measures at source and in the water body is most appropriate and cost-effective to reduce and eliminate eutrophication in a water body or part of marine area. At this stage, a balanced division of costs between upstream and downstream areas and between the various sectors has to be decided upon, taken into account the principles of polluter-pays and proportionality. The quality of the information gathered on the various measures will be crucial in acceptance of the justification of measures in upstream water bodies/countries where no eutrophication exists but where nutrient loads contribute to eutrophication in downstream water bodies/marine areas. The mechanism for the decision making is laid down in the WFD by preparing river basin management plans and agreement on this at the (international) catchment area level.

8.3. Identification of gaps that need to be addressed

248. A lot of the tools, guidance and mechanisms that are necessary to carry out the steps outlined in the preceding section are already available.

249. For *step 1*, the pressures and impact analysis according to Article 5 of the WFD and the drawing up of a river basin management plan has ideally resulted in an overview and assessment of all the sources.

250. For *step 2a*, on the establishment of effectiveness and cost-effectiveness of measures and the scale at which measures need to be considered is subject of the policy summary and background document on cost-

effectiveness[73]. The WFD Article 5 analysis already gives indications on the scale by identifying issues/risks that need to be considered at the international catchment level. Considerations to measures with regard to agricultural losses of nutrients have been produced by the CIS activity on "Links between WFD and agriculture"[74].

251. Several tools and examples exist or are in development to establish in a quantitative way the link between measures at sources of nutrients and the expected reduction of eutrophication effects in the fresh water and marine environment. It concerns flow studies (e.g. in Rhine and Danube catchment, COST initiative on evaluation of mitigation options for reducing nutrient losses to surface water), retention models and models for quantification of losses from diffuse sources and discharges from point sources (e.g. OSPAR HARPNUT guidelines, EUROHARP, COST action 626 European aquatic modelling network), HARMONICA. The challenge is to embed these tools in a sustainable way and to have the budgets/means to maintain the systems in the future.

252. In the area of measures in the water body itself (*step 2b*), available information and experience should be shared at European level.– a list of examples of such measures might be helpful.

253. For *step 3*, the results of the CIS Activity on cost-effectiveness deliver a useful framework to assist in the decision making.

8.4. Conclusion

254. In general, all the necessary tools, guidance and mechanisms are available to develop and decide upon the measures aiming at elimination of eutrophication in water bodies/catchments/marine areas. The challenge will be to apply all these tools in practice and to balance these with the implementation of measures in other policy areas such as agriculture or land-use.

ANNEX 1: THE UNDERSTANDING OF EUTROPHICATION

1. EU LEGISLATION AND POLICIES

1.1. Water Framework Directive (2000/60/EC)

1.1.1. Overview of the Water Framework Directive

255. The Water Framework Directive (WFD) establishes an integrated and co-ordinated framework for the sustainable management of water. Its purposes include preventing deterioration of water bodies, promoting sustainable water use, and ensuring "enhanced protection and improvement of the aquatic environment". This last point requires that rivers, lakes, estuaries, coastal waters and groundwater achieve and /or maintain at least ‘good status’ by 2015. For surface waters this requires both Ecological Status and Chemical Status to be at least ‘good’. Good status will be achieved by implementing a programme of measures as reported in River Basin Management Plans (Articles 11 and 13), and based on the results of river basin characterisation. The WFD stipulates detailed procedures for its implementation including the classification and monitoring of water bodies (see WFD Annex V).

256. Ecological status is derived from Ecological Quality Ratios (EQRs), which reflect the deviation of observed values from type-specific reference conditions. ‘High’, ‘good’, ‘moderate’, ‘poor’ and ‘bad’ Ecological Status have normative definitions (see Annex V of the WFD) based on the deviation, as a result of human activity, of quality elements from corresponding type-specific reference conditions. At good ecological status, the values of biological quality elements (communities of phytoplankton, plants, fish, macroinvertebrates etc.) should ‘deviate only slightly from those normally associated with the surface water body type under undisturbed conditions’ (Annex V 1.2). The boundary between good and moderate ecological status is crucial because it determines when restoration measures need to be taken.

257. The values for the biological quality elements set by Member States for the ‘high’-‘good’ class boundary and the ‘good’-‘moderate’ class boundary will be compared as part of the intercalibration exercise, which is further described below.

258. Several directives will coexist with the WFD, including: the UWWT Directive (91/271/EEC), Nitrates Directive (91/676/EEC), Bathing Water Directive (76/160/EEC), Habitats Directive (Directives 92/43/EEC) and the Birds Directive (Directive 79/409/EEC). Areas designated under these directives will have the status of Protected Areas under the WFD (Annex IV), for the protection of their surface water, groundwater or for the conservation of habitats or species directly depending on water. Several of these directives address eutrophication, increasing the need for a common framework for eutrophication assessments.

259. Sections of the WFD particularly relevant to assessing eutrophication are: Article 1 a (purpose); Article 4.1.a.i and ii (Environmental objectives and programmes of measures for surface waters); Article 5

(Characterisation); Article 6 (Register of Protected areas); Article 7.3 (Drinking Water); Article 8 (Monitoring); Article 10 (The combined approach for point and diffuse sources); Article 11 (Programme of measures); Annex II (1) (Characterisation), Annex IV.1.iv, (Protected Areas, nutrient-sensitive areas); Annex V (1) (Assessment of Surface Water Status) and Annex VIII (indicative list of main pollutants).

1.1.2. Summary of the Water Framework Directive's requirements

260. The term eutrophication is not explicitly defined in the Water Framework Directive. It is defined in two of the Directives that are to be integrated into the river basin planning process[75], Directive 91/271/EEC and Directive 91/676/EEC.

261. According to Directive 91/271/EEC concerning urban waste water treatment (the UWWT Directive), eutrophication means "the enrichment of water by nutrients especially compounds of nitrogen or phosphorus, causing an accelerated growth of algae and higher forms of plant life to produce an undesirable disturbance to the balance of organisms present in the water and to the quality of the water concerned". Directive 91/676/EEC concerning the protection of waters against pollution caused by nitrates from agricultural sources (the Nitrates Directive) has an identical definition of eutrophication. However, for the purposes of the Nitrates Directive, these effects must be caused by the enrichment of water by nitrogen compounds rather than by nutrients in general.

262. The Water Framework Directive requires Member States to classify the ecological status of surface water bodies[76] into one of five ecological status classes; high, good, moderate, poor or bad ecological status. The ecological status of a water body is an expression of the quality of the structure and functioning of its aquatic ecosystem.

263. The Directive provides general qualitative definitions for each ecological status class, and more detailed qualitative definitions for high, good and moderate ecological status for each surface water category.

264. Among other things, the definitions of each ecological status class describe the extent to which biological components of the aquatic ecosystem, called biological quality elements, may differ in that class compared to their reference, or high status, conditions as a result of the effects of human activity.

265. The reference conditions relevant to a particular water body depend on the type of water body. They are type-specific. This enables the classification system to take account of the natural variety of aquatic ecosystems across the Community's different water types.

---

75 See Article 10; Article 11.3.a; and Article 4.1.c and Annex IV of the Water Framework Directive

76 The status of heavily modified water bodies and artificial water bodies is defined by their ecological potential rather than their ecological status. When considering such bodies, references to ecological status should be read as meaning ecological potential.

266. The Directive requires the Commission to facilitate an intercalibration exercise. This exercise is designed to ensure that the numeric class boundaries for good ecological status, which have to be set by each Member State to make the classification scheme operational, are consistent with the Directive's 'normative' definitions and comparable between Member States.

267. The environmental objectives of the Directive require Member States to prevent deterioration of the status of water bodies. They also require Member States to aim to restore all surface water bodies to good ecological status, except where doing so would be unfeasible or disproportionately expensive. The Directive's ecological status classification scheme is therefore central to water management across the Community.

268. Nutrient enrichment is one of the many different anthropogenic pressures on water bodies that may affect their ecological status. As such, management measures may be required to control nutrient enrichment in order to achieve the objectives of the Directive.

269. The sensitivity of water bodies to nutrient enrichment may vary depending on their physical characteristics and on the extent of other anthropogenic alterations to them. For example, modifications to hydrology or morphology may significantly influence whether or not a given concentration of nutrients causes accelerated growth of algae or higher forms of plant life to produce undesirable disturbances. Changes to hydromorphology (e.g. residence time of water in lakes) could enable accelerated growth of algae or higher forms of plant life and thus impact on the ecological status of a water body even in the absence of further anthropogenic inputs of nutrients.

270. Operational monitoring must be undertaken for water bodies, or groups of water bodies, that are at risk of failing to achieve the Directive's objectives. The monitoring data obtained through operational monitoring must be used to establish the status of those bodies and to assess changes to their status resulting from management measures.

271. Monitoring must be designed to ensure that an adequate level of confidence and precision in the classification of ecological status can be achieved. Guideline minimum monitoring frequencies are set out in the Directive. However, the actual frequencies selected must provide sufficient data for a reliable assessment of the status of the relevant quality elements.

272. For the purposes of monitoring water bodies at risk because of nutrient enrichment, Member States must monitor parameters indicative of the biological quality element, or elements, most sensitive to the effects of nutrient enrichment as well as the nutrients that are being discharged into the water body in significant quantities[77].

[77] See Annex V 1.3.2. The term 'discharge' in this context is clearly intended to include the direct or indirect introduction into water as a result of human activity of nutrients from point or diffuse sources

273. Where appropriate, Member States may group water bodies and use representative monitoring to assess the status of the water bodies in the group[78].

1.1.3. Conceptual understanding of eutrophication in the WFD

274. The WFD classifies water bodies in relation to type-specific reference conditions. This enforces the view of eutrophication as a process, where nutrient enrichment through human activities causes adverse changes in the aquatic environment, rather than as a particular level of primary production or trophic state.

275. The assessment of eutrophication is strongly implied in the classification of surface water bodies. The definition of good ecological status for the quality elements 'Phytoplankton' and 'Macrophytes and Phytobenthos' uses very similar wording as the definition of eutrophication used in the UWWT and Nitrates Directives and by OSPAR. For example, good ecological status of lake macrophytes and phytobenthos requires that '…changes do not indicate any accelerated growth of phytobenthos or higher forms of plant life resulting in undesirable disturbances to the water balance of organisms present in the water or to the physico-chemical quality of the water.' (Annex V1.2.2.).[79] In other words good status includes an absence of eutrophication problems.

276. Nutrients, as part of the physicochemical quality element, must be at a level to ensure the functioning of the ecosystem and the values specified for biological quality elements (i.e. to ensure that the above definition is met). Specific mention of eutrophication is made in the requirement to estimate the magnitude of all significant point and non-point source pollution, including 'substances that contribute to eutrophication (in particular nitrates and phosphates)' (Annex II 1.4, Annex VIII).

1.1.4. Methods specified for assessing eutrophication

277. Under the WFD Ecological Status is assessed by using quality elements. Many of these quality elements are traditionally used for assessing eutrophication, in particular 'nutrient conditions' as well as the 'composition, abundance and biomass of phytoplankton and macrophytes'. At good Ecological Status biological quality elements should have only slight deviation from type-specific reference conditions. Corresponding values for nutrients necessary to support the achievement of good ecological status may be estimated from response curves based on knowledge of the relationships between nutrient concentrations and the biological quality elements.

278. High nutrient concentrations without any corresponding biological impacts may not necessarily result in down grading Ecological Status. Thus assessments of eutrophication consistent with the WFD should

---

[78] Guidance on grouping water bodies is provided in the CIS IMPRESS Guidance and the CIS Monitoring Guidance

[79] Compared to the UWWT Directive definition:*' The enrichment of water by nutrients, especially compounds of nitrogen and/or phosphorus, causing an accelerated growth of algae and higher forms of plant life to produce an undesirable disturbance to the water balance of organisms present in the water and to the quality of the water*

primarily focus on the biological effects resulting from elevated nutrient levels, taking also into account possible effect of transboundary transport of nutrients. Measures to reduce nutrient loading may still be needed (see section 1.1.6 on CIS Classification Guidance for more details) to reduce the impact of the discharge of nutrients in the area of discharge or elsewhere.

279. The main challenge for Member States is to find quantitative expressions (criteria or metrics) for the response in abundance and taxonomic composition for the different biological quality elements along the nutrient gradient, to quantify the impact of increased algal/plant biomass on other organisms and water quality and to quantify slight, moderate and large deviations from reference conditions, corresponding to 'good', 'moderate' and 'poor' Ecological Status. One challenge will be to obtain monitoring data for the required parameters from a sufficient number of sites and with a sufficient measurement frequency to ensure that assessments have sufficient accuracy and precision to differentiate between natural variation and human impact and to estimate the extent of anthropogenic pollution.

280. The CIS Monitoring Guidance recommends measurement frequencies for each parameter used in the assessments of Ecological Status. These frequencies are higher than the minimum frequencies specified in Annex V of the WFD, for many of the parameters relevant to eutrophication, such as phytoplankton and nutrient parameters (monthly or bi-weekly during growth season in the guidance as opposed to once every 3-6 months in Annex V).

281. The WFD furthermore focuses on managing whole river basins on a European scale, thus a down-stream water body failing the WFD objective of good status e.g. being eutrophic, may require measures to be taken, in the entire upstream catchment or even in other river basins including coastal water bodies or exporting coastal water bodies, even if upstream water bodies meet the objectives (transboundary transport of nutrients).

282. Further elaboration on the interpretation of ecological status and how to understand the different status classes is given in Chapter 3.

1.1.5. WFD Guidance documents

283. The following guidance documents for the implementation of the WFD with reference to eutrophication assessment have been prepared within WFD Common Implementation Strategy (CIS) working group:

- COAST: WFD CIS Guidance Document No. 5, 2003,
- Intercalibration: WFD CIS Guidance Document No. 6, 2003,
- Monitoring: WFD CIS Guidance Document No. 7, 2003,
- REFCOND: WFD CIS Guidance Document No.10, 2003,
- Classification WFD CIS Guidance Document No. 13, 2003.

concerned'.

284. These guidance documents contain helpful information assisting guidance on eutrophication assessment. Key issues mentioned in these documents for ecological classification of eutrophication are presented in the following section.

1.1.6. Common understanding of Ecological Classification from CIS guidance documents

Introduction

285. The WFD requires the establishment of classification schemes to reflect the Ecological Status or potential of surface water bodies as measured by the condition of specific biological, hydromorphological and physico-chemical quality elements. The relevant elements, and the specific conditions required for these elements in each of the classes of the classification schemes, depend on the surface water category and type to which the water body belongs, the pressures acting on the water body, and on whether the body is artificial or heavily modified. In addition the WFD requires Member States to achieve adequate confidence and precision in classification, and to give estimates of the level of confidence and precision achieved in the River Basin Management Plans.

286. The purpose of the overall ecological classification guidance is to provide general guidance on the assessment of Ecological Status and Potential leading to the overall ecological classification of water bodies for the purposes of the EC Water Framework Directive. The document also provides specific guidance on the role of the general physico-chemical quality elements in ecological classification. The guidance document draws on the existing guidance documents REFCOND, COAST, Monitoring, and HMWB&AWB.

Relationship between biological, hydromorphological and physico-chemical quality elements

287. As a basic step the values of the biological quality elements must be taken into account when assigning water bodies to any of the Ecological Status and Ecological Potential classes. In order to ensure comparability the results of the biological monitoring systems shall be expressed as ecological quality ratios for the purposes of ecological classification. The ratio shall be expressed as a numerical value between zero (worse class) and one (best class).

288. The values of the hydromorphological quality elements must be taken into account when assigning water bodies to the high Ecological Status class and the maximum Ecological Potential class (i.e. when downgrading from high Ecological Status or maximum Ecological Potential to good Ecological Status/Potential). For the other status/potential classes, the hydromorphological elements are required to have "conditions consistent with the achievement of the values specified for the biological quality elements." Therefore, the assignment of water bodies to the good, moderate, poor or bad Ecological Status/Ecological Potential classes may be made on the basis of the monitoring results for the biological quality elements and also, in the case of the good Ecological Status/Potential the physico-chemical quality elements. This is

because if the biological Quality Element values relevant to good, moderate, poor or bad status/potential are achieved, then by definition the condition of the hydromorphological quality elements must be consistent with that achievement and would not affect the classification of Ecological Status/Potential.

289. The values of the physico-chemical quality elements must be taken into account when assigning water bodies to the high and good Ecological Status classes and to the maximum and good Ecological Potential classes (i.e. when downgrading from high status/maximum Ecological Potential to good Ecological Status/Potential as well as from good to moderate Ecological Status/Potential). For the other status/potential classes the physico-chemical elements are required to have "conditions consistent with the achievement of the values specified for the biological quality elements." Therefore, the assignment of water bodies to moderate, poor or bad Ecological Status/Ecological Potential may be made on the basis of the monitoring results for the biological quality elements. This is because if the biological Quality Element values relevant to moderate, poor or bad status/potential are achieved, then by definition the condition of the physico-chemical quality elements must be consistent with that achievement and would not affect the classification of Ecological Status/Potential. The "physico-chemical quality elements" mean the physico-chemical elements supporting the biological elements listed in Section 1.1 of Annex V for each surface water category, except those for which an EQS has been set at EU-level.

290. The relationships between the biological, hydromorphological and physico-chemical quality elements in status classification are presented in Figure 6 for all natural water categories and types. The classification of heavily modified and artificial water bodies (see HMWB&AWB Guidance Document) is done in a comparable way to identify high, good, moderate, poor and bad Ecological Potential.

291. The Directive requires that Member States achieve an adequate level of confidence that water bodies are assigned to their true status classes. The level of confidence achieved must be reported in the river basin management plans. Further guidance is given in the technical Annex I to the ecological classification guidance document and may also be found in REFCOND Guidance and specifically in the Monitoring Guidance.

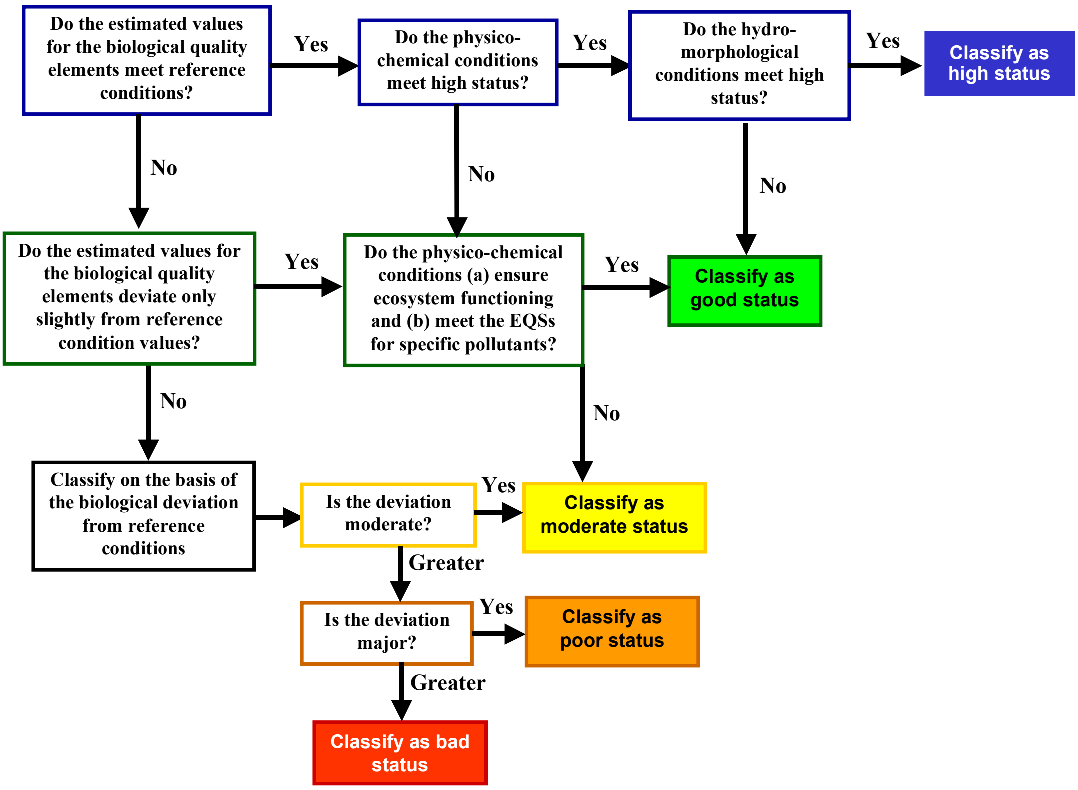

Figure 6. The relative roles of biological, hydromorphological and physico-chemical quality elements in classifying Ecological Status (Annex V 1.2) (Source: REFCOND & COAST guidance documents).

<u>Parameters indicative of the biological Quality Elements and most sensitive Quality Elements</u>

292. Member States must monitor parameters indicative of the condition of biological quality elements as part of their monitoring programmes. The Directive requires the assessment of the Ecological Status /Potential class of a water body to be based on the estimate of the condition of the Quality Element provided by these monitored parameters. In some circumstances, achieving a reliable assessment of the condition of a particular biological Quality Element may require consideration of the monitoring results for several parameters indicative of that Quality Element.

293. Figure 7 illustrates the relationship between biological quality elements and indicator parameters and their use in classification decisions. The example in the upper part of the figure illustrates the results for individual parameters of a biological Quality Element like phytobenthos with general sensitivity to a broad range of pressures (e.g. pressures resulting in morphological and hydrological changes as well as in changes to nutrient conditions). Parameters may be combined by, for example, averaging or weighting to estimate the status of the Quality Element.

294. The second example in Figure 7 illustrates the procedure of combining parameters, if pressure-related, multi-metric approaches are used. Under this approach, individual parameters indicative of the effects of a particular type of pressure on a biological Quality element are identified. Where several parameters responsive to the same pressure are identified, these may be grouped and the results for individual parameters in the group combined in order to increase confidence in the assessment of the impact of that pressure on the quality element. If several groups of parameters are identified, each indicating the effects of a different pressure on the quality element, the status of the quality element will be indicated by the results for the group that indicates the greatest impact on the element. However, if the parameters in a group are actually responding to the effects of a range of pressures on the quality element or there is low confidence in the results for a group of parameters, such pressure-related, multi-metric approaches may not be possible. In such cases, where the groups of parameters are not clearly signalling how the quality element has been affected by different pressures, the approach outlined above and the upper part of Figure 7 may be more appropriate.

The role of the general physico-chemical quality elements in the ecological classification

295. The Directive's normative definitions for Ecological Status describe the conditions required for the general physico-chemical quality elements and the specific pollutants at good status/potential. The general physico-chemical quality elements should not reach levels outside the range or exceed the levels established to ensure ecosystem functioning and the achievement of the values specified for the biological quality elements (see point (a) in the middle box in Figure 7). The concentrations of specific pollutants should not exceed environmental quality standards (EQSs) set in accordance with Annex V, Section 1.2.6 of the Directive (Figure 8).

296. The ranges and levels established for the general physico-chemical quality elements must support the achievement of the values required for the biological quality elements at good status or good potential, as relevant. Since the values for the biological quality elements at good status will be type-specific, it is reasonable to assume that the ranges and levels established for the general physico-chemical quality elements should also be type-specific. Several types may share the same ranges or levels for some or all of the general physico-chemical quality elements.

297. The Ecological Status/Potential of the water body is represented by the lowest value from the biological quality elements and physico-chemical quality elements as indicated in Figure 6. Thus good Ecological Status will only be attained if the monitoring results for both the biological quality elements and physico-chemical quality elements meet the conditions required for good Ecological Status/Potential (see WFD Annex V, 1.4.2.i, ii).

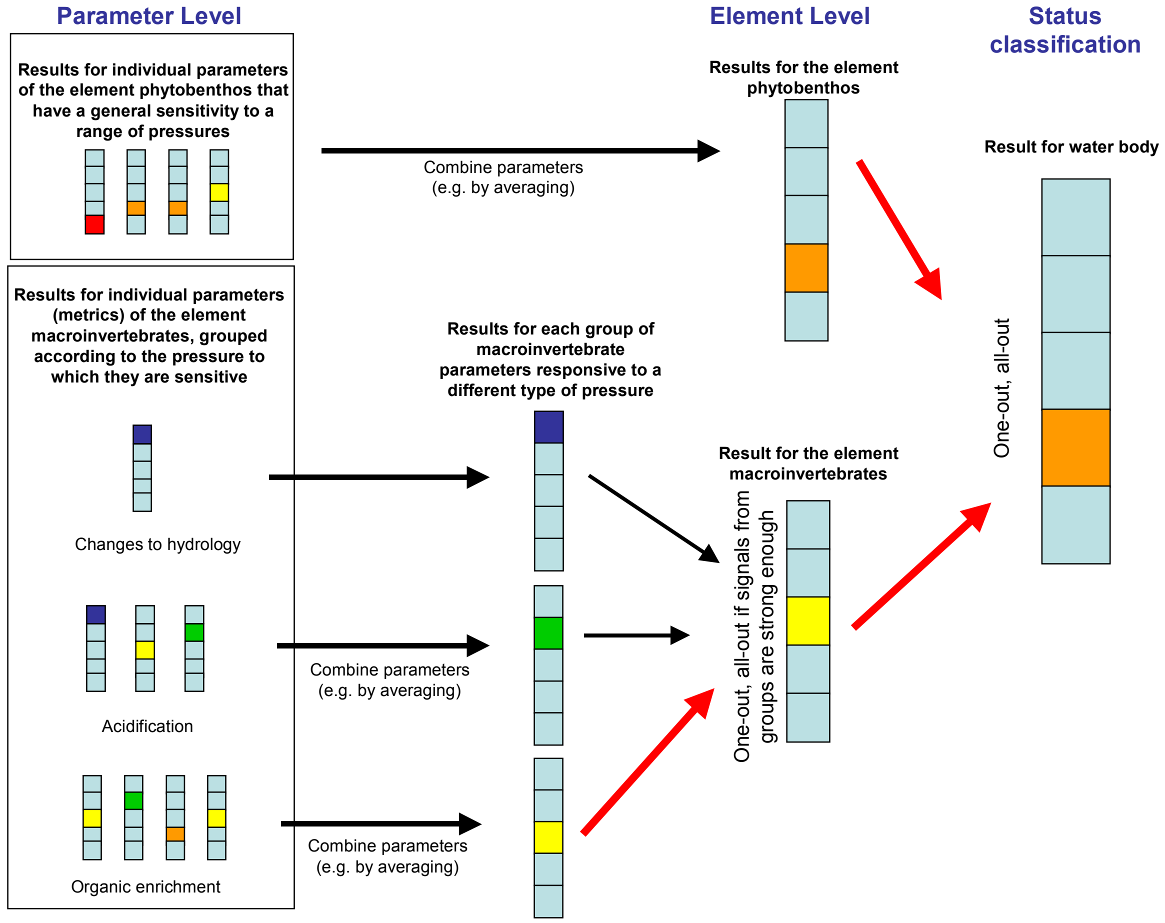

Figure 7. Examples of how indicative parameters may be combined to estimate the condition of biological quality elements. The one-out all-out principle is used at the quality element level.

298. In individual water bodies, there will be cases where the monitoring results for the biology are good but the results for the general physico-chemical quality elements appear, at face value, to be less than good. Such a situation could occur if one or more of the specific pollutants exceeds the EQS-values established, or if there is a time lag between the change of the general physico-chemical quality elements and the response in the biological quality elements. Furthermore, this situation could be common even though the physico-chemical ranges are thought to be valid, due to statistical errors in sampling and analysis. In these cases, Member States may decide to classify the body as less than good only when they have checked that the statistical confidence is adequate to say that the general physico-chemical quality elements are really less than good. Where it is not, Member States may take steps to improve confidence, for example, by doing more monitoring.

299. There may also be other cases where the levels or ranges proposed for a general physico-chemical quality element in a type are being exceeded as a result of anthropogenic effects, but no biological impacts are being detected. In such cases, it is recommended that a checking procedure should be undertaken. This procedure should be used to assess whether the established type-specific levels or ranges for the elements are

more stringent than is necessary to ensure the functioning of the ecosystem and the achievement of the values specified for the biological quality elements at good status/potential.

300. The mismatch between the biological monitoring results and the general physico-chemical monitoring results may also be because the biological methods being used in monitoring are not sensitive to the effects of anthropogenic changes in the condition of the physico-chemical quality element. In such cases, improvements to the biological methods should be made on an on-going basis with the aim of developing methods that are sufficiently sensitive. This improvement work should not stop after the first classification decisions are made.

301. Water bodies in which an established level or range for a general physico-chemical quality element is exceeded should be classified as moderate status/potential or worse unless the established level or range for the type is revised as a result of the checking procedures.

302. To support the proposed practical approach, the relevant box in the general Figure 6 on ecological classification should be expanded for clarification as illustrated in Figure 8.

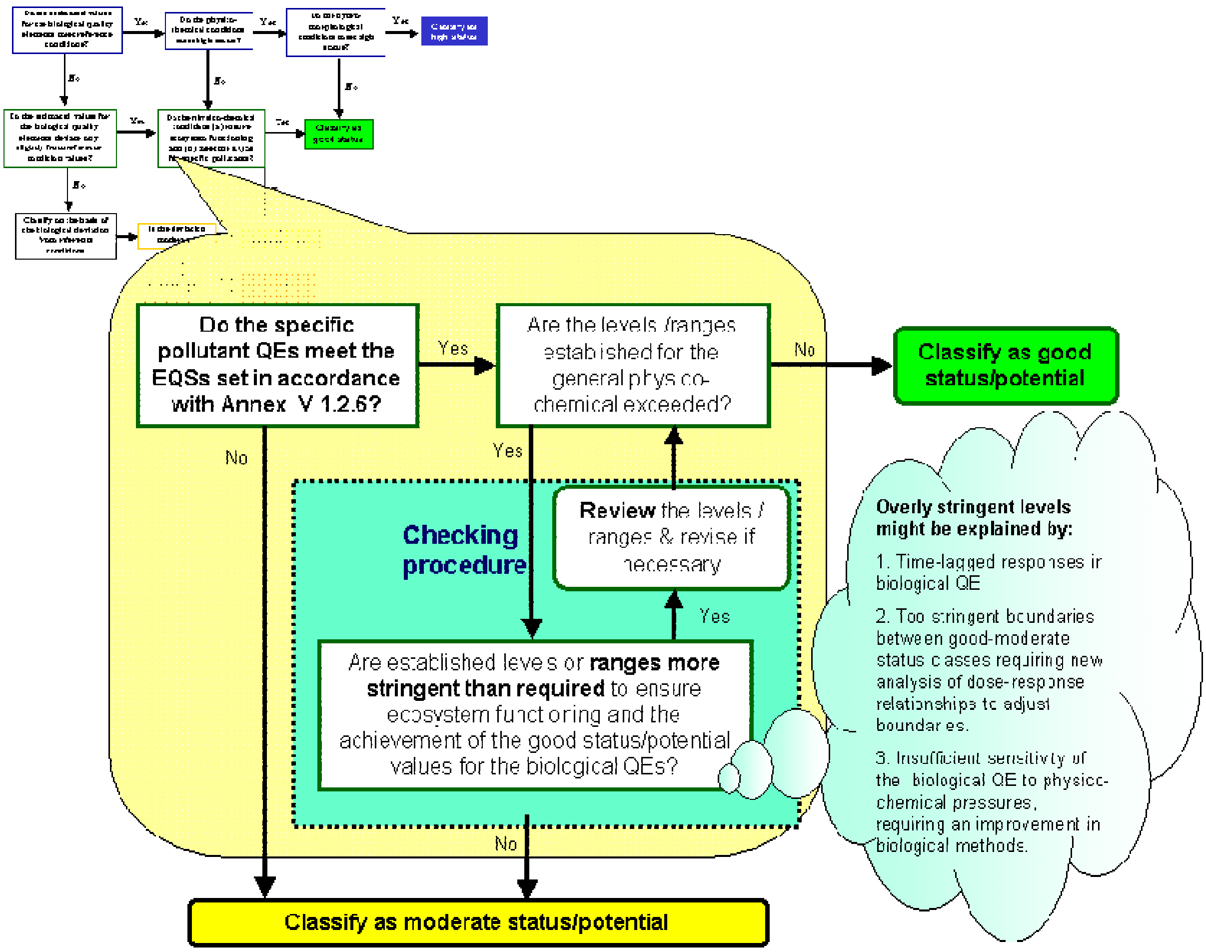

Figure 8. Elaboration of second box in the good Ecological Status line of the ecological classification diagrams (see Figure 6)

Conclusion

303. The analysis set out in the sections above concludes that the Directive requires the establishment of, and compliance with, specific values for the physico-chemical quality elements for the high and good Ecological Status classes as well as for the maximum and good Ecological Potential. For the lower Ecological Status/Potential classes (i.e. moderate, poor and bad status/potential) it only appears to require the establishment of, and compliance with, values for the biological quality elements. Where monitoring results indicate that the condition of the physico-chemical quality elements is worse than good, the status/potential class assigned to the water body must also be less than good, and should be determined with reference to the type-specific condition of the biological quality elements.

1.2. Urban Waste Water Treatment Directive (91/271/EEC)

1.2.1. Overview of UWWT Directive

304. The Urban Waste Water Treatment Directive (UWWT Directive) aims to protect the environment from adverse effects of urban waste water discharges and direct discharges from certain (food processing) industries. It sets treatment levels on the basis of the agglomeration size and the sensitivity of waters receiving the discharges.

305. Surface waters must be designated as sensitive areas if, inter alia, they are eutrophic or if they may become eutrophic in the near future if protective action is not taken (Annex II A(a)). Discharges from agglomerations of >= 10,000 population equivalent to sensitive areas require more stringent treatment for nitrogen and/or phosphorus. However, Member States do not have to identify sensitive areas if more stringent treatment is implemented over the whole of its territory (Article 5 (8)). The designation of sensitive areas needs to be reviewed at least every four years (Article 5 (6)), and for newly designated sensitive areas more stringent treatment, with nitrogen and/or phosphorus removal, must be in place within 7 years of their designation.

306. Sections of the UWWT Directive that particularly refer to eutrophication and surface water monitoring are: Article 2 (11) which defines eutrophication; Article 5 on the identification of sensitive areas and treatment requirements; and Annex II, which specifies criteria for identification of sensitive areas.

1.2.2. Conceptual understanding of eutrophication

307. Article 2.(11) of the UWWT Directive defines eutrophication as: "the enrichment of water by nutrients, especially compounds of nitrogen and/or phosphorus, causing an accelerated growth of algae and higher forms of plant life to produce an undesirable disturbance to the balance of organisms present in the water and to the quality of the water concerned".

308.. This definition implicitly defines eutrophication by the confluence of four criteria[80]:

- enrichment of water by nutrients;
- accelerated growth of algae and higher forms of plant life;
- an undesirable disturbance to the balance of organisms present in the water
- deterioration of the quality of the water concerned.

309. It focuses more on changes in the aquatic environment rather than a particular state of primary production. It can apply to waters of any natural trophic state if their ecology or water quality has been adversely affected or is at risk due to nutrients from urban waste water discharges. The term "anthropogenic" eutrophication can be used to make this distinction clear.

1.2.3. Methods specified for assessing eutrophication

310. The UWWT Directive does not specify any methods or guideline values for assessing eutrophication[81], which results in Member States developing their own assessment systems and criteria, and may consequently lead to different levels of protection of their water bodies.

311. Several Member States[82] have developed criteria based on the three elements in the definition: nutrient enrichment, algae or plant life growth and other undesirable effects (e.g. oxygen depletion).

312. When designating sensitive areas, consideration should be given to which nutrient should be reduced by further treatment.

- "*Discharges to lakes and streams reaching lakes/reservoirs/closed bays with poor water exchange. Whereby accumulation may take place, should have removal of phosphorus unless it can be demonstrated that the removal will have no effect on the level of eutrophication. Where the discharges from large agglomerations are made, the removal of nitrogen may be also considered*" (Annex II A (a, i)).
- *"Discharges to estuaries, bays and coastal waters with poor water exchange or receiving large quantities of nutrients should have removal of phosphorus and /or nitrogen unless it can be demonstrated that the removal will have no effect on the level of eutrophication"* (Annex II A (a, ii)).

1.2.4. Relevant Case Law

313. The European Court of Justice (ECJ) is dealing with cases brought by the European Commission against several Member States, which address the designation of sensitive areas. The Court has recently ruled on a case brought against France (decision number C-280/02, ECJ judgement on 23/09/2004)[83].

---

80 See also §§ 18 of the ECJ judgement for the case C-280/02

81 Surface freshwaters intended for the abstraction of drinking water must have nitrate levels less than 50 mg NO_3/l, but this is well above concentrations likely to cause eutrophication.

314. It is related to the breach of the Directive requirements in relation to non-designation of sensitive areas and lack of infrastructure for 130 agglomerations discharging into sensitive areas. The ECJ ruling addresses the following points:

a. Broader interpretation of purposes of Directive 91/271/EEC (which is based on the legal base of the Directive, i.e. Article 130s (now Article 175 EC) in order to achieve the objectives of Article 130r (now Article 174 EC)). It was stated that:

- The objective pursued by Directive 91/271 goes beyond the mere protection of aquatic ecosystems and attempts to conserve man, fauna, flora, soil, water, air and landscapes from any significant harmful effects of the accelerated growth of algae and higher forms of plant life resulting from discharges of urban waste water.
- *"undesirability must also be considered to be established where there are significant harmful effects not only on fauna and flora but also on man, the soil, water, air or landscape*" (pt. 22 of the judgement).
- undesirable disturbances of the balance of organism present in the water are: "*species changes involving loss of ecosystem biodiversity, nuisances due to proliferation of opportunistic macro algae and sever outbreaks of toxic or harmful phytoplankton"* (pt. 23).

b. Important guidance on component parts of definition of "eutrophication" by

- clearly defining that eutrophication is characterised by the confluence of four main criteria and extensively explaining the meaning of those criteria.
- stating that "*for there to be eutrophication, there must be a cause and effect relationship between enrichment by nutrients and the accelerated growth of algae and higher forms of plant life on the one hand and, on the other hand, between the accelerated growth and an undesirable disturbance of the balance of organisms present in the water and to the quality of the water concerned"* (pt. 19).
- highlighting that criterion "deterioration of water quality" means not only deterioration of the quality of the water which produces harmful effects for ecosystems but also "*deterioration of the colour, the appearance, taste or odour of the water or any change which prevents or limits water use such as tourism, fishing, fish farming, clamming and shellfish farming, abstraction of drinking water or cooling of industrial installations*." (pt. 24)

---

[82] e.g. UK, Ireland, Portugal.

[83] http://curia.eu.int/jurisp/cgi-bin/form.pl?lang=en

c. Need to decouple duty to designate sensitive areas from whether or not agglomerations with more than 10 000 population equivalents exist in catchment (pt. 69), but also considering that (according to pts. 40, 52, 69, 77, 87)

- it is not important to define what percentage of pollution goes from urban waste water discharges or from agricultural pollution since both of them may contribute to eutrophication of water body as 91/271/EEC and 91/676/EEC are complimentary. When urban wastewater discharges involve in combination to nitrate flows of agricultural origin, Member States have to designate water body in question as being as a sensitive area in accordance with the directive 91/271/EEC
- the significance of a nutrient loading to a water body should be not only importance of the percentage of that nutrient input but also of the absolute amount of nutrient in tonnes . The decision of its importance in the overall nutrient budget has to be taken on case-by-case basis.

315. It is evident that the interpretation of the European Court of Justice must be used as minimum requirement for the level of protection in environmental laws of the European Communities. The interpretation of terms and criteria in this and related judgements must be used as benchmarks for any assessment method applied under any EC Directive applicable to eutrophication. In particular, the outcome of the intercalibration exercise and the guidance provided by this document in relation to the WFD classification must meet, at least, the obligations that can be derived from this judgement.

1.3. Nitrates Directive (91/676/EEC)

1.3.1. Overview of the Nitrates Directive

316. The Nitrates Directive (91/676/EC) aims to reduce water pollution from nitrates stemming from agricultural sources and to prevent such pollution occurring in the future. The Directive requires Member States to set up water monitoring programmes, to identify waters affected by pollution or that could be affected by pollution if no action is taken, to designate vulnerable zones (areas that drain into identified waters), to establish action programmes for designated vulnerable zones (in order to reduce and/or prevent further pollution) and to establish codes of good agricultural practices. The codes are to be applied by farmers on a mandatory basis within vulnerable zones and implemented on a voluntary basis outside those zones. Member States can opt to apply action programmes throughout their national territory and are in this case exempted from the obligation to identify specific vulnerable zones.

317. Vulnerable zones cover all land draining to identified waters, including natural freshwater lakes, other freshwater bodies, estuaries, coastal waters and marine waters which are eutrophic or may become so in the near future if protective action is not taken (Annex I of the directive).

318. In order to designate and revise nitrate vulnerable zones, the eutrophic state of surface freshwaters, estuaries and coastal waters needs to be reviewed and reported every four years (Article 6).

319. Sections of the Nitrates Directive that refer to eutrophication and surface water monitoring are: Article 2(i), which defines eutrophication; Article 3, on the identification of polluted waters and designation of Vulnerable Zones; Article 5(6) on the monitoring programmes for the purpose of assessing the effectiveness of action programmes; Article 6, on water monitoring for the purpose of the first designation and revision of nitrate vulnerable zones; and Annex 1, which specifies criteria for identifying polluted waters.

1.3.2. Conceptual understanding of eutrophication

320. The Nitrates Directive has the same definition of eutrophication as the UWWT Directive except that it only relates to nitrogen compounds.

1.3.3. Methods specified for assessing eutrophication

321. The Nitrates Directive does not specify any methods or guideline values for assessing eutrophication, which has resulted in Member States developing their own assessment criteria, and may result in different levels of protection of their water bodies. However the European Commission has developed a draft monitoring guidance that includes some preliminary elements for setting eutrophication criteria.

1.3.4. Relevant Case Law

322. Three rulings of the European Court of Justice (ECJ) address specifically the issue of eutrophication and designation of nitrates vulnerable zones under the Nitrates Directive, the Judgement of 27 June 2002 in case C 258/00 *Commission v France,* the Judgement 11 March 2004 in case C 396/01 *Commission v Ireland*, and the judgement of 22 September 2005 in case C 221/03 *Commission v Belgium.*

323. In these cases, the Commission considered that the designation of nitrate vulnerable zones made by the Member State concerned did not adequately take account of the criterion of eutrophication in identification of polluted waters and designation of nitrate vulnerable zones, as required by Annex I.A of the Directive. In the cases related to France and Ireland it was argued by the Member State concerned that the obligation to identify waters and designate nitrate vulnerable zones in the context of the Nitrates Directive did not arise as phosphorus was the main factor causing eutrophication. The ECJ rejected this line of argument. For instance, paragraph 45 of ruling in the case concerning France, stated that *"restricting the scope of the Directive to exclude certain categories of waters owing to the supposedly fundamental role of phosphorus in the pollution of those waters is incompatible with both the logic and the objective of the Directive"*. This Case Law indicated that it is contrary to the Directive to take a restrictive approach in relation to the criterion concerning eutrophication.

In the case related to Belgium, the Member State argued that Wallonia only makes a small contribution to Eutrophication of the North Sea and for this should not be considered for designation of vulnerable zones.

The ECJ rejected this argument by among others stating *'(...), it must be observed that, according to a document supplied by the Belgian Government, Walloon agriculture contributes 19 % of the total nitrogen in the Meuse basin and 17 % of the total nitrogen in the Escaut basin. Those two rivers cross the Walloon Region and drain into the North Sea. It must be pointed out that, although minor, those contributions are by no means insignificant'* (paragraph 86 of the ruling).

1.4. Habitats Directive (92/43/EEC)

324. The Habitats Directive (92/43/EEC) requires Member States to designate Special Areas of Conservation (SACs) (Article 4.4) and Special Protection Areas (SPAs) (Articles 12 and 13) for habitats of plants and animals listed in Annexes I-IV of the directive. For the habitats and species of selected sites, measures must be implemented to maintain or restore to 'a favourable condition' (i.e. Favourable Conservation Status). The Conservation Status must be monitored for all habitats and species of Community interest, and this is not restricted to Natura 2000 sites. The monitoring of habitats can focus on 'typical species'.

325. The Conservation Status of a species means the sum of the influences acting on the species concerned that may affect the long-term distribution and abundance of its populations (Article 1 (i)). Although not explicitly mentioned in the Directive, the impact of point and diffuse pollution by nutrients on water quality is an important part of conservation status in aquatic habitats.

326. The Habitats Directive does not specify any methods for assessing eutrophication. However eutrophication is relevant to the Habitats Directive to the extent that it might affect protected species and habitats. Nutrient enrichment leading to eutrophication can have significant detrimental effects on specific aquatic species and habitats. For example, excessive growth of benthic algae from elevated phosphorus can threaten the habitat for the pearl mussel. More generally, changes in water quality can also help explain trends in biodiversity.

1.5. Shellfish Waters Directive (79/923/EEC)

327. The Shellfish Waters Directive seeks to protect and improve shellfish waters in order to support shellfish life and growth and thus to improve the high quality of shellfish products for consumption. The Directive sets physical, chemical and microbiological water quality requirements that designated shellfish waters must either comply with or endeavour to meet. The Shellfish Water Directive will be repealed by the WFD by 2013.

328. The Shellfish Water Directive does not require an assessment of eutrophication per se, however Article 6 does require a number of parameters to be monitored to check the quality required for shellfish waters. Some of these parameters are relevant to assessments of eutrophication – in particular dissolved oxygen and saxitoxins (produced by dinoflagellates).

329. The Annex of the Shellfish Water Directive requires that dissolved oxygen saturation is monitored monthly, with a minimum of one sample representative of low oxygen conditions on the day of sampling. However where major daily variations are suspected, a minimum of two samples should be taken in a day; 95-percent of the samples should be greater than 70 percent saturation. There are standards and monitoring frequencies specified for saxitoxin.

330. These standards are set to protect shellfish waters and shellfish populations against pollution. They are absolute and apply regardless of whether the values reflect human induced impacts or naturally poor but undisturbed conditions.

1.6. Freshwater Fish Directive (78/659/EEC)

331. The purpose of the Freshwater Fish Directive (78/659/EEC) is to protect or improve the quality of running or standing freshwaters capable of sustaining fish populations. It sets physical and chemical water quality objectives for salmonid waters and cyprinid waters. Member States must designate salmonid waters and cyprinid waters and ensure they meet the quality objectives. The Freshwater Fish Directive will be repealed by the WFD by 2013.

332. There is no direct requirement for an assessment of eutrophication in the Directive. However, standards are set to safeguard waters capable of supporting fish life from the harmful consequences resulting from the discharge of pollutant substances into waters (including the reduction of the number of fish belonging to a certain species). To enable the designated waters to comply with the Directive, Article 6 does require that designated waters are sampled at a minimum frequency and that the waters comply with the quality objectives set by the Member States (Article 3). Many of the parameters specified in Annex 1 of the directive are relevant to eutrophication, for example mandatory minimum values are set for ammonia and dissolved oxygen, and guideline values are specified for total phosphorus. The values set for phosphorus are expressed as indicative in order to reduce eutrophication.

1.7. Bathing Water Directive (2006/7/EC)

333. The EU Bathing Water Legislation seeks to protect the environment and public health, by reducing the pollution of bathing waters and protecting such waters from further deterioration. Bathing waters are classified as all surface freshwater and seawater, where bathing is authorised by competent authorities of Member Sates and is not prohibited.

334. Physical, chemical and microbiological parameters applicable to bathing waters are set by the Directive and all necessary measures taken to ensure that the quality of the bathing water conforms to the limit values (see Article 3 and Annex). Some concept of type-specific reference conditions is included in Article 8 of the Directive through the ability to derogate the Directive requirements where deviation from the prescribed value is caused by exceptional weather or geographic conditions (for certain parameters) or by natural enrichment of certain substances.

335. The old Bathing Waters Directive (76/160/EEC) does not require a direct assessment of eutrophication. However, there is a requirement to monitor several parameters relevant to the assessment of eutrophication, i.e. transparency (fortnightly) and dissolved oxygen, when the quality of the water has deteriorated. Furthermore, samples must be collected for ammonia, nitrates and phosphate, and nitrogen (Kjeldahl) when there is a tendency towards eutrophication of the water.

336. Directive 76/160/EEC was revised and updated through the new Bathing Water Directive 2006/7/EC. The new Directive is based on scientific knowledge on protecting health and the environment, as well as environmental management experience, provides better and earlier information for citizens about the quality of their bathing waters, and moves from simple sampling and monitoring of bathing waters to bathing quality management. The new Directive is fully integrated into the Water Framework Directive.

337. The new Directive does not maintain the monitoring requirements of the old Directive. It requires only monitoring of microbiological parameters: Intestinal enterococci and Escherichia coli, but there is a link to eutrophication parameters, in particular in Article 8 and 9 of the Directive:

- Art. 8: When the bathing water profile indicates a potential for cyanobacterial proliferation[84], appropriate monitoring shall be carried out to enable timely identification of health risks. When cyanobacterial proliferation occurs and a health risk has been identified or presumed, adequate management measures shall be taken immediately to prevent exposure, including information to the public.
- Art. 9: When the bathing water profile indicates a tendency for proliferation of macro-algae and/or marine phytoplankton, investigations shall be undertaken to determine their acceptability and health risks and adequate management measures shall be taken, including information to the public.

338. The new Directive repeals the old Directive (from 31 December 2014) but at present Member States are free to use both Directives.

1.8. Marine Strategy Framework Directive (2008/56/EC)

339. The Marine Strategy Framework Directive 2008/56/EC (MSFD) establishes a framework within which Member States shall take the necessary measures to achieve or maintain 'Good Environmental Status'(GES) in the marine environment by the year 2020 at the latest. GES is defined according to Article 3(5) as "*the environmental status of marine waters where these provide ecologically diverse and dynamic oceans and seas which are clean, healthy and productive within their intrinsic conditions, and the use of the marine environment is at a level that is sustainable, thus safeguarding the potential for uses and activities by current and future generations*."

[84] Cyanobacterial proliferation' means an accumulation of cyanobacteria in the form of a bloom, mat or scum.

340. The Member States shall pursue this objective through the progressive elaboration of strategies for their marine waters. Further, GES shall be determined at the level of the marine region or subregion (specified in MSFD Article 4) on the basis of eleven qualitative 'descriptors' specified in MSFD Annex 1.

341. The descriptor 5 regards eutrophication, which is described as: "*Human-induced eutrophication is minimised, especially adverse effects thereof, such as losses in biodiversity, ecosystem degradation, harmful algae blooms and oxygen deficiency in bottom waters*."

342. Further, the Directive Annex III (Table 2 'Pressures and Impacts') includes two pressures (i.e. nutrient and organic enrichment) that need to be considered in the determination of GES and that influence compliance with the eutrophication descriptor.

343. The implementation of the MSFD is at a start and one of the main aspects of the work in the first phase will be the development of criteria and methodological standards for the descriptors of GES (July 2010 in accordance with Article 9(3)).

344. It is particularly important that this work consider the links, overlap and synergies with existing policies and Directives. A most important link is expected with the Water Framework Directive (WFD). Indeed the concept of Good Environmental Status in the Marine Directive is very similar to that of the Good Ecological Status in the WFD, and the marine Directive explicitly recognizes the need to develop approaches in accordance with the WFD. This is particularly relevant for the eutrophication.

1.9. National Emission Ceilings for Atmospheric Pollutants Directive (2001/81/EC)

345. The Emission Ceilings Directive (2001/81/EC) aims to limit atmospheric emissions of acidifying and eutrophying pollutants and ozone precursors in order to improve the protection of the environment and human health. The protection will be against the adverse effects of acidification, eutrophication and ground level ozone. The long-term objectives of the Directive are to establish national emission ceilings aiming at avoiding exceedances of critical loads and levels[85] and to protect all people against recognised health risks from air emissions.

346. The Emissions Ceilings Directive covers atmospheric emissions from Member States which arise as a result of human activity. It is expected that Member States will lower their annual national emissions of acidifying and eutrophying substances (i.e. sulphur dioxide, nitrogen oxides and ammonia) to levels not greater than those laid down in Annex I by 2010 (Article 4 and 5). Meeting these objectives is expected to result in a reduction of water and soil eutrophication by deposition of nitrogen.

347. There is no direct requirement for an assessment of eutrophication in the Directive. However, the Directive does refer to the quantitative relationship between the emission levels of pollutants and levels of

[85] The concept of critical load and level is defined in the Working Group on Effects under the LRTAP Convention, see: http://www.unece.org/env/wge/definitions.htm

eutrophication. This is based on the exceedance of critical loads at which level the pollutants have a significant adverse effect on the environment, in this instance causing eutrophication, acidification and the formation of ground level ozone.

348. Following the adoption of the Thematic Strategy on air pollution in September 2005, new objectives for eutrophication, acidification, ozone and health have been defined to be met in 2020. The NEC Directive will be reviewed accordingly in 2006. The objective for what concerns eutrophication is a reduction of 43 % of the ecosystems in which the critical loads are exceeded as to compare to 2000 situation.

2. OVERVIEW OF WORK ON EUTROPHICATION IN OTHER INTERNATIONAL POLICIES

349. The control of eutrophication is addressed by a number of international and regional conventions, agreements and policies. These include OSPAR, HELCOM, PARCOM, the Barcelona Convention, the Bucharest Convention, UNECE-LRTAP as well as several river basin conventions such as the Rhine, the Elbe, and the Danube Protection Convention. These are briefly described in Table 11. The rest of this section focuses on the approach taken by the marine conventions.

2.1. OSPAR Convention for the Protection of the Marine Environment of the North-East Atlantic

Aims of the OSPAR Convention

350. OSPAR is the mechanism by which 15 governments of the Western coasts and catchments of Europe, together with the European Community, cooperate to protect the marine environment of the North-East Atlantic. The mission is to conserve marine ecosystems and safeguard human health in the Convention Area by preventing and eliminating pollution; by protecting the marine environment from adverse effects of human activities and by contributing to the sustainable use of the seas. OSPAR's work is organised under six strategies, applying the ecosystem approach. There are obvious synergies between the objectives and measures taken in the context of OSPAR and those of the Water Framework Directive. The geographical scope of OSPAR is, however, broader, as it covers the whole maritime area.

The OSPAR Eutrophication Strategy

351. The OSPAR Eutrophication Strategy sets the objective to combat eutrophication in the OSPAR maritime area, in order to achieve and maintain by 2010 a healthy marine environment where eutrophication does not occur. The strategy builds on long-standing commitments of OSPAR Contracting Parties to achieve a substantial reduction at source, in the order of 50 % compared to 1985, in inputs of phosphorus and nitrogen into areas where these inputs are likely, directly or indirectly, to cause pollution (see also PARCOM Recommendations 88/2[86], 89/4[87] and 92/7[88]).

Table 11. Summary of international and regional conventions addressing eutrophication

Name	General objective	Waters covered	Website
OSPAR Convention	To take steps to prevent and eliminate pollution and the necessary measures to protect the maritime area against the adverse effects of human activities so as to safeguard human health and to conserve the marine ecosystem and, when practicable, restore marine area which have been adversely affected.	North-East Atlantic Sea	www.OSPAR.org
Helsinki Convention (HELCOM)	To take measures to prevent and eliminate pollution in order to promote the ecological restoration of the Baltic Sea Area and the preservation of its ecological balance.	Baltic Sea	www.helcom.fi
Barcelona Convention (UNEP/MAP)	To take concerted actions to prevent and eliminate marine pollution and sustainable management of the Mediterranean.	Mediterranean Sea	www.unepmap.org
Bucharest Convention	To take all necessary measures… to prevent, reduce and control pollution in order to protect and preserve the marine environment of the Black Sea.	Black Sea	www.blacksea-environment.org
UNECE Convention on Long-range Transboundary Air Pollution (LRTAP)	An international legally binding instrument to deal with problems of air pollution on a broad regional basis. Signed by 34 governments and the EC. Includes a protocol to abate acidification and eutrophication. The Working Group on Effects under the Convention is in charge of monitoring the impact of air pollution on health and environment (notably eutrophication and acidification).	Air Pollution (Europe)	www.unece.org/env/lrtap/welcome.html http://www.unece.org/env/wge/welcome.html
Convention for the Protection of the Rhine	Aims to strengthen cooperation between the Community and the Rhine riparian States in order to preserve and improve the ecosystem of the river. Council Decision 2000/706/EC	Rhine River Basin	http://europa.eu.int/scadplus/leg/en/lvb/l28115.htm
Danube River Protection Convention	Aims to achieve sustainable and equitable water management in the Danube Basin. Agreement to reduce pollution loads to the Black Sea. International Commission for the Protection of the Danube River (ICPDR) acts as the permanent secretariat. Supported by a communication from Commission -COM (2001) 615 - on Environmental Co-operation in the Danube.	Danube River Basin	http://www.icpdr.org/pls/danubis/danubis_db.dyn_navigator.show http://europa.eu.int/scadplus/leg/en/lvb/l28016.htm
Elbe River Protection Convention	Aims to prevent the pollution of the Elbe River and its drainage area. International Commission for the Protection of the Elbe River	Elbe River Basin	http://www.ikse-mkol.org/

[87] http://www.ospar.org/v_measures/get_page.asp?v0=pr89-04e.doc&v1=4

[88] http://www.ospar.org/v_measures/get_page.asp?v0=pr92-07e.doc&v1=4

352. PARCOM recommendation 89/4 deals with the set up of national action plans to reach the aims set out in PARCOM Recommendations 88/2. PARCOM recommendation 92/7 dealt with the implementation of appropriate reduction measures in the agricultural sector.

353. The implementation of the Eutrophication Strategy takes place within the framework of obligations and commitments of the various Contracting Parties under international agreements. This includes EC legislation to reduce nutrient discharges and emissions, including the Nitrates Directive, Urban Waste Water Treatment Directive, the Water Framework Directive and the Marine Strategy Framework Directive.

354. To assist Contracting Parties in identifying these areas in a consistent way and to periodically assess the eutrophication status of the OSPAR maritime area and progress made towards the Strategy's objective, OSPAR developed a common harmonised assessment framework: the Common Procedure for the Identification of the Eutrophication Status of the OSPAR Maritime Area (Agreement 2005-3).

Eutrophication monitoring

355. OSPAR's respective assessment work is supported by monitoring under the Eutrophication Monitoring Programme and by monitoring to estimate waterborne and atmospheric inputs of nutrients to the OSPAR maritime area under the RID (Riverine Inputs and Direct Discharges) Study and the CAMP (Comprehensive Atmospheric Monitoring Programme) monitoring programme.

2.1.1. Eutrophication assessment

356. OSPAR has developed a harmonised assessment of eutrophication through the Common Procedure to identify the regions of the OSPAR Marine Area in which the recommendations mentioned above apply. OSPAR defines "eutrophication" as the enrichment of water by nutrients causing an accelerated growth of algae and higher forms of plant life to produce an undesirable disturbance to the balance of organisms present in the water and to the quality of the water concerned, and therefore refers to the undesirable effects resulting from anthropogenic enrichment by nutrients as described in the OSPAR Common Procedure.

357. The Common Procedure consists of an initial screening procedure (a "one-off broad-brush approach") to identify obvious non-problem areas, followed by the application of the Comprehensive Procedure to identify whether other waters should be classified as (potential) problem areas or non-problem areas with respect to eutrophication. The Comprehensive procedure is applied as an iterative process, with periodic reassessments and feedback from its application being used to refine the procedure. The screening procedure has been finalised in 2004.

358. The Comprehensive Procedure (COMPP) consists of a set of assessment criteria that are linked to form a holistic assessment of eutrophication status (OSPAR Commission 2005-3). It is based on a conceptual

framework of the eutrophication process and a checklist of qualitative parameters for a holistic assessment. The widely used uniform assessment procedure with respect to yearly trends and elevated concentrations of DIN and DIP in winter**,** and silicate in salinity gradient (riverine influenced) waters is as follows:

a. Mixing diagrams and salinity-specific background concentrations:

> In marine coastal waters with salinity gradients yearly trends in winter nutrient concentrations are assessed by plotting the winter nutrient concentrations of each year in relation to the respective measured salinity values ("mixing diagrams"). In winter, defined as period when algal activity is lowest, DIN and DIP (but also silicate) show a conservative behaviour and, therefore, a good linear relationship with salinity (decreasing concentration with increasing salinity from coast to offshore).

b. Trends and increased concentrations compared with salinity-specific background concentrations:

> In order to compensate for differences in salinity at the various locations and during the various years, nutrient concentrations are normalised for salinity. This is done by calculating the winter nutrient concentration at a given salinity (e.g. 30) from the mixing diagram of a particular year. The salinity normalised nutrient concentration (with 95 % confidence interval) is plotted in relation to the respective year in order to establish trends in the winter nutrient concentrations and the assessment level (compared with background concentration).

359. The conceptual framework and these categories take into account interactions and cause and effect relationships. The conceptual framework is further discussed in section 2.2 along side a modified version of the COMPP holistic checklist.

360. Harmonised quantitative criteria linking assessment parameters have been developed for a sub-group of the checklist, as shown in Table 12. The results of this assessment are combined using a matrix to distinguish problem areas from non-problem areas, as shown in Table 13.

Table 12. Harmonised assessment parameters and related elevated levels (OSPAR 2005-3)

Note: Parameters found at levels above the assessment level are considered as "elevated levels" and entail scoring of the relevant parameter category as (+) (cf. 'score' table at Annex 5 of the Common Procedure). For concentrations, the "assessment level" is defined as a justified area-specific % deviation from background levels not exceeding 50 %.

Assessment parameters		
Category I	**Degree of nutrient enrichment**	
	1	**Riverine inputs and direct discharges[89] (area-specific)** Elevated inputs and/or increased trends of total N and total P (compared with previous years)
	2	**Nutrient concentrations (area-specific)** Elevated level(s) of winter DIN and/or DIP
	3	**N/P ratio (area-specific)** Elevated winter N/P ratio (Redfield N/P = 16)
Category II	**Direct effects of nutrient enrichment (during growing season)**	
	1	**Chlorophyll *a* concentration (area-specific)** Elevated maximum and mean level
	2	**Phytoplankton indicator species (area-specific)** Elevated levels of nuisance/toxic phytoplankton indicator species (and increased duration of blooms)
	3	**Macrophytes including macroalgae (area-specific)** Shift from long-lived to short-lived nuisance species (e.g. *Ulva*). Elevated levels (biomass or area covered) especially of opportunistic green macroalgae).
Category III	**Indirect effects of nutrient enrichment (during growing season)**	
	1	**Oxygen deficiency** Decreased levels (< 2 mg/l: acute toxicity; 2-6 mg/l: deficiency) and lowered % oxygen saturation
	2	**Zoobenthos and fish** Kills (in relation to oxygen deficiency and/or toxic algae) Long-term area-specific changes in zoobenthos biomass and species composition
	3	**Organic carbon/organic matter (area-specific)** Elevated levels (in relation to III.1) (relevant in sedimentation areas)
Category IV	**Other possible effects of nutrient enrichment (during growing season)**	
	1	**Algal toxins** Incidence of DSP/PSP mussel infection events (related to II.2)

89 Principles of the Comprehensive Study on Riverine Inputs and Direct Discharges (RID) (reference number: 1998-5, as amended).

Table 13 Examples of the integration of categorised assessment parameters (see Table 1) for an initial classification (OSPAR 2005-3)[14]

	Category I	Category II	Categories III and IV	Initial Classification
	Degree of nutrient enrichment Nutrient inputs Winter DIN and DIP Winter N/P ratio	Direct effects Chlorophyll *a* Phytoplankton indicator species Macrophytes	Indirect effects/other possible effects Oxygen deficiency Changes/kills in zoobenthos, fish kills Organic carbon/matter Algal toxins	
a	+	+	+	problem area
	+	+	-	problem area
	+	-	+	problem area
b	-	+	+	problem area[90]
	-	+	-	problem area
	-	-	+	problem area
c	+	-	-	non-problem area [91]
	+	?	?	potential problem area
	+	?	-	potential problem area
	+	-	?	potential problem area
d	-	-	-	non-problem area

(+) = increased trends, elevated levels, shifts or changes in the respective assessment parameters in Table 12
(-) = neither increased trends nor elevated levels nor shifts nor changes in the respective assessment parameters in Table 12
? = not enough data to perform an assessment or the data available is not fit for the purpose

Note: Categories I, II and/or III/IV are scored '+' in cases where one or more of its respective assessment parameters is showing an increased trend, elevated level, shift or change.

2.1.2. Procedures for assessing eutrophication in OSPAR and WFD

361. Procedures for assessing eutrophication are stipulated in the WFD and have been developed by OSPAR and HELCOM. A comparison of the criteria used to assess Good Ecological Status under the WFD and HELCOM, and non-problem areas under the OSPAR Common Procedure and the related OSPAR Ecological Quality Objectives is made in Table 14. The table shows considerable similarities between the quality elements used for WFD classifications and the parameters used by OSPAR/HELCOM. The classification of Ecological Status incorporates most factors involved in eutrophication (i.e. causative factors, direct effects, and indirect effects) with the exception of algal toxins. A further comparison between WFD quality elements and OSPAR/HELCOM criteria is made below:

---

90 For example, caused by transboundary transport of (toxic) algae and/or organic matter arising from adjacent/remote areas

91 The increased degree of nutrient enrichment in these areas may contribute to eutrophication problems elsewhere.

Phytoplankton – the WFD requires 'composition, abundance and biomass of phytoplankton' for all water body categories with exception of rivers. OSPAR has identified area-specific phytoplankton indicator species as an important element of composition, has set abundance thresholds for these species; OSPAR and HELCOM have defined area-specific reference conditions and thresholds for chlorophyll a, as an operational indicator of phytoplankton biomass. Furthermore, HEAT uses water transparency as an assessment criterion for the eutrophication status.

Aquatic flora – the WFD requires the assessment of the 'composition and abundance of other aquatic flora' for all water body categories. OSPAR and HELCOM have agreed that shifts in species composition and aerial coverage of macrophytes/macroalgae should be assessed at an area-specific level (e.g. for the OSPAR Wadden Sea area or beaches and shallow waters of the Baltic Sea). Assessments seek to distinguish long-lived from short-lived nuisance species. In addition, HEAT is considering limited depth distribution of submerged aquatic flora as an effect of eutrophication.

Benthic invertebrate fauna – the WFD requires the assessment of the 'composition and abundance of benthic invertebrate fauna' for all water body categories. OSPAR has not developed this criterion in depth for the time being, and simply seeks to distinguish long-term changes in zoobenthos species composition. However, these changes can also be caused by other factors like bottom trawling which may have an overriding effect compared with eutrophication effects. Kills of benthic fauna due to anoxia events and toxic phytoplankton (if caused by eutrophication) are used as more qualitative (descriptive) assessment criteria for assessing (non)occurrence of these events without any quantitative consideration. HEAT is evaluating the composition of animal communities living on the sea floor as a yardstick for eutrophication such as increasing organic enrichment of sediments.

Fish – the WFD requires the assessment of the 'composition, abundance and age structure of fish fauna' for all water body categories with exception of coastal waters. OSPAR is considering the criterion of fish kills due to anoxia events and toxic phytoplankton caused by eutrophication. It is used as a more qualitative (descriptive) criterion for assessing (non)occurrence of these events without any quantitative consideration.

Other elements – the WFD requires also the assessment of hydromorphological and physico-chemical quality elements supporting the biological quality elements. OSPAR and HELOM have developed thresholds for nutrients (OSPAR and HELCOM: winter DIN and DIP concentrations, HELCOM: annual means for TN and TP; OSPAR winter N:P ratios), and for oxygen. OSPAR and HELCOM also take into account possible trends in riverine loads and direct nutrient inputs to the maritime area in the assessment. OSPAR recognises a set of supporting environmental elements but these are not used in the same way as in the WFD.

362. Assessments under the WFD cover all types of pressures, whereas the OSPAR COMPP and HEAT are focused on the impact of nutrient enrichment. A further difference between OSPAR COMPP, HEAT and the

WFD is the methodology by which the various elements are integrated in the final assessment. The WFD and HEAT compare the deviation of recent monitoring data from type-specific reference conditions to calculate an EQR, and base the Ecological Status on the quality element with the worst status (one-out all-out principle). The OSPAR COMPP uses area-specific/historical reference levels for each criterion and has an additive process across the four categories (causative factors, direct effects, indirect effects and other possible effects) to integrate the results of the parameters considered. The result is – as for the WFD – driven by the worst result within each category (nutrient enrichment, direct effects, and indirect effects). The initial outcome might be reviewed, taking into account the influence of environmental factors.

2.1.3. Water body typology

363. The OSPAR, HELCOM and WFD methods to assess eutrophication are based on recognition of differences between different types of waters. Typology forms the basis for classifications under the WFD since reference conditions for the biological elements are type-specific. Two systems for typing are prescribed and Member States must apply one of them. OSPAR has developed a procedure to derive a Characterisation of the OSPAR Convention area:

364. In order to enable area-specific reference conditions to be established, there might be a need for Contracting Parties to carry out an analysis of the relevant characteristics ("typology") for their parts of the OSPAR maritime area. Relating thereto, further relevant information can be found in the Quality Status Reports for the North Sea and the whole OSPAR maritime area (QSR 1993 and QSR 2000).

365. For transitional (e.g. estuarine) and coastal waters falling under the regime of the Water Framework Directive, the respective typology could be used also for the application of the Common Procedure. When carrying out the characterisation, Contracting Parties should focus on the overall purpose of the Common Procedure to identify the eutrophication status of various parts of the OSPAR maritime area.

366. If Contracting Parties see a need to (further) divide their waters outside the area of jurisdiction of the Water Framework Directive, the factors such as

a. salinity gradients and regimes,
b. depth,
c. mixing characteristics (such as fronts, stratification),
d. transboundary fluxes,
e. upwelling,
f. sedimentation,
g. residence time/retention time,
h. mean water temperature (water temperature range),
i. turbidity (expressed in terms of suspended matter),
j. mean substrate composition (in terms of sediment types), and
k. typology of offshore waters

can assist in the characterisation.

Table 14. Comparison of the normative definitions of good Ecological Status for WFD quality elements (coastal waters) (Annex V 1.1) with OSPAR Ecological Quality Objectives and HELCOM Ecological Objectives.

Quality Element	WFD	OSPAR COMMP	OSPAR EcoQO Objectives	HELCOM Ecological Objectives	HELCOM Eutrophication Assessment
Biological quality elements					
Composition, abundance and biomass of phytoplankton	The composition and abundance of phytoplanktonic taxa show slight signs of disturbance. There are slight changes in biomass compared to type-specific conditions. Such changes do not indicate any accelerated growth of algae resulting in undesirable disturbance to the balance of organisms present in the water body or to the quality of the water. A slight increase in the frequency and intensity of the type-specific planktonic blooms may occur.	No elevated levels (and increased duration) of region-specific phytoplankton indicator species. Maximum and mean chlorophyll a concentrations in during the growing season should remain below elevated levels. (Elevated if concentration > 50 % above background concentrations).	Region/area-specific phytoplankton eutrophication indicator species should remain below respective nuisance and/or toxic elevated levels (and increased duration). Maximum and mean chlorophyll a concentrations during the growing season should remain below elevated levels, defined as concentrations >50 % above the spatial (offshore) and/or historical background concentrations.	Clear water, natural level of algal blooms	Mean summer area-specific chlorophyll a concentrations should remain below elevated levels, defined as mean concentrations less than maximum 50 % above reference concentrations

Quality Element	**WFD**	**OSPAR COMMP**	**OSPAR EcoQO Objectives**	**HELCOM Ecological Objectives**	**HELCOM Eutrophication Assessment**
Composition and abundance of aquatic flora (macroalgae and angiosperms)	Most disturbance-sensitive macroalgal and angiosperm taxa associated with undisturbed conditions are present. The level of macroalgal cover and angiosperm abundance show slight signs of disturbance.	Macrophytes including macroalgae: no shifts from long-lived to short-lived nuisance species (e.g. Ulva, Enteromorpha). No reduced depth distribution.	-	Natural distribution and occurrence of plants	Depth distributions of bladderwrack and eelgrass close to those of undisturbed conditions (maximum – 25 % deviation from reference conditions)
Composition and abundance of benthic invertebrate fauna,	The level of diversity and abundance of invertebrate taxa is slightly outside the range associated with the type-specific conditions. Most of the sensitive taxa of the type-specific communities are present.	No kills in zoobenthos due to oxygen deficiency and/or toxic algae) No long term changes in zoobenthos species composition.	There should be no kills in benthic animal species as a result of oxygen deficiency and/or toxic phytoplankton species.	Natural distribution and occurrence of animals, natural oxygen levels	Regional diversity of benthic invertebrates is within the natural variability for the assessed region
Composition, abundance and age structure of fish (T)	The abundance of the disturbance-sensitive species shows slight signs of distortion from type-specific conditions attributable to anthropogenic impacts on physicochemical or hydromorphological quality elements.	No kills in fish due to oxygen deficiency and/or toxic algae).	There should be no kills in benthic animal species as a result of oxygen deficiency and/or toxic phytoplankton species.	-	-

Quality Element	**WFD**	**OSPAR COMMP**	**OSPAR EcoQO Objectives**	**HELCOM Ecological Objectives**	**HELCOM Eutrophication Assessment**
Chemical and Physicochemical quality elements					
General Physicochemical quality elements • Transparency • Thermal conditions • Oxygenation conditions • Salinity • Nutrients conditions	Temperature, oxygenation conditions and transparency do not reach levels outside the ranges established so as to ensure the functioning of the ecosystem and the achievement of the values specified above for the biological quality elements. Nutrient concentrations do not exceed the levels established so as to ensure the functioning of the ecosystem and the achievement of the values specified above for the biological quality elements.	Oxygen levels should remain above region-specific oxygen deficiency levels (< 2 mg/l = acute toxicity; 2-6 mg/l = deficiency). Winter DIN and/or DIP concentrations should remain below elevated levels (defined as concentration >50 % above salinity related and/or region-specific background concentration). Winter N/P ratios should remain below elevated levels (defined as ratio >50 % above Redfield ratio (N/P=16 molar ratio))	Any decrease in oxygen concentration as an indirect effect of nutrient enrichment should remain above region-specific oxygen deficiency levels. Winter DIN and/or DIP should remain below elevated levels defined as concentrations >50 % above salinity related and/or region-specific background natural background concentrations.	Clear water, concentrations of nutrients close to natural levels, natural oxygen levels	Mean winter area-specific DIN and DIP concentrations should remain below elevated levels, defined as mean concentrations less than maximum 50 % above reference concentrations
Specific Pollutants		-	-	-	-

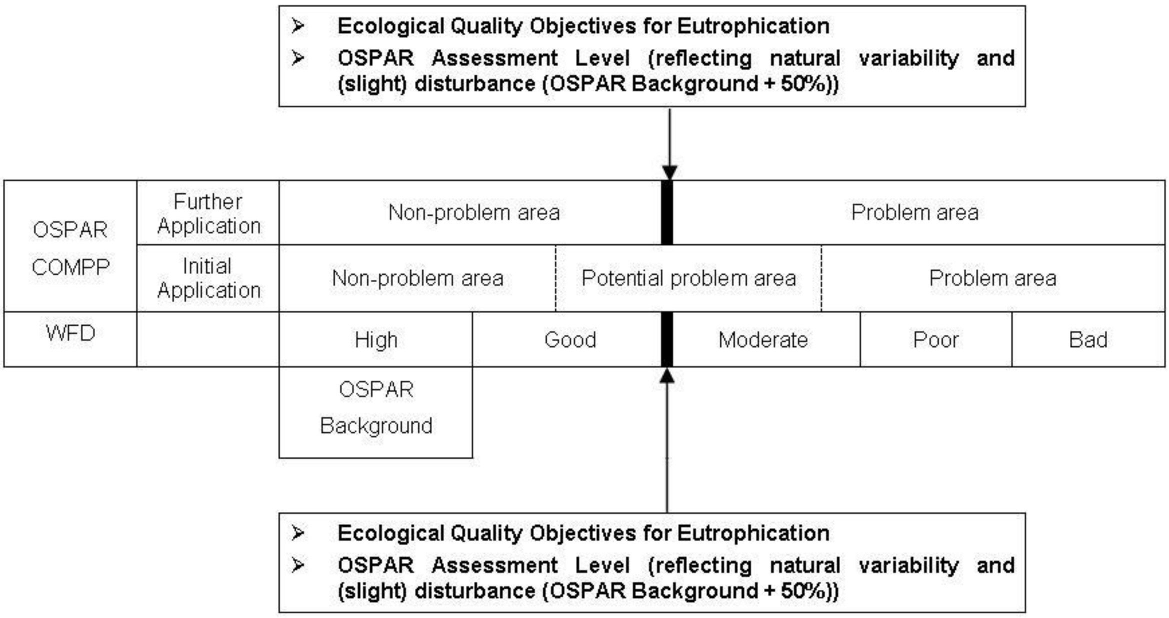
Quality Element	WFD	OSPAR COMMP	OSPAR EcoQO Objectives	HELCOM Ecological Objectives	HELCOM Eutrophication Assessment
Hydromorphological					
Tidal regime	Conditions consistent with the achievement of the values specified above for the biological quality elements.	Supporting environmental factors such as physical and hydrodynamic aspects or climate (e.g. flushing, wind, temperature, light availability).	-	-	-
Morphological conditions	Conditions consistent with the achievement of the values specified above for the biological quality elements.	-	-	-	-

367. The background levels and elevated assessment levels determined for some elements of the OSPAR harmonised assessment criteria could be used to influence the setting of WFD reference conditions and classification boundaries, e.g. background levels potentially equal to WFD reference conditions and these could therefore correspond to the high-good boundary, and the elevated assessment level could correspond to the good-moderate boundary (OSPAR 2005). HEAT is based on the comparison of reference conditions and recent data resulting in a classification according to WFD.

2.1.4. Comparison of OSPAR and WFD class boundaries

368. A more detailed comparison of ecological classification under the WFD and classification under OSPAR COMPP was made by OSPAR (2005) and is shown in Figure 9.

369. The assessment of good Ecological Status under the WFD is similar to the assessment of non-problem areas in the OSPAR Common Procedure. A water body will fail to achieve good Ecological Status if any single quality element fails good status, similarly the OSPAR Common Procedure requires that none of the categories I, II, III & IV (causative factors, direct effects and indirect effects) show increased trends, elevated levels or adverse changes. However, there is not always a direct match in how different parameters are combined. Category II, for example, requires two objectives related to phytoplankton to be met (‘chlorophyll a’ and ‘indicator species’), which correspond to a single quality element (‘composition, abundance and biomass of phytoplankton’).



Note: Assessment levels are based on a justified area-specific % deviation from background levels not exceeding 50 %. OSPAR COMPP = the Comprehensive Procedure; WFD = the Water Framework Directive.

Figure 9. Relationship between the classification under the OSPAR Comprehensive Procedure, the integrated set of OSPAR EcoQOs for eutrophication and the Water Framework Directive. (OSPAR 2005: Publication No. 231) [14]

2.2. Helsinki Convention on the Protection of the Marine Environment of the Baltic Sea

2.2.1. Aims of the Helsinki Convention[92]

370. The Helsinki Convention aims to protect the marine environment of the Baltic Sea from all sources of pollution, and to restore and safeguard its ecological balance. The Helsinki Commission operates through intergovernmental co-operation and is the governing body of the "Convention on the Protection of the Marine Environment of the Baltic Sea Area" (known as the Helsinki Convention).

2.2.2. HELCOM work on eutrophication

371. The control of eutrophication is a major priority of HELCOM. It is widely acknowledged that excessive amounts of nutrients are entering the semi-enclosed Baltic Sea and disturbing the ecological balance of the fragile sea. Under certain hydrological and environmental conditions this leads to algal blooms, oxygen depletion and occasionally fish kills (e.g. 2002 in the Belt Sea and 2003 in the Gulf of Gdansk). In many coastal regions the perennial algal belts have been reduced and partly replaced by short-lived filamentous algal species.

372. Since mid 1980, HELCOM has adopted several HELCOM Recommendations to reduce the load of nutrients and oxygen consuming substances from point and non-point sources in the Baltic Sea catchment. In addition the 1988 HELCOM Ministerial Declaration sets goals for all Contracting Parties to reduce their anthropogenic waterborne nutrient loading by 50 % between 1987 and 1995. Furthermore, in 1992, the Baltic Sea Joint Comprehensive Environmental Action Programme (JCP) was established to facilitate and monitor the elimination of the 162 most polluting sources within the Baltic Sea catchment area – known as "hot-spots". By March 2008 sufficient abatement measures were taken in half of them (83) and they consequently were eliminated from the list of hot spots.

2.2.3. HELCOM Monitoring

373. The HELCOM monitoring system consists of several complementary programmes, The Pollution Load Compilation programmes (PLC-Air and PLC-Water) quantify inter alia emissions of nutrients to the air (nitrogen), discharges and losses to inland surface waters, and the resulting air and waterborne inputs to the sea. The COMBINE programme assesses nutrients and certain eutrophication effects in the marine environment, including examination of trends.

374. Pollution Load Compilations are periodically carried out in order to compile:

a. Total loads of nutrients on an annual basis (from rivers and coastal areas as well as point sources and diffuse sources discharging directly to the Baltic Sea); and

[92] For further information see: http://www.helcom.fi/groups/monas/en_GB/monas_main/

b. Waterborne discharges from point sources and losses from non-point pollution sources as well as natural background losses into inland surface waters within the catchment area of the Baltic Sea located within the borders of the Contracting Parties.

375. These are reported every six year starting in 1987 (PLC-1). The latest report (PLC-4, HELCOM 2004) covers the period 1994 - 2000 for riverine loads and both point and non-point sources in the Baltic Sea catchment area for the year 2000. The next report, PLC-5 will be based on data collected up to 2006 and finalised in 2009. This main objective of the PLC-5 report is to:

- quantify and describe the waterborne discharges from point sources and losses from non-point pollution sources as well as the quantified natural background losses into inland surface waters (source oriented approach) within the catchment area of the Baltic Sea
- quantify and describe the loads (from rivers, unmonitored and coastal areas as well as point sources) discharging directly to the Baltic Sea (load oriented approach);
- evaluate changes in the pollution load since 1994;
- explain to which extent changes are caused by human activities or natural variations; and
- overall evaluate the significance of various water protection measures applied in the Baltic Sea catchment area to reduce the pollution load from land-based sources.

376. This information is required to assess the effectiveness of measures taken to reduce eutrophication in the Baltic Sea catchment area as well as to interpret and evaluate the environmental status and related changes in coastal waters and the open sea.

377. Comprehensive HELCOM assessments were published every five years. For the purpose of an eutrophication assessment, background concentrations of nutrients in the open marine environment are used as one of the criteria for assessments. Ecological Quality Objectives (EcoQOs) for eutrophication have been developed.

2.2.4. Thematic HELCOM eutrophication assessment

378. HELCOM MONAS launched the project "Development of tools for a thematic eutrophication assessment (HELCOM EUTRO)" which aims at a Baltic Sea wide harmonisation of eutrophication assessment criteria and procedures including the establishment of reference conditions for different parts of the Baltic Sea in 2004. The project was based on monitoring data produced within the COMBINE programme, other national monitoring and research data, and they cover both, coastal areas and the open sea. The project developed a "HELCOM Eutrophication Assessment Tool" (HEAT).

379. During a second phase of this project "Towards an integrated thematic assessment of eutrophication in the Baltic Sea" the integrated HELCOM thematic assessment of the eutrophication status of the Baltic Sea

has been executed. The assessment linked sources, inputs, and concentrations of nutrients with primary and secondary eutrophication effects in the marine environment.

380. The assessment applied a common, harmonised approach in assessing eutrophication, the HELCOM Eutrophication Assessment Tool. HEAT is in accordance with the WFD and the relevant guidelines under the CIS process. The report "Eutrophication in the Baltic Sea – An integrated thematic assessment of nutrient enrichment in the Baltic Sea region" was published in March 2009 (Baltic Sea Environment Proceedings No. 115A). Figure 10, taken from the mentioned report, shows the relationships between the HELCOM Baltic Sea Action plan and other water policies and directives.

Policy driver	**Status classification**				
	Unaffected/Acceptable		Affected/Unacceptable		
HELCOM BSAP	Unaffected by eutrophication		Affected by eutrophication		
OSPAR	Non-problem areas		Potential problem areas and problem areas[93]		
MSFD	Good Environmental Status		Polluted		
WFD	High ES	Good ES	Moderate ES	Poor ES	Bad ES
UWWTD	Unpolluted/non-sensitive		Polluted/sensitive		
Nitrates D	Unpolluted		Polluted		

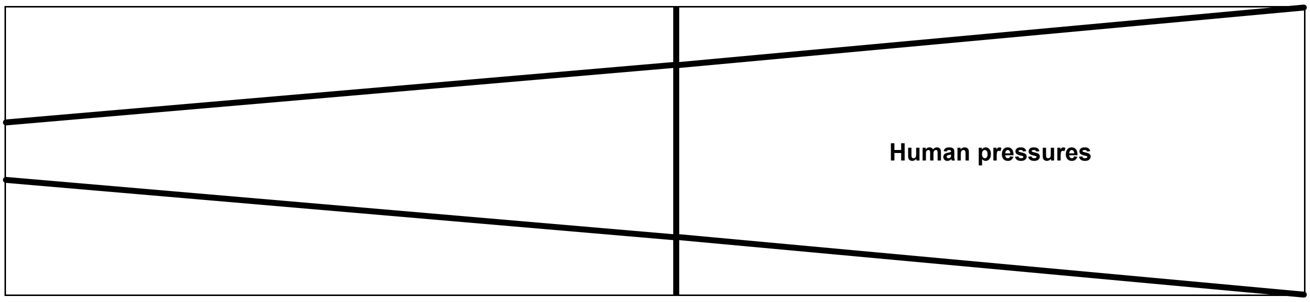


Figure 10. Relationships between the Baltic Sea Action Plan and some key European water policy directives with direct focus on eutrophication status. BSAP = Baltic Sea Action Plan; ES = Ecological Status sensu WFD. Based on HELCOM (2006).

The HELCOM Eutrophication Assessment Tool (HEAT)

381. HEAT, the HELCOM Eutrophication Assessment Tool, is a multi-metric indicator based tool. The development started with consideration of the OSPAR Common Procedure for the identification of the eutrophication status of the OSPAR Convention waters. It has been developed according the relevant principles of the EC Water Framework Directive. It is targeted for assessment of eutrophication in transitional, coastal and open marine areas. HEAT is based on the use of reference conditions determined according to the WFD principles and an acceptable deviation from these reference conditions which defines the boundary between good and moderate status. The assessment results are calculated as Ecological Quality

93 For potential problem areas, latest within five years of their classification, monitoring and assessment and/or research have to prove whether they finally classify as non-problem or problem areas.

Ratio and presented as one of five classes (high, good, moderate, bad, poor). HEAT comprises two assessment steps. The first step is an interim assessment for specific selected indicators and/or biological quality elements (such as phytoplankton, submerged aquatic flora, benthic fauna). By a second step, these individual assessment results are merged into an overall classification using the “one out, all out” principle as laid out in the WFD. HEAT will further be improved in order to meet the requirements of the Baltic Sea Action Plan and eutrophication relevant EC directives such as the WFD, Habitats Directive and the MSFD.

382. HEAT has successfully been tested for coastal and marine waters along the Baltic Sea. It was applied in 189 areas (163 in coastal waters and 16 in open sea areas). Only 13 (11 coastal areas and 2 open basins) were considered unaffected by eutrophication.

2.2.5. The Baltic Sea Action Plan aims at a Baltic Sea unaffected by Eutrophication

383. At the HELCOM Ministerial Meeting in Krakow in November 2007, all HELCOM Member States signed the Baltic Sea Action Plan (BSAP). It has four segments: eutrophication, biodiversity, hazardous substances and maritime issues. The eutrophication segment states “the overall goal of HELCOM is to have a Baltic Sea unaffected by eutrophication”. The aim is to reach HELCOM's vision for good environmental status in the Baltic Sea by achieving five ecological quality objectives to describe the characteristics of a Baltic Sea, which is unaffected by eutrophication:

- Concentrations of nutrients close to natural levels,
- Clear water,
- Natural level of algal blooms,
- Natural distribution and occurrence of plants and animals,
- Natural oxygen levels.

384. In order to make these objectives operational, indicators with target values, reflecting good ecological and environmental status of the marine Baltic environment, have been agreed upon. Clear water was chosen as the primary ecological objective with water transparency as the indicator.

385. For the achievement of the overall goal the Contracting Parties agreed on the principle of identifying maximum allowable inputs of nutrients. They further agreed on the need to reduce the nutrient inputs and that the reductions needed shall be fairly shared by all Baltic Sea countries.

386. In the Baltic Sea there are long time series for some measurements (salinity, temperature, transparency). This provides modellers with excellent reference data, and a number of models describe the Baltic Sea dynamics. Related to eutrophication the Baltic Sea, the MARE NEST model is a marine physical bio-geo-chemical model for the seven sub-basins (Bothnian Bay, Bothnian Sea, Gulf of Finland, Baltic proper, Gulf of Riga, Danish Straits and Kattegat) in the Baltic Sea. This model is linked to a model of the catchment area and to an economic model. HELCOM used the MARE NEST model to derive the figures on maximum allowable nutrient inputs and the needed reductions for waterborne inputs for each sub-basin and

to determine the respective country-wise nutrient reduction requirements which are laid out in the eutrophication segment of the Baltic Sea Action Plan. These data are provisional due to the best available knowledge at that time and the state of national nutrient data deliveries for the preparation of the BSAP. The figures are currently under revision. This process comprises the update of the available data on nutrients from Contracting Parties (e.g. by the 5th HELCOM Pollution Load Compilation and EMEP data an atmospheric nitrogen), and a further improvement of MARE NEST, e.g. by incorporation of more indicators in addition to water transparency.

2.3. Barcelona Convention for the Protection of the Mediterranean Sea Against Pollution

2.3.1. Aims of the Barcelona Convention and the Mediterranean Action Plan

387. The Mediterranean Action Plan (MAP) was adopted by 16 Mediterranean countries and the European Community in 1975. In 1976 these Parties adopted the Convention for the Protection of the Mediterranean Sea Against Pollution (Barcelona Convention). Seven Protocols have completed the initial MAP legal framework intended to address different aspects of the environmental conservation in the Mediterranean Sea.[94] In 1995 Phase II of the MAP Programme and at the same time an amended version of the Barcelona Convention were adopted.

388. The assessment and control of marine pollution, the protection of the environment through prevention and reduction of pollution and, as far as it is feasible, the elimination of pollution, are amongst the main objectives of the Convention.

2.3.2. MED POL work on eutrophication

389. Within the MAP structure, the MED POL Programme is the pollution assessment and control component. It is responsible for the work related to the implementation of the protocols dealing with pollution from land-based activities and sources[95], dumping[96] and hazardous wastes.[97] MED POL assists Mediterranean countries in the formulation and implementation of pollution monitoring programmes, including pollution control measures and action plans to eliminate pollution from land-based sources

---

94 Institutional and legal information and texts on the Mediterranean Action Programme, the Barcelona Convention and the Protocols cand be found at: http://www.unepmap.org/index.php

95 Protocol for the Protection of the Mediterranean Sea against Pollution from Land-Based Sources and Activities, accessible at: http://195.97.36.231/dbases/webdocs/BCP/ProtocolLBS96_eng_P.pdf

96 Protocol for the Prevention of Pollution in the Mediterranean Sea by Dumping from Ships and Aircrafts, accessible at: http://195.97.36.231/dbases/webdocs/BCP/ProtocolDumping76_Eng.pdf

97 Protocol on the Prevention of Pollution of the Mediterranean Sea by Transboundary Movements of Hazardous Wastes and their Disposal, accessible at: http://195.97.36.231/dbases/webdocs/BCP/ProtocolHazardousWastes96_eng.pdf

390. Activities carried out within the programme have contributed to improving the information on the presence of nutrients in the Mediterranean. Many activities have taken place over different phases, according to the recommendations and decisions of the Parties to the Convention. They encompassed for instance the upgrading of technical facilities, the development of national monitoring projects or the construction of a data base on nutrient values that are available for a number of Mediterranean countries.

2.3.3. Monitoring under MED POL

391. The MED POL Programme has been responsible of the preparation of an **indicator-based monitoring strategy on eutrophication**,[98] finally endorsed by the Conference of the Parties in 2003. The MED POL Strategy of Eutrophication Monitoring in Mediterranean coastal waters uses a stepwise approach:

1. The first step of the implementation of the strategy in the short-term is the classification of the sites to be monitored within individual pilot projects, as being eutrophic or sensitive to eutrophication.

   Three different site typologies were proposed to provide a common approach for the selection of sites (an affected marine site together with a reference site, an off-shore fish farm and a coastal lagoon). In addition, the concerned countries would make use of other general criteria such as representativity, sensitiveness to eutrophication phenomena and availability of basic information on the main hydromorphological parameters as well as associated historical records of ecological events and socio-economical trends in land use.

   The monitoring parameters adopted were selected as to fulfil the minimum necessary scientific requirements and also to support the state indicators developed by the European Environment Agency as well as the TRIX index. A number of parameters to be monitored were also specified:

   - Temperature (C°) Dissolved oxygen (mg/L, %)
   - PH Chlorophyll a (μg/L)
   - Transparency Total Nitrogen (N μmole/L)
   - Salinity (psu)
   - Nitrate (NO_3-N μmole/L, μg/L)
   - Orthophosphate (PO_4-P μmole/L, μ g/L)
   - Ammonium (NH_4-N μmole/L, μg/L)
   - Total phosphorus (P μmole/L, μg/L)
   - Nitrite (NO_2-N μmole/L, μg/L)
   - Silicate (SiO_2 μmole/L)
   - Phytoplankton (total abundance, abundance of major groups, bloom dominance)

   Minimum requirements as regards the sampling strategy, frequency and spatial coverage were also defined.

98 The details of the programme and the background evaluation can be found in the document UNEP(DEC)/MED WG.231/14, accessible at: http://195.97.36.231/acrobatfiles/03WG231_14_eng.pdf

2. For a medium/long term strategy the development of new biological parameters/indicators of eutrophication was proposed. It was needed to introduce biological parameters both for the phytoplankton population dynamics and for the benthic component of the coastal ecosystem.

   In addition, the importance of historical data to reconstruct the story of the site and support the assessment and management of the area according to integrated coastal zone management approaches, recommended their collection and assessment, although was not considered mandatory.

392. The implementation of this strategy was revised in 2005[99].

2.3.4. Thematic eutrophication assessment

393. The Trophic Index TRIX, the assessment method adopted in the MEDPOL Programme, is defined by a linear combination of the logarithms of four state variables: chlorophyll *a* (ChA), oxygen as absolute percent deviation from saturation (aD%O), mineral nitrogen (min N) and total phosphorus (TP) (Vollenweider et al., 1998). The TRIX Index is a numeric expression which provides a direct measure of trophic levels, it works as a multimetric index, and moreover it offers the advantage of utilising, as components, environmental variables directly measured and routinely collected, and it is an index in compliance with WFD requirements. TRIX has also been applied to the assessment of transitional waters (for more information, see Chapter 5.4.1 of this Guidance).

394. The TRIX Index has been tested in different areas of the Mediterranean Sea, e.g. in the Adriatic and the Tyrrhenian Sea (Giovanardi & Vollenweider, 2004).

2.3.5. Overview of the state of eutrophication in the Mediterranean Sea

395. In 2007, MED POL presented an **overview of the state of eutrophication in the Mediterranean Sea**.[100] The information came from the responses from Mediterranean countries to a relevant questionnaire, the results of pilot projects carried out within the Monitoring Strategy, and a literature survey. All this information is used to present drivers and pressures related to eutrophication as well as eutrophication state and impact (DPSIR approach) in the Mediterranean by region or country. Remote sensing data are also used.

396. On the basis of the information received through the questionnaires, it was concluded that very few countries follow the MED POL monitoring strategy and that most countries prefer to follow their own monitoring strategies and assessment methods. Following this conclusion, the challenge for the MED POL and the countries is the harmonization of the monitoring strategies and assessment methods on a basin-wide scale.

[100] See document UNEP(DEPI)/MED WG.321/Inf.6, accessible at: http://195.97.36.231/acrobatfiles/07WG321_Inf6_eng.pdf

397. The Conference of the Parties in 2008 endorsed the MED POL proposal to continue eutrophication monitoring, building upon the strategies developed and tested in the initial phase through pilot projects. The strategies would be re-evaluated and if necessary modified after further implementation.

2.4. Bucharest Convention on the Protection of the Black Sea Against Pollution

2.4.1. Aims of the Bucharest Convention[101]

The Convention on the Protection of the Black Sea Against Pollution was signed in Bucharest on 21 April 1992 and ratified by all six legislative assemblies of the Black Sea countries (Bulgaria, Georgia, Romania, the Russian Federation, Turkey and Ukraine) in the beginning of 1994. The basic objective of the Convention is to prevent, reduce and control the pollution in the Black Sea in order to protect and preserve the marine environment and to provide the legal framework for cooperation. One of the main specific objectives is to reduce and control the pollution from land-based sources.

2.4.2. Work on eutrophication

The decrease in the importance of agriculture as an economic powerhouse of the region has been clearly shown by decreasing trends in livestock numbers and a shift from major livestock farms to smaller-scale or subsistence-level farming. However, indicators suggest that this decline in agricultural productivity may have bottomed-out, so a gradual re-intensification of agricultural practices my begin in the near future.

Direct discharges from large municipal/industrial plants to the Sea are equivalent to only a small proportion of nutrients discharged to the Sea via rivers, of which the Danube is by far the most important. Available information also suggests that atmospheric deposition of nitrogen to the Sea may be of a similar order of magnitude to river loads, but there is considerable uncertainty over the data used, with a clear need for updating and harmonisation of monitoring protocols.

Based on the data reported by the Black Sea coastal states and the results presented in the 2007 Black Sea Transboundary Diagnostic Analysis, it is suggested that more than 80 % of the river-borne inorganic nitrogen load and around 50 % of the river-borne phosphate load enters the Sea from the Danube. However, the Danube has by far the most rigorous nutrient loads monitoring programme of all rivers, and it is likely that nutrient loads from other rivers are under-estimated by comparison. The importance of freshwater nutrient inflows to the Sea of Azov could not be estimated because of a lack of data for the Kerch Strait.

Between 1996 and 2005 there has been no evidence of a change in river-borne DIN loads to the Sea, albeit with a moderate (15 %) decrease in river-borne PO_4-P loads over the same period. However, the level of confidence associated with the PO_4-P lead decrease is very low, due to the large inter-annual variability.

---

2.4.3. Monitoring of the Black Sea

In the frame of the Black Sea Integrated Monitoring and Assessment Programme nutrients are monitored in water, sediment and biota.

2.4.4. The Strategic Action Plan for the Protection and Rehabilitation of the Black Sea

The first Strategic Action Plan for the Rehabilitation and Protection of the Black Sea was signed in Istanbul on 31 October 1996, and amended in 2002. Based on the existing cooperation and the previous action plan, a new Strategic Action Plan for the Environmental Protection and Rehabilitation of the Black Sea was adopted in Sofia, Bulgaria on 17 April 2009. It focuses on concerted action to assist in the continued recovery of the Black Sea and describes the policy actions required to meet the major environmental challenges now facing the Sea, and includes a series of management targets. Ecosystem Quality Objectives (EcoQOs) have been developed as long-term management objectives. One of these objectives is to reduce eutrophication.

ANNEX 2: INDICATIVE CHECKLISTS FOR WATER CATEGORY-SPECIFIC FEATURES OF THE IMPACT OF EUTROPHICATION

398. The following tables are the complete water category-specific checklists developed during the Eutrophication Workshop in Ispra in September 2004.

RIVERS – Checklist for a holistic assessment

The qualitative assessment parameters are:

a. The causative factors:

The degree of nutrient enrichment:
- With regard to inorganic/organic nitrogen
- With regard to inorganic/organic phosphorus

Taking account of:
- Sources (differentiating between anthropogenic and natural sources)
- Increased/upward trends in concentration
- Elevated concentrations
- Change in N/P ratios
- Fluxes and nutrient cycles (including internal nutrient loading, direct and atmospheric inputs).
- Changes in hydromorphology.

b. The environmental factors:
- Light availability (irradiance, turbidity, suspended load, shading)
- Hydromorphology (e.g. water depth, velocity, flood frequency, substrate type and mobility, stratification, deposition)
- Climatic/weather conditions (rainfall, temperature)
- Chemical status (e.g. suppression of algae growth by pesticides).

c. The direct effects of nutrient enrichment/eutrophication:

i. Phytoplankton;
- Increased biomass (e.g. chlorophyll a, organic carbon and cell numbers or volume)
- Increased frequency and duration of blooms
- Increased annual primary production
- Shifts in species composition (e.g. from diatoms to green algae or cyanobacteria some of which are nuisance or toxic species)

ii. Macrophytes;
- Increased biomass
- Shifts in species composition (from long-lived species to short-lived species, some of which are nuisance species)
- Reduced depth distribution

iii. Phytobenthos
- Increased biomass
- Increased aerial cover on substrate
- Shifts in species composition (e.g. from diatoms to green algae or cyanobacteria)

d. The indirect effects of nutrient enrichment/eutrophication

i. organic carbon/organic matter;
- Increased dissolved/particulate organic carbon concentrations
- Occurrence of foam and/or slime
- increased concentration of organic carbon in sediments (due to increased sedimentation rate)

ii. oxygen;
- Decreased concentrations and saturation percentage
- Increased frequency of low oxygen concentrations
- More extreme diurnal variation
- Occurrence of anoxic zones at the sediment surface ("black spots")

iii. Fish;
- Mortalities resulting from low oxygen concentrations
- Changes in species composition
- Changes in abundance
- Disruption of migration or movement

iv. benthic invertebrate community;
- Changes in abundance
- Changes in species composition
- Changes in biomass

v. Increased growth and biomass of benthic heterotrophic organisms, such as fungi and bacteria

e. Other possible effects of nutrient enrichment

i) Algal toxins (still under investigation, the recent increase in toxic events may be linked to eutrophication).

ii) Amenity values compromised e.g. clogging of pipes and filters, build up of iron deposits due to low DO, amenity value of the river.

LAKES – Checklist for a holistic assessment

The qualitative assessment parameters are:

a. The causative factors:

The degree of nutrient enrichment:

With regard to total and inorganic/organic nitrogen
With regard to total and inorganic/organic phosphorus
With regard to silicon

Taking account of:

Sources (differentiating between anthropogenic and natural sources)
Increased/upward trends in concentration
Elevated concentrations
Changed N/P, N/Si, P/Si ratios
Fluxes and nutrient cycles (including *internal nutrient loading,* across boundary fluxes, recycling within environmental compartments and riverine, direct and atmospheric inputs)

b. Typology factors and other pressures:

Typology factors (alkalinity, colour, depth, size etc.),
Other pressures (hydromorphological impacts and anthropogenic toxic substances)
Light availability (irradiance, mineral turbidity, suspended load)
Hydrodynamic conditions (e.g. stratification, flushing, retention time,)
Climatic/weather conditions (wind, temperature, wet and dry deposition)
Zooplankton grazing (which may be influenced by other anthropogenic activities)

c. The direct effects of nutrient enrichment:

i. Phytoplankton;

Increased biomass (e.g. chlorophyll a, organic carbon and cell numbers)
Increased frequency and duration of blooms
Increased annual primary production
Shifts in species composition (e.g. from *chrysophytes and* diatoms to flagellates */cyanobacteria*, some of which are nuisance or toxic species)

ii. Other aquatic flora, including macroalgae *(such as Characeans)*;

a) Submerged macrophytes:

Changes in biomass (can also be decreased in lakes due to light limitation)
Changes in species composition (, some of which are nuisance species)
Reduced depth distribution

b)phytobenthos;

Increased biomass and primary production, and changes in taxonomic composition

d. The indirect effects of nutrient enrichment

i. organic carbon/organic matter;

Increased dissolved/particulate organic carbon concentrations
Occurrence of foam and/or slime
increased concentration of organic carbon in sediments (due to increased sedimentation rate)

ii. oxygen;

Decreased concentrations and saturation percentage in bottom water and under icecover
Increased occurrence of low oxygen concentrations in bottom water and under icecover
Increased consumption rate
Occurrence of anoxic zones at the sediment surface (“black spots”)
Oversaturation of oxygen in surface water

iii pH increase in littoral zone and surface layers

iv. reduced top-down control of primary producers (reduced grazing by zooplankton and benthic fauna)

v Littoral and profundal macroinvertebrates;

Changes in abundance and species composition

vi. Fish;

Changes in abundance
Changes in species composition (from salmonids and coregonids to perchids and cyprinids)
Changes in age structure
Fish kills

COASTAL/TRANSITIONAL WATERS – Checklist for a holistic assessment

The qualitative assessment parameters are:

a. The causative factors:

The degree of nutrient enrichment:
- With regard to inorganic/organic nitrogen
- With regard to inorganic/organic phosphorus
- With regard to silicon

Taking account of:
- Sources (differentiating between anthropogenic and natural sources)
- Increased/upward trends in concentration
- Elevated concentrations
- Changes in N/P, N/Si, P/Si ratios
- Fluxes and nutrient cycles (including across boundary fluxes, recycling within environmental compartments and riverine, direct and atmospheric inputs)

b. The supporting environmental factors:
- Light availability (irradiance, turbidity, suspended load)
- Hydrodynamic conditions (stratification, flushing, retention time, upwelling, salinity gradients, deposition)
- Climatic/weather conditions
- Zooplankton grazing (which may be influenced by other anthropogenic activities)
- Coastal morphology
- Typology factors for coastal waters

c. The direct effects of nutrient enrichment:

i. Phytoplankton;
- Increased biomass (e.g. chlorophyll a, organic carbon and cell numbers)
- Increased frequency and duration of blooms
- Increased annual primary production
- Shifts in species composition (e.g. from diatoms to flagellates, some of which are nuisance or toxic species)

ii. Macrophytes including macroalgae;
- Increased biomass
- Shifts in species composition (from long-lived species to short-lived species, some of which are nuisance species)
- Reduced depth distribution

iii. Microphytobenthos;
- Increased biomass and primary production

d. The indirect effects of nutrient enrichment

i. organic carbon/organic matter;
- Increased dissolved/particulate organic carbon concentrations
- Occurrence of foam and/or slime
- increased concentration of organic carbon in sediments (due to increased sedimentation rate)

ii. oxygen;
- Decreased concentrations and saturation percentage
- Increased frequency of low oxygen concentrations
- Increased consumption rate
- Occurrence of anoxic zones at the sediment surface (“black spots”)

iii. zoobenthos and fish;
- Mortalities resulting from low oxygen concentrations

iv. benthic community structure;
- Changes in abundance
- Changes in species composition
- Changes in biomass

v. Ecosystem structure;
- Structural changes

e. Other possible effects of nutrient enrichment

i) Algal toxins (still under investigation, the recent increase in toxic events may be linked to eutrophication)

Foreword

In the context of the WFD Common Implementation Strategy, an activity on Climate Change and Water was initiated in 2007 to produce guidance on how Member States should incorporate consideration of climate variability and change into the implementation of EU water policy. In 2008, the Water Directors discussed and agreed key policy messages on Climate Change and Water.[1] These focused on the following topics:

– EU water legislation and its ability to allow and support adaptation to climate change.

– The importance of integration with other policies.

– WFD and objective-setting under a changing climate.

– How adaptation is addressed in the 1st RBMPs.

– The role of adaptation in the 2nd and 3rd river basin management cycles.

This EU guidance builds upon these policy messages and is a mentioned as a priority action in the EC's White Paper on Adapting to Climate Change (2009).

It has been discussed with a wide range of stakeholders and experts in the framework of the Common Implementation Strategy, and it reflects the important role of water managers in adapting to climate change.

This guidance intends to give support to river basin managers in incorporating climate change in the next river basin management cycles. Further work may be needed and will be undertaken in the Common Implementation Strategy.

Executive Summary

Introduction

1. Europe's fresh, transitional and marine waters have been affected by centuries of deliberate management as well as by the unintended consequences of changes in land-use, water abstraction and pollution. Without proactive measures, the continent's water bodies may be further modified by growing pressures from the direct and indirect effects of climate variability and change.
2. Climate change is projected to lead to major changes in yearly and seasonal precipitation and water flow, flooding and coastal erosion risks, water quality, and the distribution of species and ecosystems. Models indicate that at a general level the south of Europe will show a significant drying trend and the north of Europe one of wetting. At a regional scale, the patterns of potential changes can be rather diverse. These changes will most likely become significant in the second half of this century.
3. The European Commission White Paper *Adapting to climate change; Towards a European framework for action* (COM/2009/147) calls for a more strategic approach to climate change adaptation across different sectors and levels of governance. It calls for guidance to integrate climate change adaptation into implementation of the EU water policy. This is also recommended by the European Water Directors.
4. Several existing European Union (EU) policies address water management issues. The most important are the EU Water Framework Directive (WFD) and its daughter directives, the EU Floods Directive, and the EU Water Scarcity and Droughts Strategy. Collectively, these provide legal instruments for protecting and restoring the water environment, as well as steps that can be taken to reduce risks to human health, cultural heritage and economic activity.
5. Although climate change is not explicitly included in the text of the WFD, the step-wise and cyclical approach of the river basin management planning process makes it well suited to adaptively manage climate change impacts. This approach means that we can revisit plans to scale up or down our response to climate change in accordance to monitored data, and can avoid over-investment now. On the other hand, it is important that long term climate projections are built in to the design of measures (driven by current pressures) that have a long design life and high costs. As such, inclusion of climate change in assessment of pressures is important.
6. In addition the river basin management planning process is the best mechanism through which to balance available water resources and demands, thus avoiding long term water scarcity, and provides clear links to the management of flood risk in catchments, which is specifically addressed through requirements in the Floods Directive.
7. The purpose of this Guidance Document is to illustrate ways in which preparations can be made for climate change within the second and third River Basin Management Planning (RBMP) cycles, including provision for floods and droughts. As a minimum, this will require Member States to clearly demonstrate how climate change projections have been considered in the assessment of pressures and impacts, monitoring programmes and appraisal of measures.
8. This Guidance Document describes guiding principles for adaptation, and relates each to steps in RBMP. The principles are intentionally broad to be applicable across all Member States regardless of regional variations in potential impacts. Where feasible, entry points have been identified within existing processes and frameworks. Examples

are provided to show how the principles might be applied in practice. This guidance document is not focused around climate change mitigation measures, although some principles related to integration of different sectors are also applicable to specific mitigation measures such as measures related to renewable energy. Moreover, there is a potential for win-win solutions contributing both to mitigation and adaptation.

9. The Guidance is conveyed in five blocks that explain: (1) how to handle available scientific knowledge and uncertainties about climate change; (2) how to develop strategies that build adaptive capacity for managing climate risks; (3) how to integrate adaptive management within key steps of the RBMP of the WFD; and how to address the specific challenges of managing future (4) flood risk and (5) water scarcity.

10. This Guidance is endorsed by Water Directors. It is aimed at those with responsibility for river basin management, including flood and drought risk management, for delivery of the second and third RBMP cycles (from 2015 until 2027). This will require a combined approach that balances action on monitoring and understanding climate-driven impacts, with implementing no regret actions to improve resilience and ensuring that long life-time investments are climate resilient.

Handling scientific knowledge and uncertainties about climate change

11. Projections of future climate change are obtained from global climate models. These use mathematical equations to characterize fundamental processes involving the transfer of heat, mass, momentum and water vapour amongst major earth systems (such as the ocean, atmosphere, hydrosphere and cryosphere).

12. Depending on the assumed greenhouse gas emissions scenarios and approximations used to represent some natural processes (such as cloud formation), climate change projections can diverge significantly over the second half of the 21st century. However, over the next few decades, the outlook for temperature is largely independent of the emissions scenario because it will be dominated by natural variability and the response of the oceans to past emissions.

13. Over the longer term, major changes in annual water availability are expected across Europe. In general, water availability is projected to increase in northern regions, although summer river flows may decrease. Southern and south eastern parts of Europe, which already suffer water stress, could experience reductions in water resources due to increased frequency and intensity of droughts. On the other hand, increasing intensities of heavy rain events are projected to increase peak river flows across some parts of the continent. Several European research projects focus on better predicting these future trends.

14. Although there are regional variations, upward trends in surface air and water temperatures are projected for Europe. However, temporary cooling is still expected to occur in individual years and decades due to natural climate variability. Projections of changes in precipitation and flows at the river basin scale are less certain, due to large natural variability in these quantities, as well as the limitations of climate models, and assumptions used to downscale information between climate and hydrological models.

15. Potentially all elements included in the definition of WFD qualitative and quantitative status of water are sensitive to climate change. This includes: water availability (river flows and groundwater levels); water demand (especially peak demands during droughts); intensity and frequency of extreme events (floods and low flow episodes); water quality (including temperature, salinity, nutrient and contaminant concentrations.

sediments); and biodiversity of aquatic ecosystems. However, disentangling the effects of climate factors from other changes will continue to be difficult.

16. Given deep uncertainty about regional climate change projections and realised impacts on aquatic ecosystems, RBMP should incorporate management strategies that deliver benefits regardless of the climate outlook. Robust and adaptive RBM measures are low regret, or reversible, incorporate safety margins, employ 'soft' solutions, are flexible, and mindful of the actions being taken by others to either mitigate or adapt to climate change.

17. In practice this means embracing uncertainty by analysing the performance of river basin management plans against the projections of a wide range of climate model and emissions scenarios. Through sensitivity testing it should then be possible to establish which individual or combinations of measures are most effective at achieving water management objectives.

Developing strategies that build adaptive capacity for managing climate risks

18. According to the Intergovernmental Panel on Climate Change (IPCC), adaptive capacity may be defined as the *ability to cope, adapt or recover from the effects of a hazard* (in this case, climate change). Examples of steps that can be taken to build adaptive capacity include: increasing knowledge of potential climate risks for individual river basins; strengthening data collection and knowledge exchange amongst key stakeholders; cross-sectoral integration and partnership working; awareness raising education and training.

19. National and regional climate risk assessments can provide valuable contextual information for individual river basins. Information inventories and meta-analysis can also help pool evidence of observed or anticipated water sector impacts at basin scales. Furthermore, existing work may point to potential transboundary impacts and adaptation options, or good-practice case studies and implementation experience that can be shared amongst neighbours.

20. Reviews of existing knowledge may highlight information gaps that can only be filled by extending data collection and monitoring programmes. However, any consideration of data requirements should be anticipatory of changed patterns of climate pressures and receptor responses. Likewise, long-term monitoring will be needed to track emerging risks and to evaluate the effectiveness of any adaptation interventions.

21. Meaningful and early stakeholder engagement can improve the chance of acceptance of measures and hence the delivery of an integrated, cross-sectoral adaptation strategy. This will also help to minimize potential cross-sectoral conflicts whilst maximising possible synergies between adaptation plans. Therefore, effective lines of communication and coordinated action should be established at all levels of management within the River Basin District (RBD).

22. All water related sectors should be well-informed about the possible impacts of climate change. This might require further training and professional development in climate change science, or forums to enable knowledge transfer between organisations, and broadening of the audience through the public participation processes of the WFD and the Floods Directive.

23. Transboundary river basins pose especially complex challenges with regard to the building of adaptive capacity for climate change. Joint bodies such as international river basin commissions should oversee the development of coordinated adaptation strategies and put in place mechanisms for implementing and monitoring measures.

This may require more technical capacity and foresight needed to undertake such tasks.

Integrating adaptation within key steps of River Basin Management Planning

24. As noted before, the underpinning rationale and processes of the WFD are amenable to the delivery of adaptation. In particular, the integrated approaches to land, water and ecosystem management, combined with the cyclical review process, are all consistent with the ideals of adaptive management. Steps in the RBMP process provide a convenient structure for incorporating adaptation to climate change through: risk appraisal, monitoring and assessment, objective setting, economic analysis and Programmes of Measures (PoMs) to achieve environmental objectives.

25. The Guiding Principles summarised below are intended to help river basin managers to take well informed decisions that are proportionate and robust, given acknowledged uncertainties in regional climate change impacts. Where feasible, "no-regret", or "win-win" measures should be adopted as these yield beneficial outcomes regardless of the eventual outcomes of climate variability and change.

26. As a minimum Member States should clearly demonstrate in the second and third cycle RBMP how climate change projections have informed assessments of WFD pressures and impacts; how monitoring programmes are configured to detect climate change impacts; and how selected measures are as robust as possible to projected climate conditions.

27. Apart from exceptional circumstances, it is not expected that, within the timeframe of WFD implementation (i.e., up to 2027), and within the metrics used for status assessment, that a climate change signal will be statistically distinguishable from the effects of other human pressures at a level requiring reclassification of sites. It is more likely that indirect pressures arising from human responses to climate change – both adaptation and mitigation - will have a greater impact (such as elevated water abstractions for irrigated agriculture, new flood defence infrastructure or effects on water quality and quantity of intense production of energy crops).

28. The following sections provide additional commentary on key guiding principles included in the Guidance. These 11 key guiding principles are considered most useful for river basin managers who want to get acquainted with principles of adaptation in water management in a general way. For additional guiding principles, and for more detailed commentary, suggested actions, case studies and examples the reader is referred to the main body of the guidance.

29. <u>Principle 1: Assessing direct and indirect climate pressures</u>. Member States are required to carry out a review of the impact of human activities on the status of surface and ground waters (e.g., point and diffuse source pollution, abstraction). Potentially all such pressures will be sensitive to climate change, therefore, it is helpful to distinguish between primary and secondary pressures. The former describe direct links between climate driver(s) and natural system response(s) (e.g., increased metabolic rates due to higher water temperatures, more frequent flushing of sewer outflows). Secondary pressures arise from indirect links to climate change due to societal responses (e.g., increase storage to avert water scarcity). Risk assessments that are too narrowly focused on existing pressures within river basins may overlook important but physically remote, indirect or longer-term drivers of water body status.

30. <u>Principle 2: Detecting climate change signals</u>. Monitoring data will be needed to identify and react to climate change signals as they emerge, so it is important to assess how

best use can be made of available data from existing networks, and that sites with relevant long data records are sustained over coming years as part of wider surveillance efforts. Knowledge of when and where climate change might be first detected can help target investigative monitoring and reporting of effects in the most vulnerable water bodies (i.e., "hot spots"). Climate change indicators can be deployed that improve the chance of early detection, and hence the lead-time for invoking adaptive measures.

31. Principle 3: Monitoring change at reference sites. Human activities and climate changes at the river basin scale may have similar outcomes in the quality elements used for status assessment. Therefore, robust information on changes at reference sites – locations that by definition are subject to limited anthropogenic modification – is the primary means of isolating the two sets of impacts.

32. Principle 4: Setting objectives. Although the use of exemptions is an integral part of RBMP, applying exemptions without justification in line with the WFD cannot be seen as a general strategy for coping with the consequences of climate variability and change. Therefore, climate change should only be used as justification for exemptions where there is convincing evidence and certainty that climate projections will combine with a lack of proportionate and feasible measures to require lower than default objectives to be set.

33. Principle 5: Forecasting the economics of water supply and demand. Sequential steps in the economic analysis of the WFD should be followed, but with the integration of potential additional pressures, impacts and constraints due to climate change. The value of water could be affected as the balance between supply and demand is reconfigured. Therefore, economic analyses should identify the most cost-effective combinations of measures under a plausible range of climate change and water supply-demand scenarios.

34. Principle 6: Checking the effectiveness of measures. Due to the fact that substantial financial resources will be invested within coming river basin management cycles, and that many measures will have a long lifespan and/or preclude future adjustments, Member States/RBD authorities have to screen for potential effects by undertaking a "climate check" of the PoMs. This check should involve a sensitivity analysis of the proposed measure or group of measures to evaluate long-term effectiveness and cost-efficiency under changing conditions. If it is found that the measure(s) are potentially sensitive to the anticipated climate change, then the measure should be re-evaluated and adjusted accordingly. Preferred options will be able to cope with a range of climate conditions or are sufficiently flexible to be adapted to changing conditions. The methodology of the climate check should be fully transparent and documented so that the process can be replicated should new or improved evidence of future climate risks become available. Monitoring programmes should also be in place to verify or amend the findings of the climate check.

35. Principle 7: Favouring robust adaptation measures. Proactive adaptation measures may be required if climate change threatens to jeopardise the achievement of WFD objectives. In practice, other, non-climatic pressures are more likely to be of concern over the course of the second and third RBMP cycles. Therefore, the first priority should be to establish/safeguard monitoring programmes that will help benchmark and track long-term climate change impacts as they materialise. Indeed, monitoring and reporting are crucial elements of any adaptive management system. However, if investments are being planned for infrastructure with long life spans it is prudent to favour measures that are resilient to a wide range of plausible climate conditions. Ideally these measures should also work with natural processes and realise multiple

benefits (e.g., for flood risk management, drought management, nature conservation, navigation and recreation.

36. Principle 8: Maximise cross-sectoral benefits and minimise negative effects across sectors. Robust adaptation measures will also make provision for the actions being taken by others to either mitigate or adapt to climate change. For instance, policies intended to reduce greenhouse gas emissions could lead to hydropower development or biomass cultivation with potentially significant consequences for aquatic ecosystems. On the other hand measures taken to improve water status through waste water treatment or reuse, artificial recharge of aquifers, inter-basin transfers, and so forth, imply higher energy consumption and greenhouse gas emissions. The main body of the guidance offers criteria to help select adaptation measures that are effective and cost-efficient, yet minimise side-effects, promote equity, and are technically and socially feasible within the implementation time-scale. Land use planning is an important tool in preventing long term negative effects.

37. Principle 9: Apply WFD Article 4.7. In the event that no *significantly better environmental options* exist, and all practicable steps have been taken to minimise the adverse effect of the proposed measure, WFD Article 4.7 may be invoked. This provides the possibility of exemption from achieving good status when a physical alteration to a water body is deemed to offer benefits that outweigh the costs to the environment.

38. Principle 10: Flood risk management: Start adapting flood risk management to potential climate change as soon as possible, when information is robust enough since full certainty will never be the case. Follow the guiding principles set out for the WFD.

39. Principle 11: Drought management and water scarcity: Use the Water Framework Directive as the basic methodological framework to achieve climate change adaptation in water scarce areas and to reduce the impacts of droughts.

Specific issues relating to flood risk

40. Future changes in the intensity and frequency of extreme precipitation events, combined with changing land use, are expected to cause an increase in flood risk across much of Europe. The Flood Directive shares many features of the WFD, such as the cyclical approach to risk assessment, preparation of management plans, and consultation process. However, what distinguishes the Flood Directive from the WFD is that the risk assessment places safety issues at the centre. Many of the above mentioned guiding principles are therefore directly applicable to flood management.

41. The Flood Directive further highlights the need for coordinated action on climate change throughout the RBD, particularly where there are transboundary or shared flood risk issues. Some information collected under the WFD is of relevance to flood management. The Preliminary Flood Risk Assessment also requires that past floods are taken into account, so efforts to homogenize and remove biases from river flow records will be helpful to trend detection more generally.

42. WFD and flood risk management objectives potentially overlap in several places with respect to climate change. For example, more frequent floods can have benefits for aquatic ecology, soil fertility, groundwater recharge and biodiversity. WFD Article 4.6 makes provision for temporary deterioration in the case of extreme floods, but should not be used by Member States as a means of avoiding obligations under the Directive.

As noted above, WFD Article 4.7 refers to possible exemptions for new infrastructure projects.

Specific issues relating to water scarcity

43. Climate change is expected to aggravate the structural problems that already lead to water scarcity in some European countries. However, a distinction should be made between drought and water scarcity: – the former refers to a temporary deviation of the natural water cycle from the long-term average; the latter to a long-term, systemic imbalance between water supply and demand. Both supply and demand have the potential to affect the status of water bodies as the frequency, duration and intensity of droughts could change in the future.

44. River Basin Management Plans required by the WFD offer considerable potential for addressing the consequences of drought and water scarcity issues. The planning process provides scope for analysing pressures, setting objectives and establishing cost-effective counter measures. For example, achieving good groundwater quantitative status may require rebalancing of abstraction and recharge of groundwater. Measures to achieve these objectives may include economic instruments such as water pricing, and other incentives to use water resources more efficiently. As with the Floods Directive, WFD Articles 4.6 and 4.7 may also be invoked, but in this case, for respectively unforeseen prolonged droughts and new infrastructure designed to tackle water scarcity.

45. Given the high degree of uncertainty in climate change projections and the growing pressure on water resources, it is essential that hydrometric networks are in place to monitor droughts, and that the causes for water scarcity are thoroughly diagnosed, e.g. to monitor water demand and long-term trends in water supply.

46. A further priority is to intensify efforts to manage demand and thereby reduce pressure on water supply sources, especially in times of droughts. The greatest scope for action is in reducing irrigation demands which usually account for the largest fraction of total demand in water scarce regions. Other measures include reducing leakage in water distribution networks, wastewater recycling, and market-based instruments. Further robustness can be built into water resource systems by integrating multiple sources of supply and demand in conjunctive schemes, whilst the potential consequences for water ecosystems have to be considered thoroughly.

47. The above common concerns underline the need for close coordination and active participation of all interested parties in the river basin and flood risk management process, extending beyond the traditional remit of water managers and engineers, to spatial planners, insurance providers, private and public stakeholders.

1 INTRODUCTION

European freshwaters, transitional and marine waters are already being affected by many human activities, e.g. due to land-use, water abstraction and pollution with nutrients and hazardous substances. There are many indications that water resources, which are already under stress from human activities, are highly susceptible to climate change impacts and that climate change may hinder attempts to prevent deterioration and/or restore some water bodies to good status. Climate change is projected to lead to major changes in yearly and seasonal water availability across Europe in the long run, and an increase in extreme river flows is projected for large parts of Europe.

However, on the basis of current knowledge, it is unlikely that within the timeframe of the Water Framework Directive (WFD) implementation (i.e. up to 2027), the effects of a climate change signal will be adequately distinguishable from other human pressures and natural variability to the extent that extensive changes in status become necessary. Only in relatively few particularly sensitive cases, is it likely that climate change could impact status assessment in the relatively short term. It is more likely that first climate change related effects on water status are to be expected from adding to the burden of existing anthropogenic pressures on water bodies, such as increased water abstraction because of higher summer temperatures, or increasing diffuse pollution due to increasing rainfall intensities.

What is the purpose of this Guidance?

The present Guidance Document focuses on **how climate change could be integrated into the 2nd and 3rd river basin management (RBM) cycles of the WFD also broadening the scope to floods and droughts**. This EU Guidance was identified as a priority action by the White Paper of the European Commission on "Adapting to climate change: Towards a European framework for action".

Across Member States, consideration of climate change has been introduced to river basin management processes in a largely qualitative way, if at all, for the **1st RBM cycle for the WFD**. In some cases, adaptation has tended to be considered towards the end of the river basin management process. For the 1st cycle, the Policy Paper of the Water Directors placed particular emphasis on ensuring that the Programmes of Measures are sufficiently adaptive to future climate conditions (so-called climate-check of the Programme of Measures, based on available knowledge, data and common sense).

For the **2nd and 3rd RBM cycles for the WFD**, it is expected that climate change should be fully integrated into the process of river basin management. As such the pillars of the approach to adaptation through river basin management under the WFD should be 1) effective long term monitoring (to enable climate change signals to be identified and reacted to in due course), 2) the assessment of the likely additional impact of climate change on existing anthropogenic pressures, and 3) the incorporation of this information into the design of measures (particularly for proposed measures with a long term design life). Thus, it is expected that as a minimum, Member States should clearly demonstrate how climate change projections have been considered in the **pressures & impacts assessment**, in the **monitoring programmes**, and in the **choice of measures**.

Regarding the Floods Directive, climate change should be considered in the first flood risk planning cycle within the preliminary flood risk assessment and based on available information, as well as in subsequent cycles of planning, when carrying out the revision and updating of the preliminary flood risk assessment and the flood risk management plans.

To whom is this Guidance addressed?

This Guidance is aimed at those with responsibility for river basin management, including flood and drought risk management, in particular for delivery of the 2nd and 3rd river basin management cycles of the WFD (from 2015 until 2027).

What to find in this Guidance?

The main chapters of this document (chapters 3-7) follow a similar pattern in terms of the structure of the guidance provided:

Guiding principles

Guiding principles are introduced in text boxes in the beginning of each chapter or key subchapter. The principles are meant to be generally applicable and intentionally broad to be valid across all Member States. The text boxes are followed by more detailed text explaining the principles.

↓

Suggested actions

Following the explanatory texts of the guiding principles, text boxes introduce more concrete and practical actions to be taken in the coming years in order to apply the principles.

↓

Examples

The guiding principles and suggested actions are complemented by examples which intend to show how the principles and actions might be applied in practice. Some of the examples are generic or fictive and no specific source of reference for further information can be given.

The Guidance starts with an overview of the EU policy framework relevant to water issues and climate change as well as reference to relevant adaptation initiatives in the Member States (*chapter 2*).

Chapter 3 provides a concise introduction to the use of models, projections and scenarios as key tools and information sources for those with responsibilities in river basin management to determine the likely impacts of climate change in river basins. Guiding principles are proposed on how to handle uncertainty from models, projections and scenarios in river basin management decision-making.

Going beyond the handling of available scientific knowledge and related uncertainties, *chapter 4* provides guidance on setting up a strategy for building adaptive capacity for management under climate change, serving as a reminder of key aspects such as awareness-raising, stakeholder involvement, proper staff training and cooperation between different levels of authorities and sectors.

Chapter 5 puts forward guiding principles for adaptation to climate change in relation to the key steps in River Basin Management under the WFD (pressure and impact assessment; monitoring and status assessment; objective setting; economic analysis; measures for adaptation related to the WFD).

Chapters 0 and 7 provide specific guidance on flood risk management and drought management under climate change.

Which guiding principles are put forward in this Guidance?

Table 1 gives an overview of the overall guiding principles proposed in the different blocks of this Guidance Document.

Table 1 Overview of guiding principles in this Guidance Document

Issue	Guiding principles
Climate modelling, projections, scenarios, potential impacts and uncertainty (chapter 3)	
Models, projections and scenarios (section 3.1)	1. Climate projections and scenarios should be used for improving river basin management planning. 2. It is crucial to have a clear understanding of the assumptions made and the uncertainties related to these assumptions. 3. The best climate change model or scenario for a certain region or river basin should be decided on a case-by-case basis, because there is no "one-size-fits-all" model or scenario for Europe.
Managing the water environment based on uncertainty of projections and scenarios (section 3.3)	4. Despite uncertainty in models, 'doing nothing' is not an option. For the next river basin management cycle, accept uncertainty where it is rational to do so and take first actions for adaptation to climate change. 5. Take best available scientific information into account. 6. Use a range of climate projections or scenarios in the analyses for river basin management planning in order to accept and work within the context of an uncertain future. 7. Prefer adaptation options which are robust against a range of future changes or postpone commitment to a particular projection of the future by building flexibility into your system.
How to build adaptive capacity for management under climate change? (chapter 4)	
Using ongoing research and adaptation activities to increase knowledge at river basin scale (section 4.2.1)	1. Link river basin management adaptation activities to national and regional climate change adaptation strategies and activities. 2. Check existing relevant science and research information on climate change modelling and impacts in the river basin. 3. Make use of good-practice examples coming, e.g. from existing research and implementation experience regarding adaptation strategies and measures. 4. Look beyond the borders of your river.
Data collection and building of partnerships (section 4.2.2)	5. Evaluate coverage of data (e.g. meteorological, hydrological, water quality, soil moisture data, stake, damage cost data, etc). 6. Use the WFD consultation process (Art. 14) to bring in sector-specific knowledge and data from key stakeholders. 7. Ensure communication and coordination on climate change adaptation issues between different levels of management within an RBD. 8. Work in cross-sectoral partnerships and across administrations. Ensure that climate change aspects are discussed between the relevant public administrations, in stakeholder meetings and discuss how relevant water-related sectors can contribute to adaptation. 9. Make sure to receive information related to the influence of

	climate change on other sectors which are directly related to water management (e.g. agriculture-water demands, water needs for energy production, etc). 10. Integrate cross-sectoral delivery of adaptation measures and coordinate activities with land use planning.
Broadening the audience and increasing its capacities - Awareness-raising, education and training (section 4.2.3)	11. Include the issue of climate change impacts in the river basin in your RBD awareness-raising activities as part of the WFD public participation process. 12. Establish staff training and capacity building programmes on climate change issues, e.g. to introduce staff to climate change modelling, scenarios and projections.
Looking beyond the borders (section 4.2.4)	13. Develop joint or coordinated adaptation strategies in transboundary RBDs.
Water Framework Directive (WFD) and adaptation (chapter 5)	
Assessing pressures and impacts on water bodies (section 5.3)	1. Assess, over a range of timescales, direct influences of climate change and indirect influences where pressures are created due to human activities adapting to climate change.
Monitoring and status assessment (section 5.4)	2. Maintain both surface and groundwater surveillance monitoring sites for long time series. Set up an investigative monitoring programme for climate change and for monitoring climate change "hot spots", and try to combine them as much as possible with the results from the operational monitoring programme. 3. Include reference sites in long term monitoring programmes to understand the extent and causes of natural variability and impact of climate change.
Objective setting (section 5.5)	4. Avoid using climate change as a general justification for relaxing objectives, but follow the steps and conditions set out in the WFD.
Economic analysis of water use (section 5.6)	5. Consider climate change when taking account of long term forecasts of supply and demand and favour options that are robust to the uncertainty in climate projections.
How to do a climate check of the Programme of Measures? (section 5.7.2)	6. Take account of likely or possible future changes in climate when planning measures today, especially when these measures have a long lifetime and are cost-intensive, and assess whether these measures are still effective under the likely or possible future climate changes. 7. Favour measures that are robust and flexible to the uncertainty and cater for the range of potential variation related to future climate conditions. Design measures on the basis of the pressures assessment carried out previously including climate projections. 8. Choose sustainable adaptation measures, especially those with cross-sectoral benefits, and which have the least environmental impact, including GHG emissions.
What to do if other responses to climate change are impacting on the WFD objective of good status? (section 5.7.3)	9. Avoid measures that are counterproductive for the water environment or that decrease the resilience of water ecosystems. 10. Apply WFD Article 4.7 to adaptation measures that are modifying the physical characteristics of water bodies (e.g. reservoirs, water abstractions, dykes) and deteriorate water status. 11. Take all practicable steps to mitigate adverse effects of

	counterproductive measures.
Flood risk management and adaptation (chapter 6)	
Overall guiding principle on flood risk management and adaptation (section 6.1)	1. Start adapting flood risk management to potential climate change as soon as possible, when information is robust enough, since full certainty will never be the case. Follow the guiding principles set out for the WFD.
Preliminary flood risk assessment (section 6.2)	2. Understand and anticipate as far as possible climate change impact on flood patterns. 3. Use best available information and data. 4. Homogenize time series, and remove bias as far as possible. 5. Understand and anticipate as far as possible increased exposure, vulnerability and flood risk due to climate change, for establishing areas of potential significant flood risk
Flood Hazard and Risk Maps (section 6.3)	6. When identifying the different flood scenarios, incorporate information on climate change 7. Present uncertainties surrounding climate change in maps transparently. 8. Use the 6-year review of flood maps to incorporate climate change information
Flood Risk Management Objectives (section 6.4.1)	9. Incorporate climate change in setting flood risk management objectives 10. Ensure coordination at catchment level, also respecting the Directive's coordination requirements at RBD/unit of management level
Awareness raising, early warning, preparedness (section 6.4.2)	11. Include climate change scenarios in ongoing initiatives and in the planning processes.
Measures (section 6.4.3)	12. Perform a climate check of flood risk measures 13. Favour options that are robust to the uncertainty in climate projections a. Focus on pollution risk in flood prone zones b. Focus on non-structural measures when possible c. Focus on "no-regret" and "win-win" measures d. Focus on a mix of measures 14. Favour prevention through the catchment approach 15. Take account of a long term perspective in defining flood risk measures (e.g. with respect to land use, structural measures efficiency, protection of buildings, critical infrastructure, etc). e. Include long-term climate change scenarios in land-use planning f. Develop robust cost-benefit methods which enable taking into account longer term costs and benefits in view of climate change. g. Use economic incentives to influence land use [Link insurance] 16. Assess other climate change adaptation (and even mitigation) measures by their impact on flood risk: h. Hydropower and flow regulation

	i. Link with water scarcity
Links to WFD (section 6.4.4).	17. Pay special attention to the requirements of WFD Article 4.7 when developing flood protection measures 18. Determine on the basis of robust scientific evidence and on a case-by-case basis whether an extreme flood allows for the application of WFD Article 4.6. 19. Pay special attention to the vulnerability of protected areas in view of changed flood patterns
Drought management and water scarcity and adaptation (chapter 7)	
Overall guiding principle on drought management, water scarcity and adaptation (section 7.2)	1. Use the Water Framework Directive as the basic methodological framework to achieve climate change adaptation in areas of water scarcity and to reduce the impacts of droughts.
River basin management plans as a tool for addressing water scarcity and droughts (section 7.2)	2. Make full use of the Water Framework Directive environmental objectives, e.g. the requirement to achieve good groundwater quantitative status helps to ensure a robust water system, which is more resilient to climate change impacts. 3. Determine, on the basis of robust scientific evidence and on a case-by-case basis, whether a prolonged drought allows for the application of WFD Article 4.6, and take into account climate change predictions in this case-by-case approach. 4. Pay special attention to the requirements of WFD Article 4.7 when developing measures to tackle water scarcity under a changing climate and which may cause deterioration of water status.
Monitoring and Detecting Climate Change Effects (section 7.3)	5. Diagnose the causes that have led to water scarcity in the past and/or may lead to it in the future. 6. Monitor water demand closely and create forecasts based on improved knowledge of demands and trends. 7. Collect as much high quality information as possible to anticipate changes in water supply reliability which may be imposed by climate change, in order to detect water scarcity early. 8. Distinguish climate change signals from natural variability and other human impacts with sufficiently long monitoring time series.
Adaptation measures related to water scarcity & droughts (section 7.4)	9. Take additional efforts to prevent water scarcity and be better prepared to tackle the impacts of droughts. 10. Incorporate climate change adaptation in water management by continuing to focus on sustainability (balance between water availability and demand). 11. Follow an integrated approach based on a combination of measures (compared to alternatives based on water supply or economic instruments only). 12. Build adaptive capacity through robust water resources systems. 13. Engage stakeholders to produce decisive measures to tackle water scarcity. 14. Assess other climate change adaptation and mitigation

	measures by their impact on water scarcity and drought risks.

2 WATER AND CLIMATE CHANGE – POLICY FRAMEWORK

Several existing EU policies and initiatives contribute to efforts for adaptation to climate change with regard to water issues. The most important ones are the EU Water Framework Directive (WFD) and its daughter directives, the EU Floods Directive, the Water Scarcity and Droughts EU Policy as well as the EC's White Paper on Adaptation (see following sections for details). These policies and initiatives refer to:

- Building resilience against the added risk of climate change by acting on existing anthropogenic risk,
- Using a cyclic management approach to include increasing knowledge over time on climate change impacts,
- Using the opportunity of implementation of existing initiatives to:
  - restore natural ecosystem function within catchments, in particular the ability of catchments to retain and slowly release water and to degrade pollutants,
  - reduce fragmentation and improve connectivity of habitats to allow species movements,
  - balance ecology and economic developments.

2.1 Introduction to WFD

The **Water Framework Directive** 2000/60/EC (WFD) establishes a legal framework to protect and restore the water environment across Europe by 2015 and to ensure the long-term sustainable use of water. Although climate change is not explicitly included in the text of the WFD, the step-wise and cyclical approach of the WFD river basin management process makes it well suited to handle climate change.

Climate change should be comprehensively considered in the different steps of the WFD implementation and RBM planning and implementation process, such as characterisation, analysis of pressures and impacts, economic analysis, monitoring, design of the programmes of measures and the default and water body objective setting processes (see chapter 5 of this Guidance).

In many cases, climate change impacts may put additional pressure on European water resources. From the Article 5 characterisation reports assessed for the Commission's WFD implementation report in 2007,[2] there were no indications that climate change pressures are significantly putting the achievement of good status at risk in the first RBM cycle. However, it is important that river basin management plans take account of the medium and long-term implications of climate change, as there is a large potential for synergies between WFD objectives and adaptation aims. **Thus the second river basin management plans due in 2015 should be designed to be robust to the impacts of climate change and climate variability.** As such, it must be ensured that measures are either flexible enough to be adjusted appropriately to changing climate conditions or that those of a fixed nature with a longer term design life incorporate climate projections in their design.

[2] COM(2007) 128 final, 'Towards sustainable water management in the European Union' and its Annex SEC(2007) 362

2.2 Introduction to Floods Directive

Besides the WFD, the **Floods Directive** 2007/60/EC also provides a framework for adaptation with regard to water issues. This Directive establishes a legal framework for the assessment and management of flood risks across Member States, aiming at reducing the adverse consequences of floods to the human health, the environment, cultural heritage and economic activity. The Directive requires Member States to produce the first flood risk management plans (FRMPs) in 2015 in those areas for which potential significant flood risk has been assessed. FRMPs should provide adequate and coordinated measures to reduce this flood risk, taking into account the possible impact of climate change. The core elements of the flood risk management cycle are **preliminary flood risk assessment**, **flood hazard and risk maps** and **flood risk management plans**.

In contrast to the WFD, climate change is explicitly included in the Floods Directive, and Member States are clearly expected to take into account the likely impacts of climate change on the occurrence of floods.[3]

In addition, for the implementation of the Floods Directive, co-ordination with the implementation of the WFD is required by its article 9 from the second cycle of the WFD river basin management plans (RBMP) and onwards. There is an opportunity through alignment to deliver alternative more cost-effective and sustainable catchment based approaches that deliver multiple benefits for flood risk management, water scarcity and drought management and river basin management outcomes. The requirement to coordinate the two Directives therefore establishes an appropriate framework for implementation, so that differing and conflicting interests can be properly balanced and maximum synergies gained.

Chapter 0 of this Guidance focuses on how to address the potential changes in flood hazards due to climate change from the first cycle and how - in view of potential increased flood risk - to limit the vulnerability and potential adverse consequences.

2.3 Introduction to water scarcity and droughts policy

The European Commission adopted an official Communication regarding water scarcity and droughts on 18 July 2007 (EC 2007b), which aims to further develop adaptation measures to address expected increasing impacts of water scarcity and droughts in next decades.

The Communication presents a range of possible options for managing the problems of water resource scarcity and drought, and quotes a certain number of good practices existing in various countries thereby stressing that water saving should become the priority; furthermore, it recommends drafting Drought Management Plans, provides support to establish a European Strategy, proposes to establish a European Drought Observatory (under development by JRC) and introduces the possibility of using European funds for countries suffering prolonged droughts.

The Communication recommends that all possibilities to improve water efficiency must be explored, and that policymaking should be based on a clear water hierarchy, i.e. additional water supply infrastructures should be considered as an option when other options have been exhausted. The Council endorsed the Communication and considered it as a fundamental and well-developed first set of policy options for future action, within the framework of EU water management principles, policies and objectives. In particular, the

---

[3] Article 4 (FD) states that the preliminary flood risk assessment shall be based on among other things "impact of climate change on the occurrence of floods" from the first cycle, and article 14.4(FD) makes the consideration of the "likely impact on climate change on the occurrence of floods shall be taken into account in the reviews [of the preliminary flood risk assessment and the flood risk management plans]".

Council stressed that the WFD river basin management plans are the appropriate means to address water scarcity and droughts and that demand side measures should clearly be favoured over supply side measures to the extent possible.[4]

The Guidance at hand emphasises the importance of the common implementation of the WFD and its river basin management plans with the EU policy initiatives on scarcity and droughts. The EU Communication on water scarcity and drought therefore served as a building block for developing the guidance provided in chapter 7 of this document on drought management, water scarcity and adaptation. The follow-up report of the Communication on water scarcity and droughts (EC 2008) shows that, while progress has been made, a great deal still needs to be done in order to improve water demand management more widely across Europe and to avoid mismanagement of water resources, especially in areas of water scarcity.

2.4 EC White Paper on Adaptation

The White Paper of the European Commission "Adapting to climate change: Towards a European framework for action" (COM/2009/147) was issued in April 2009 and sets out a framework to reduce the EU's vulnerability to the impact of climate change.

As efforts are underway to reduce greenhouse gas emissions in the EU, there is further need to take adaptive action in order to deal with the unavoidable climate change and subsequent risks. The White Paper argues that adaptation is already taking place in a piecemeal manner across Europe, therefore a more strategic approach is needed to ensure that timely and effective adaptation measures are taken, ensuring coherency across different sectors and levels of governance.

Next to a number of other fields, the proposed EU framework of the White Paper includes objectives and actions to increase the resilience of EU water systems. Specific emphasis is given to the proper implementation of the WFD, the Floods Directive as well as the Water Scarcity and Droughts Strategy for the delivery of adaptation with regard to water.

The following specific water-related actions (on EU and Member State level) are proposed:

- Develop guidelines and a set of tools (guidance and exchange of best practices) by the end of 2009 to ensure that climate change is built into further implementation of River Basin Management for the WFD.
- Ensure that climate change is taken into account in the implementation of the Floods Directive.
- Assess the need for further measures to enhance water efficiency in agriculture, households and buildings.
- Explore the potential for policies and measures to boost ecosystem storage capacity for water in Europe.
- Look for possibilities to deliver adaptation action which deliver multiple-benefits for flood risk management, water scarcity and drought management and river basin management through better alignment of planning and implementation and catchment based approaches.
- Establishing a Clearing House Mechanism as a database on climate change impact, vulnerability and best practices on adaptation.

---

[4] Water scarcity and droughts - Council conclusions, 13389/07 ENV 486 DEVGEN 170 AGRI 307, Brussels, 15 October 2007.

- Explore possible ways of improving policies and developing measures which address biodiversity loss and climate change in an integrated manner to fully exploit co-benefits and avoid ecosystem feedbacks that accelerate global warming'.
- Draft guidelines on dealing with the impact of climate change on the management of Natura 2000 sites.

2.5 Other relevant EU policies and legislation

The following EU policies are considered relevant for climate change adaptation and river basin management. Some of them include tools to incorporate climate change impacts, others still may need to be refined to contribute to climate change adaptation related to river basin management.

The **EU marine and coastal policy** is also relevant to adapting to climate change with regard to water issues. In particular the Marine Strategy Framework Directive (2008/56/EC), which requires the achievement of good environmental status of the EU's marine waters by 2020, provides an additional planning framework for adaptation. Effective implementation of this Directive will help increase resilience in the marine environment and facilitate adaptation efforts.

In addition, the White Paper on Adaptation asks for action to ensure that adaptation in coastal and marine areas is taken into account in the framework of the Integrated Maritime Policy as well as the reform of the Common Fisheries Policy.

Specific developments related to reducing the impacts of climate change by implementing **EU policy on renewable energy** (e.g. hydropower development, biomass production) may have impacts on aquatic ecosystems, particularly when such activities either do not recognise or take insufficient account of environmental protection as part of the multi-purpose uses of water bodies. On the other hand, requirements to protect the water environment might impact the potential of certain climate change mitigation measures. Therefore, a well-balanced approach of all relevant EU policy is needed to meet both climate and water protection objectives.

A well-balanced approach with **EU transport policy** is also needed to meet both climate mitigation and adaptation and water protection objectives. With emissions of greenhouse gases from transport still on the increase, a shift from high-carbon road transportation to low-carbon maritime and inland shipping is encouraged by EU transport policy as both modalities contribute relatively positively to reducing overall climate change impacts from transport. On the other hand, navigation on rain water fed rivers will become increasingly vulnerable to climate change impacts such as more varied precipitation patterns. A balanced approach should therefore ensure that both climate mitigation and adaptation and environment protection aspects are checked and reported for transportation projects with environmental implications as well as for environment projects with transport implications in environmental impact assessments (EIAs) and strategic environmental assessments (SEAs). Such a multi-disciplinary policy should guarantee actions that provide an optimum between mitigation and adaptation.

Agriculture can also make a contribution to adaptation. Thus, policy coherence with the **EU Common Agricultural Policy**'s provisions should be ensured with regard to adaptation objectives in water management.

In addition, proper soil management is expected to play a key role in the climate change efforts. Considering also the close interaction of the soil environment with the water environment, current **European policies for soil protection** should also be considered in the context of adaptation efforts in the water management sector (Soil Thematic Strategy (COM(2006) 231), proposed Soil Framework Directive (COM(2006) 232).

The **strategic environmental assessment (SEA)**, either alone or as part of a sustainability appraisal, can help to ensure that plans and programmes take full account of climate change issues. The SEA Directive (2001/42/EC) requires identification and evaluation of planned impacts on a number of environmental issues, including climatic factors; and, where appropriate, to put measures in place to minimise and respond to significant impacts identified[5]. Possible related SEA climate change objectives related to adaptation could include measures such as:

- Ensuring that drainage systems can cope with changing rainfall patterns/intensity
- Taking a precautionary and risk-based approach to developing in the floodplain
- Ensuring adequate future water supply and demand management
- Avoiding actions that limit future adaptation

More details on the possible role of SEA in climate change adaptation is provided in Annex VI.

The European Commission's communication on an **approach on the prevention of natural and man-made disasters** COM(2009) 82 final, was issued in February 2009 and sets out the framework for a strategy on prevention with links between the steps in the risk management cycle; prevention, preparedness, response, recovery and lessons identified to create conditions for developing a knowledge based disaster preventive policy at all levels of government. Between 1990 and 2007 the European Union witnessed a marked increase in the number and severity of both natural and man-made disasters. The loss of human life, the destruction of economic and social infrastructure and the degradation of already fragile ecosystems is expected to worsen as climate change increases the frequency and magnitude of extreme meteorological events, such as heat waves, storms and heavy rains.

2.6 Relevant adaptation initiatives in Member States

Annex VII of this Guidance refers to important information hubs on Member State level concerning national adaptation initiatives which may also refer to water measures (e.g. webportals on climate change and river basin management). The Commission will make further information on EU and Member State adaptation activities available at a central adaptation homepage: http://ec.europa.eu/environment/climat/adaptation/index_en.htm

A European Climate Change Adaptation Clearing House is under preparation by the EC that will contain the updates of national adaptation strategies in the future.

[5] A report published in Summer 2007 called "Strategic Environmental Assessment and Climate Change: Guidance for Practitioners" suggests how climate change issues can be considered in SEA. It presents information on the causes and impacts of climate change and how they can be described and evaluated in SEA. It also describes how adaptation and mitigation measures can be developed through SEA.

3 CLIMATE MODELLING, PROJECTIONS, SCENARIOS, POTENTIAL IMPACTS AND UNCERTAINTY

This chapter aims to provide first guidance on how to handle available scientific knowledge from models, projections and scenarios on climate change as well as related uncertainties for the purpose of river basin management.

It provides a concise summary of available global models, of projections and scenarios with emphasis on their strengths and weaknesses, as well as a general overview of the main predictions for climate change impacts on water resources across Europe. A set of guiding principles is proposed for decision-making and management of the water environment in the light of climate change and uncertainties.

This chapter refers to further sources of reading for those who are interested in climate modelling and projections. This chapter's aim is restricted to providing a general overview of the state of play of knowledge, which may serve as a sufficient basis for the subsequent chapters on EU water policy and climate change adaptation.

3.1 Models, projections and scenarios

Guiding principles

1. Climate projections and scenarios should be used for improving river basin management planning.
2. It is crucial to have a clear understanding of the assumptions made and the uncertainties related to these assumptions.
3. The best climate change model or scenario for a certain region or river basin should be decided on a case-by-case basis, because there is no "one-size-fits-all" model or scenario for Europe.

3.1.1 Global level

In order to grasp the potential range of future climate change, several **global climate projections** are conducted – in international coordination – each of them applying different emission scenarios as well as different global climate models.[6] The results are interpreted, described and published on a regular basis by the Intergovernmental Panel on Climate Change (IPCC). The IPCC recently published its fourth Assessment Report (AR4) "Climate Change 2007" (IPCC 2007). The publication of the 5th report (IPCC AR5) is planned for 2013 (WG I - Report on the Physical Science of Climate Change).

The new generation of global climate models (Atmospheric and Oceanic Global Circulation Models - AOGCM) are more reliable than their predecessors. *Important improvements are, amongst others, the consideration of relevant land surface processes and a database of the earth's surface qualities*. Additionally, the calculation of cloud formation processes has been revised and additional information is obtained as output due to the higher resolution of the new models. Further improvements of the next generation of global climate models are being planned. For example, there are plans to take land ice into account in the calculation of land surface processes.

[6] Please refer to Annex IV for concise definitions of the terms "projections", "forecasts" and "scenarios".

However, it should be kept in mind that global models are based on many simplifications and assumptions, so that their results bear a degree of uncertainty. In addition, the coarse spatial resolution of global models is insufficient for application in impact models and thereby for determining the effects of regional and local climate change. To overcome this limitation, regionalisation procedures are applied. By these, the global projections are "downscaled" to smaller grid elements of up to 25 km × 25 km; in individual studies the downscaling is even below this grid size, or adjusted to the locations of individual stations.

3.1.2 Climate change projections for the EU

Data-comprehensive analysis and synthesis of regional climate change on the European scale was carried out in the last decade by the EU projects PRUDENCE, STARDEX, the still ongoing project ENSEMBLES and the projects CECILIA and CLAVIER on Central and Eastern Europe (details on these research projects are provided in Annex II).

The project PRUDENCE has provided a series of high-resolution climate change projections for 2071-2100 for Europe, characterising the variability and level of confidence in these scenarios as a function of uncertainties in model formulation, natural/internal climate variability, and alternative scenarios of future atmospheric composition. The ENSEMBLES project has extended and updated this approach integrating climate change impact studies into an ensemble prediction system.

The STARDEX project has given a rigorous and systematic inter-comparison and evaluation of downscaling methods for the construction of regional scenarios of extremes. The aim was to identify the more robust techniques, and to use these to produce future scenarios of extremes for European case-study regions for the end of the 21st century. Large progress was made regarding the vital question as to whether extremes will occur more frequently in the future.

The EU project CECILIA provides detailed regional climate projections (and impact assessments) for Central and Eastern Europe, similarly to the EU project CLAVIER which focuses on Hungary, Romania and Bulgaria.

Summarised information on observed and projected climate change in the EU is also available from the European Environment Agency (please refer to EEA/JRC/WHO (2008) for a brief summary of key projected impacts).

3.1.3 National to local level

Currently, many national and European research activities are producing relevant and valuable results on climate change impacts on Europe's fresh, transitional and marine waters (many research projects that are relevant to climate change impact studies on water are briefly outlined in Annex II). Some Member States have also carried out their own more localised modelling (e.g. UK Climate Projections (UKCP09)). Please check Annex V for further web links on Member State local climate projections.

Although the results from research activities developed at local level can in some cases be very useful, it is recommended that the information used in the planning processes be obtained and validated at a national level by the competent authorities, so as to ensure adequate homogeneity in the treatment of different geographic areas. For instance, the Spanish Meteorological Agency (AEMET) has published Regionalized Scenarios for Climate Change Impact Assessment, and disseminated this data through its web site, in order to cope with the implementation of climate change strategies at all policy levels.

Quantitative projections of changes in precipitation and river flows at the river-basin scale remain, however, uncertain, due to the limitations of climate models, as well as scaling issues between climate and hydrological models. Nonetheless, in recent years, the resolution of regional climate model simulations has increased considerably. In addition, statistical correction methods have been developed which bring the models closer to a realistic simulation of, for instance, the amount and intensity of precipitation at the scale of river basins and small catchments.

Example 3a: Downscaling methods in France

Different statistical downscaling methods have been implemented and evaluated to generate local precipitation and temperature series, at different sites in France, based on the results from a variable resolution general circulation model[7]. These methods are being tested over various French river basins (Seine, Loire, Garonne), and could be used elsewhere.

Example 3b: Downscaling in the Thames Basin, UK

The Thames Estuary TE2100 project produced an integrated set of dynamically downscaled data for the Thames Basin over a 150 year period. This showed results from a runoff model driven by precipitation data from the same regional model, which was used to produce simulations of storm surge in the North Sea. This is a good example of high-resolution integrated modelling. It also fed into the UKCP09 marine projections.

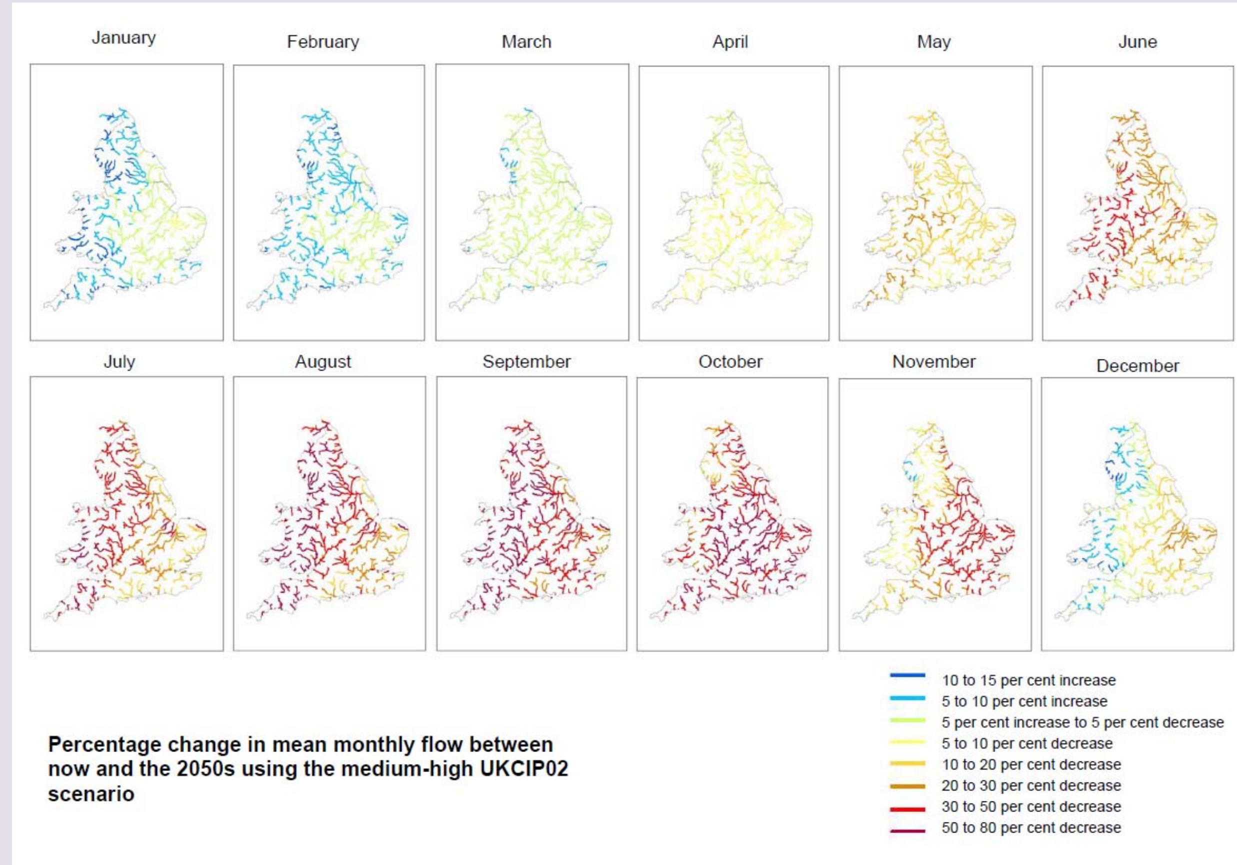
Example 3c: Change of flow between now and the 2050s in the UK

The figure below shows the results of estimation of river flows in the 2050s that were carried out using the Continuous Estimation of River Flows (CERF) model. This is a regionalised rainfall-runoff model developed by the Environment Agency of England and Wales and the Centre for Ecology and Hydrology. The model uses time series data of precipitation and potential evaporation demand to model time series of daily river flows.

The study is the first to use catchment-level models to look at river flows across the whole of England and Wales. Its finding that total annual river flow could drop by as much as 10–15 percent by the 2050s is a result of lower summer and autumn river flows and higher winter river flows.

These results show a possible decrease in mean monthly river flows during the summer and autumn months of around 50 percent, with a fall of up to 80 percent in some areas. They also show a corresponding increase in mean monthly river flows during the winter months of up to 15 percent.

[7] Boé et al, 2006 ; Déqué et al, 2007.



Percentage change in mean monthly flow between now and the 2050s using the medium-high UKCIP02 scenario

Example 3d: Bias correction methods in the Rhine Basin

By definition a model can only approximate reality and will therefore always be biased. Current climate model versions resemble reality much better that earlier versions. Nevertheless, their results cannot be used in impact models directly, unless they are corrected.

Focussing on precipitation output of various climate models and their application in hydrological models of the River Rhine, different statistical bias correction methods are being applied in current cross-bordering projects (KLIWAS, AdaptAlp, and RheinBlick2050). They are tested on different spatial scales, in topographical regions and with focus on mean and extreme values. The methods are also applicable in other catchments. From the KLIWAS project corrected data will be available for all national and international catchments of Germany.

Example 3e: Downscaling national-regional patterns in precipitation to a local level – Production of a local weather generator in Sweden

Within the project 'Extreme rainfall events in Sweden and their importance for local planning' two main tasks have been the focus: a) identifying trends of precipitation extremes in Sweden using daily precipitation observations from 220 stations during the period 1961-2004, and b) projecting future changes in the extremes over the next 100 years by using a weather generator developed for Sweden. Extreme precipitation is expressed in terms of eight indices, which are chosen from a much larger set of possible indices based on the discussion between the authors and the reference group of the project. They describe specific aspects of extreme precipitation considered to be important for Sweden. These also include indices quantifying means as well as dry conditions. All indices are calculated based on daily precipitation from measurements or simulations by the weather generator developed in this project.

The results for the trend analysis are generally in line with results from other studies concluding that regions at middle and higher latitudes are getting wetter and extremes are becoming more frequent and more intense. Separate trend analysis for the different seasons show that climate mainly gets wetter in winter, spring and summer, while decreasing trends could be observed at many stations in autumn.

By following the steps in the weather generator, future extreme precipitation at local scale in Sweden under the SRES A2-scenario is obtained and presented. As expected, the changes vary from station to station within a short distance, further demonstrating the need of downscaling from GCM scale to local scale. However, an overall trend of increased frequencies and intensity of the extremes can still be identified for the majority of the stations studied. The developed downscaling methodology is relatively simple but useful in deriving local precipitation changes including changes in the extremes for local application.

3.2 Potential impacts of climate change on the status of water resources

Water is intricately linked with climate through a large number of connections and feedback cycles, so that any alteration in the climate system will induce changes in the hydrological cycle. Global warming augments the water-holding capacity of the air and amplifies evaporation. This leads to larger amounts of moisture in the air, an increased intensity of water cycling, and changes in the distribution, frequency and intensity of precipitation. Consequently, the distribution in time and space of freshwater resources, as well as any socio-economic activity depending thereon, is affected by climate variability and climate change. For the coming decades, global warming is projected to further intensify the hydrological cycle, with impacts that will probably be more severe than those so far observed (EEA/JRC/WHO, 2008).

All quality elements included in the definition of WFD qualitative and quantitative status of water may be sensitive to climate change. Over its impact on the quantitative and qualitative status of water resources, climate change affects the following variables:

- water availability (river flows and groundwater levels);
- water demand (esp. peak demands during periods of drought);
- intensity and frequency of floods and droughts, and of strong stream or low flow conditions;
- surface water quality, including temperature, nutrient and other contaminants content;
- biodiversity in aquatic systems;
- groundwater quality.

From the several national and European research activities there is limited empirical evidence to demonstrate impacts unequivocally, because of difficulties in disentangling the effects of climatic factors from other pressures. On the other hand, there are many indications that freshwaters that are already under stress from human activities are highly susceptible to climate change impacts and that climate change may significantly hinder attempts to restore some water bodies to good status in the long term.

- **Water availability and water demand**

Climate change is projected to lead to major changes in yearly and seasonal water availability across Europe in the second half of the century. According to current results, summer flows are projected to decrease in most of Europe, including regions where annual flows will increase. Annual river flow is projected to decrease in southern and south-eastern Europe and increase in northern Europe, but absolute changes remain uncertain. Climate change is projected to result in strong changes in the seasonality of river flows across Europe (EEA/JRC/WHO, 2008).

Regions in southern Europe which already suffer most due to water stress are projected to be particularly vulnerable to reductions in water resources due to climate change. In addition, higher temperatures are expected to lead to increased water demand, especially for irrigation and urban supply. This will result in increased competition for available resources (EEA/JRC/WHO, 2008).

In addition to river flows, groundwater would also be under pressure due to climate change. In particular, additional pressures will occur due to sea-level rise, shrinking land ice and permafrost areas, declining groundwater recharge (especially in southern European countries), more extreme peak flows and more prolonged low flows of rivers, and increased groundwater abstraction. Regions with higher precipitation may experience rises in groundwater levels that may affect houses and infrastructures (EEA/JRC/WHO, 2008).

- **Floods and droughts**

With an intensified hydrological cycle, the intensity and frequency of flood events are projected to increase in large parts of Europe, although estimates of changes remain highly uncertain. In particular, flash and urban floods triggered by intense local precipitation events are likely to be more frequent throughout Europe. Projections suggest that warming could result in less snow accumulation during winter and therefore a lower risk of early spring flooding (EEA/JRC/WHO, 2008). Some projections at river basin scale also suggest that the spring flooding period (related to snow melt) could occur earlier. In autumn, flood risks could increase because of reduced water storage (snow accumulation) (Etchevers et al., 2002).

Climate change is also projected to increase the frequency and intensity of droughts in many regions of Europe, as a result of higher temperatures, decreased summer precipitation, and more frequent and longer dry spells. The regions most prone to an increase in drought hazard are southern and south-eastern Europe (EEA/JRC/WHO, 2008).

- **Water quality and biodiversity in aquatic systems**

Water quality may be impacted by climatic changes in temperature and precipitation (EEA/JRC/WHO (2008)). A rise in water temperature will affect the rate of biogeochemical and ecological processes that determine water quality. This may result in:

- *Reduced oxygen content*. Increases in water temperature in streams and lakes will reduce oxygen solubility and increase biological respiration rates, which may therefore result in lower dissolved oxygen concentrations, particularly in summer low-flow periods and in the bottom layers of lakes. Higher temperatures and lower oxygen concentrations will cause stress for, and may reduce the habitats of, cold-water species such as salmonid fish in lakes and rivers.
- *Less ice cover*. earlier ice break-up and longer ice-free period in rivers and lakes.
- *More stable vertical stratification and less mixing of water in deep-water lak*es, which in turn will affect deep-water oxygen conditions, nutrient cycling and plankton communities.
- *Eutrophication.* A warmer climate would generally enhance the pollution load of nutrients in surface and groundwater. Higher temperatures would increase mineralisation and release of nitrogen, phosphorus and carbon from soil organic matter; higher rainfall intensity will increase run-off and erosion, which will result in

increased pollution transport. On the other hand, higher soil moisture deficits would reduce mineralisation. In addition, release of phosphorus from bottom sediments in stratified lakes is expected to increase, due to declining oxygen concentrations in the bottom waters.

- *Change in timing of algal blooms and increase of harmful algal blooms*.
- *Alterations to habitats and distribution of aquatic organisms*. The geographic distribution of aquatic organisms is partly controlled by temperature. Higher water temperatures can lead to changes in distribution (species moving northwards (in Europe) and to higher elevations) and may even lead to the extinction of some aquatic species. In the Mediterranean region, numerous ephemeral aquatic ecosystems are projected to disappear and permanent ones to reduce in size.
- *Climate-induced changes in sediment quality and quantity.* Sediments form an integral part of natural aquatic systems, providing a substrate for organisms and playing an essential role (e.g. through nutrient cycling). However, contaminants can become adsorbed to sediment. Climate-induced changes in extreme weather conditions (and associated processes such as currents and erosion) could expose and remobilise sediment-associated contamination, or could result in high-energy mass flows of eroded soil or remobilised sediment, in turn impacting aquatic ecosystems.

- **Groundwater quality**

Fresh groundwater bodies will become more vulnerable to pollution through reduced turnover times and accelerated groundwater flow. Saline intrusion in coastal aquifers, making the water unsuitable for drinking, may be exacerbated by future sea-level rise. Finally, further increases in groundwater temperature will raise the salinity of groundwater due to increased evapotranspiration losses, increased soil $CO2$ pressures and increased water — rock interaction (EEA/JRC/WHO, 2008).

Due to density effects a sharp fresh-water/sea-water interface separates freshwater from seawater. The position of this interface can be influenced by a rise of the sea level in two ways. First, this interface will rise with the sea level and second, increasing water abstraction e.g. in order to compensate the sea level rise by more intense drainage activities, can lead to an uplift of the interface between seawater and freshwater as well. This uplift of the interface can be accelerated in areas where freshwater is used for water supply or irrigation purposes and harm the quality in any extraction well.

In areas where river flow and groundwater recharge may decrease, e.g. in southern Europe, water quality could also decrease due to lower dilution of pollutants. Similarly, higher intensity and frequency of floods and more frequent extreme precipitation events are expected to increase the load of pollutants (organic matter, nutrients, and hazardous substances) washed from soils and overflows of sewage systems to water bodies.

Finally, in some estuarine and coastal water bodies including coastal lagoons, there may be local changes in ecology resulting from increased saline intrusion associated with sea level rise.

3.3 Managing the water environment based on uncertainty of projections and scenarios

Guiding principles

4. Despite uncertainty in models, 'doing nothing' is not an option. For the next river basin management cycle, uncertainties should be accepted where it is rational to do so and first actions for adaptation to climate change should be taken.

5. Best available scientific information should be taken into account.
6. A range of climate projections or scenarios should be used in the analyses for river basin management planning in order to accept and work within the context of an uncertain future.
7. Adaptation options should be preferred which are robust against a range of future changes or postpone commitment to a particular projection of the future by building flexibility into your system.

Understanding the sources of uncertainty

As indicated above, climate change models and projections are based on many simplifications and assumptions, so that their results bear various uncertainties. From the perspective of climate impact research, the various sources of uncertainty can be grouped into two categories:

(i) uncertainties related to incomplete knowledge about the system under investigation (e.g. due to measurement errors or simplifications in model formulations).

(ii) uncertainties inherent to the system under investigation (e.g. due to a chaotic behaviour of the global climate or the socio-economic system).

Current and future improvements in measurement networks and model formulations can only minimize uncertainties of category (i). It is presumably unrealistic to believe that uncertainties will be completely eliminated in future climate projections.

As there will never be a single "true" model, multiple model concepts should be used in a comparative way ("*multi-model-approach*"). For instance, in the case of floods, the different models and projections have shown in some cases a large error in the generation of high extreme values of precipitation, so that the estimated impacts based on them could have a great uncertainty. In some of these cases, a multi-model approach will provide more robust estimates of changes in extreme precipitation and flood events, as well as the opportunity to quantify uncertainty inherent to the use of different scenarios. In the case of coastal flooding, there may be a need for common scenarios as regards for instance sea level rise, which could facilitate planning. On the other hand, elements such as increased storminess have a local component that makes common scenarios have less sense for them.

Example 3f – The KLIWAS project – Analysing uncertainty

The interdisciplinary research programme KLIWAS (www.kliwas.de) integrates ecological, economical, water quality and water quantity aspects of climate change for rivers and coastal waters which are used as waterways. KLIWAS strictly follows a multi-model-approach. It uses and evaluates up to 30 climate model runs (including those of the EU-FP6-Project ENSEMBLES and new runs provided by the KLIWAS group), as well as different bias correction methods and hydrological models, in order to account for different sources of uncertainty and provide a reliable basis for the assessment of various adaptation options. With the purpose of model validation and monitoring of climate change effects, historical data bases are extended, too. A model chain is established, which couples climate models to hydrological/oceanographic, hydrodynamical/sedimentological, water quality, and ecosystem models.

At each step, uncertainty is analysed in detail to assess the level of understanding of the aquatic systems and their sensitivity to low flow, floods, and other aspects of "historical" and future climate change. Changes and possible adaptation measures of the waterways are evaluated taking all functions of rivers and coastal waters into account. Thus, varied WFD relevant information is provided.

The inevitable uncertainties of category (ii) are better addressed when more model simulations are included in a so called *ensemble* (*ensemble-approach*). Ensembles help to approximate the probabilistic characteristics of the modelled system. From the ensemble of simulations, relevant information can be extracted, e.g. by using scenario techniques. Nevertheless, difficulties arise when deriving conclusions from an ensemble of projections that are not really equally probable.

Handling uncertainty

In practical terms, decisions related to climate change, its impacts and adaptation options cannot be made on simple, single values but need to encompass the range of possible future climate projections. Thus, decision makers will have to handle a bandwidth of values or different scenarios and accept and be explicit about uncertainty.

This could be through looking at the range of projections from the different models to see which results are consistent and for which we can be confident about. As an example, if all models indicate that it will get wetter in June, then we might be more confident about this projection. If the relevant results are more varied, e.g. it may get wetter or drier, then it is important to choose adaptation options which will be effective across the range of potential future changes. This might involve increasing the resilience of the system, its adaptive capacity, and the use of no-regret measures rather than options which rely on the direction of change.

The selection and priority of measures should be based on the vulnerability of the system. Research can determine which sectors are impacted most severely by climate change and where measures are needed most urgently to prevent undesired effects, even if their exact extent is not yet known.

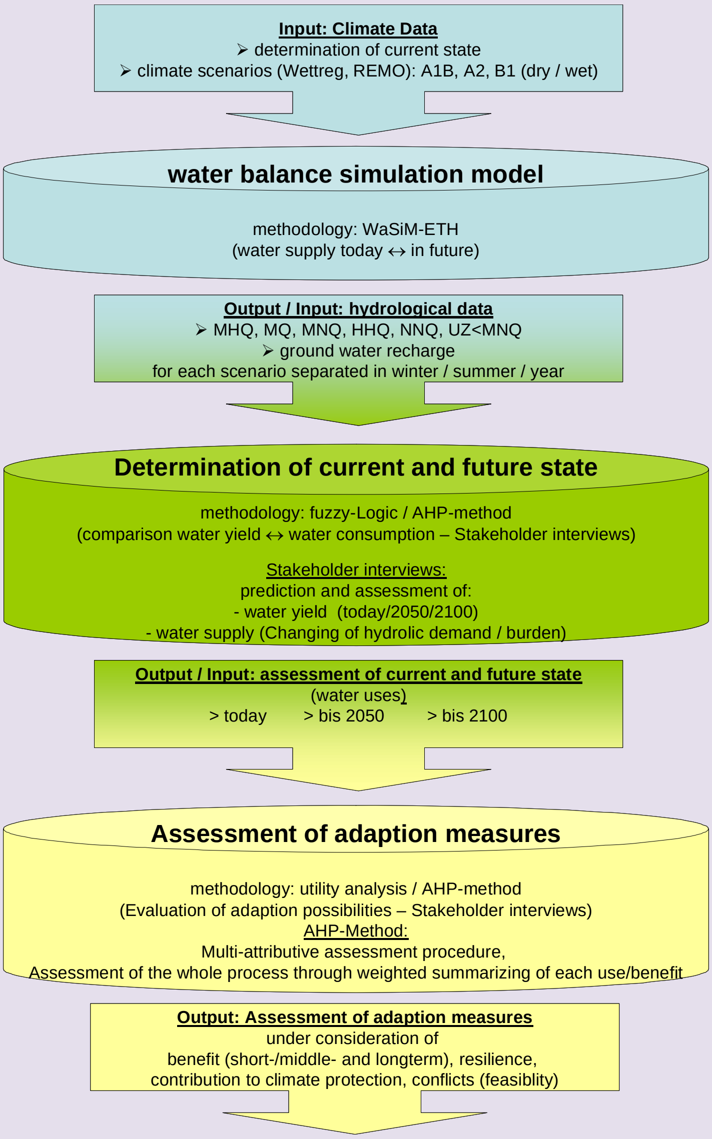
In general, adaptation to climate variability and change is both a technical and a social process of assessing and responding to present and future impacts, planning to reduce the risk of adverse outcomes, and increasing adaptive capacity and resilience in responding to multiple stresses. A key step is to make use of the best available science to identify conditions and risks, as well as their relevance for adaptation strategies and actions, to allow adapting to new boundary conditions due to climate change.

Any analysis carried out as part of river basin management planning should take into account the existence of uncertainty and, where possible, use a range of climate projections including a variety of emissions scenarios, global and regional climate models, and model runs. Thus, results will handle a range of possible impacts on pressures from climate change. Where these ranges are large, it is useful to consider the analysis as a narrative for likely future conditions. In many cases, it will be useful to take a bottom-up approach in terms of looking at potential measures and considering how each of these or combinations will perform against the range of possible climate futures modelled. In chapter 5.7, further guidance is given on how to choose measures that are robust and flexible vis-a-vis future climate conditions (including no-regret, win-win and low-regret measures).

Specific guidance on the issue of management of uncertainty is also given in chapter 0 on flood risk management in the context of uncertainty and chapter 7 on water scarcity and droughts. The example of the research and development project WASKLIM is presented below, which aims to develop a concise method that allows decision-making under uncertainty on the basis of adaptation capacities and vulnerabilities.

Example 3g: WASKLIM - Adaptation strategies in water management (state of play – June 2009)

The currently finished Research and Development Project aims to develop a concise method that allows decisions to be taken which include uncertainty on the basis of adaption capacities and vulnerabilities. Therefore, model simulations of the water balance (WaSiM-ETH), including simulations of scenarios for 2050 und 2100, have been performed for three pilot areas (based on regional models WettReg and REMO). In parallel, regional conferences in these pilot areas, questionnaires and expert interviews collected expert knowledge about the vulnerability of respective water uses. These results were fed into a fuzzy logic-based decision support system (DSS).



The combination of expert knowledge with the simulation results of further climate change effects creates the basis for the assessment of adaption measures.

The DSS results statements show which water uses have a higher need of adaptation action, as well as a pre-selection of suitable adaptation strategies.

The DSS delivers a useful building block for dialogue and participation processes. In a first step this approach requests an intensive reflection of the basic conditions for different water uses. This includes an analysis of the vulnerability of these uses, from the results of climate impact modelling. In a second step climate projections are added. In this way this approach shows the need of action through the overlapping of the spread of the modelling results and operating range given by the expert statements. How stable the priority and the recommendations are on specific adaption measures, which are outcomes of the DSS, are, can be tested by sensitivity analyses. Hence, the whole decision process can be made transparent and open for participation and public discussion.

Example 3h: The CC and Vulnerability Committee in Sweden based their work on the assessment of global climate change made by the UN's climate change panel, the IPCC.

In order to highlight vulnerability in a future climate, they are using a number of global scenarios for climate change. These comprise two global climate models and two global emissions scenarios from the IPCC. Based on these four scenarios, the Rossby Centre at the Swedish Meteorological and Hydrological Institute (SMHI) has made calculations using its regional models.

In consultation with the committee and various sectors, SMHI has developed around 40 specific climate indices as the foundation for assessing the future vulnerability of the sectors. A total of over 10,000 climate maps showing the development of the indices have been drawn up. The calculations have been made for various timeframes – 2020s, 2050s and 2080s. Data has also been produced for the trend over the past 15 years. They have constantly compared the future climate with the most recent complete reference period used in climatological contexts (1961–1990).

The scenarios analysed indicate dramatic changes in Sweden's climate at the end of the century. The winter climate near overall in Sweden will be similar to that which is currently found in northern France. Precipitation in almost the whole of the country will increase in the autumn, winter and spring. The summers will most likely be warmer and have a drier climate, particularly in southern Sweden. Torrential rain will become more intensive.

Finally, it should be kept in mind that in some Member States, "climate services" are set up to help bridge the gap between climate models/scenarios and decision-making. Examples are given in the box below.

Example 3i: "Climate services" in some Member States

UK:

There is considerable guidance on decision making, uncertainty and use of probabilistic climate projections in the UK. Please check: http://ukclimateprojections.defra.gov.uk

Germany:

Germany has a newly established climate service centre. Please check: http://www.climate-service-center.de/

France:

A French project called DRIAS, whose purpose is to give broad access to climate change scenarios and simulations for impact and adaptation studies, has been launched in 2009 (within the GICC program, managed by Météo-France).

Finland:

In Finland, the Watershed Simulation and Forecasting System (WSFS) is used for both hydrological climate change scenario simulations to estimate the impact of climate change on floods, droughts and water resources, and to assess the adaptation possibilities of water resources management. The results have been disseminated through publications, seminars and catchment specific project reports to stakeholders. WSFS is also used for real time hydrological forecasting and lake regulation planning, disseminated to stakeholders and even operated by stakeholders through internet (www.environment.fi/waterforecast), to be used in flood and water resources management.

The VACCIA-project (2009-2011) is based on data from intensively studied sites/sub-regions of the FinLTSER-network. The sites have a wealth of existing information, and are closely integrated into the local-scale economy and activities. This provides the link to the scale where realistic adaptation measures can be planned and assessed. The project will provide both detailed descriptions about the methodology and tools for making climate impacts and adaptation assessments, as well as an inventory of realistic adaptation measures for key ecosystem goods and services. This methodology and information can be used by stakeholders at local, regional, national and international scales.

In addition, FINESSI (http://www.finessi.info/finessi/index.php) is a web tool that allows the user to explore the possible impacts of climate change in Finland on chosen impact areas and at different time periods up to the end of the 21st century. The tool is intended for planners and researchers, but it may also be of interest to students and to members of the public. FINESSI offers a common platform for integrating observations of the present-day climate and environment with modelled information about future climatic conditions (scenarios) and their impacts. The impacts of climate change are presented for climate-sensitive systems and activities such as agriculture, water resources and natural ecosystems.

Czech Republic:

Useful information can be found on the following sites:

- CHMI (Czech Hydro Meteorological Institute): http://www.chmi.cz/cc
- National Climate Program of the Czech Republic: http://www.chmi.cz/nkp/nkp.html
- Ministry of the Environment: http://www.mzp.cz/

4 GETTING STARTED: HOW TO BUILD ADAPTIVE CAPACITY FOR MANAGEMENT UNDER CLIMATE CHANGE

4.1 Introduction

This chapter proposes a set of guiding principles that should help those with river basin management responsibilities in setting up a strategy for building adaptive capacity[8] to manage river basins districts under climate change.

The chapter serves to remind managers that they should consider aspects, which go beyond the handling of available scientific knowledge on climate change and related uncertainties (chapter 3), in order to carry out river basin planning and management in a changing climate (as described in the next chapters of this Guidance). "Softer" aspects of river basin management, such as awareness-raising, proper staff training and cooperation between different levels of authorities and sectors, also need to be considered in efforts to build up adaptive capacity for management under climate change.

The way climate change is incorporated in the river basin management cycle also needs to undergo public consultation (as part of the normal procedures according to WFD Article. 14), while at the same time, climate change may help in raising the public profile of sustainable water management. An efficient use of the WFD public participation process is especially relevant for climate change awareness raising in water management, but also for integrating valuable sector-specific stakeholder knowledge.

Please note: The following list of guiding principles addresses mainly those aspects that can be influenced by those with river basin management responsibilities. The development or modification of policies and regulations, which is an equally important condition for climate change adaptation, is not addressed here.

4.2 What is needed to build adaptive capacity?

Building adaptive capacity has many aspects. Below, information is presented about using available knowledge and data in a RBD, involving the relevant stakeholders and looking out for the wider audience, and getting started in an international river basin.

4.2.1 Using ongoing research and adaptation activities to increase knowledge at river basin scale

Guiding principles

1. Link river basin management adaptation activities to national and regional climate change adaptation strategies and activities.

   Such strategies are a source of relevant research, information and assessments. They are often based on detailed assessments of climate change impacts on water and in many cases include first evaluations of potential water adaptation measures. These adaptation strategies and the assessments of impacts can supplement the climate impact assessment of the WFD (Article 5, see chapter 5).

2. Check existing relevant science and research information on climate change

[8] "Adaptive capacity" can be interpreted as the "ability to cope, adapt or recover from the effects of a hazard" (in this case, climate change). The presence of adaptive capacity is considered a necessary condition for the design and implementation of effective adaptation strategies (IPCC (WGII), 2007).

modelling and impacts in the river basin.

This could include, for example, producing information inventories, meta-databases and web-pages. Please refer to chapter 3 and Annex I of this Guidance for a summary of key European information networks, an overview of key research projects and databases or toolkits on adaptation actions/measures.

3. Make use of good-practice examples coming, e.g. from existing research and implementation experience regarding adaptation strategies and measures.
4. Look beyond the borders of your river.

   Adaptation to climate change will be required across Europe. Possible future impacts in one river basin might represent the current situation in another one, and useful adaptation experience in other regions/RBDs with similar characteristics may exist. It is important to exchange knowledge and experiences with other regions/RBDs on a regular basis and integrate lessons learned.

In general, the knowledge gaps that can be addressed by water managers at the RBD level are not related to gaps in the science of climate change and water, but to *what the current state of knowledge means for their particular RBD.* This means that often river basin managers need to make use of available research and experience. In addition, relevant local knowledge should be developed to the fullest extent possible, such as predictions of climate change impacts in the basin for various future climate scenarios. Please check also the recommendations of chapter 3 on how to handle available scientific knowledge and uncertainties about climate change.

4.2.2 Data collection and building of partnerships

Gaining political backing and embedding climate change adaptation in river basin management planning requires the following two key features:

- Collecting appropriate data to improve decision making and develop a sound adaptation strategy.
- Identifying stakeholders and deciding on an approach to engagement as well as working in partnerships.

Collecting appropriate data to improve decision making and develop a sound adaptation strategy

Guiding principles

5. Evaluate data coverage (e.g. meteorological, hydrological, water quality, soil moisture data, stake, damage cost data, etc), particularly considering the following issues:

   - Does present data collection cover both current data and monitoring requirements as well as future requirements under changed climate conditions?
   - Is present data collection robust in the face of possible changes in underlying variables that define typologies and, therefore, reference conditions?
   - Does current data collection and monitoring provide adequate monitoring of climate change impacts? Does current data collection and monitoring provide monitoring of the effectiveness of adaptation measures?
   - Are historical data sets coherent and consistent in view of e.g. changes of

measurement methods over time? If problems of coherence are identified, can these be dealt with to achieve reliable historical data series?

6. Use the WFD consultation process (Article. 14) to bring in sector-specific knowledge and data from key stakeholders.

All in all, adapting to climate change implies new requirements regarding the type and the extent of data collected for river basin management. Long time series are judged essential for understanding the evolution of physical variables and selected species over time. On the issue of WFD monitoring under climate change, please refer to chapter 5.4 for more detailed guidance and suggested actions.

Identifying stakeholders and deciding on an approach to engagement – Working in partnerships

Guiding principles

7. Ensure communication and coordination on climate change adaptation issues between different levels of management within an RBD.
8. Work in cross-sectoral partnerships and across administrations- Ensure that climate change aspects are discussed between the relevant public administrations, in stakeholder meetings and discuss how relevant water-related sectors can contribute to adaptation.
9. Make sure to receive information related to the influence of climate change on other sectors which are directly related to water management (e.g. agriculture-water demands, water needs for energy production, etc). Keep in mind that, in the context of the RBMP preparation, it is not possible to carry out all studies necessary to determine the evolution of these factors for the different climate scenarios.
10. Integrate cross-sectoral delivery of adaptation measures and coordinate activities with land use planning.
    Establish links of river basin management planning to other national and regional planning activities and policies which are relevant to climate change impacts and adaptation in RBDs (e.g. municipality planning, spatial planning, land use planning). Within river basins and catchments, integrate adaptation actions with those of other sectors to develop a holistic plan that takes advantage of cross-sectoral adaptation benefits – eg reinstating floodplain wetlands that prevent flooding, retain water and provide wildlife habitat.

Meaningful and early stakeholder engagement can improve acceptance of decisions and measures and thereby increase the feasibility of the adaptation strategy. Evidence and analysis is often more accurate when carried out in conjunction with stakeholders.

Integration refers to all sectors in order to avoid negative cross-sectoral feedbacks of measures (or non-action in one sector) but also to the different levels of management within an RBD, including different kinds of authorities. Therefore, it is important to carry out a 'Stakeholder Mapping' exercise before seeking to engage stakeholders in the adaptation process in order to identify the full range of stakeholders. Based on the list of identified stakeholders, the availability of resources and preferences or experiences, an approach to stakeholder engagement should be decided. This would result in the production of an engagement strategy, setting out the objectives for and means of stakeholder engagement and a clear definition of the roles and responsibilities of each authority and stakeholder.

As concerns coordination with land use planning, it should be kept in mind that land use practices and land use planning have a major impact on water scarcity, floods and modification of water bodies. In several cases, co-benefits or win-win situations between the spatial planning and improving the ecological status are possible such as making room for the river (see Example 4b on the EU project ESPACE, Example 5r on making room for the river and Example 7d on Dutch planning of measures for sustainable freshwater supply including land use planning).

Example 4a – Institutional arrangements for assessing climate impacts on pressures in Austria

Austria is situated in a transitional zone with the high-precipitation area of the Alps on the one hand and the more drought prone eastern parts on the other hand. Within the alpine region an increasing future precipitation to the north and decreasing precipitation to the south is foreseen. However, due to high spatial variability of climatic conditions and hydrological processes the Alps are likely to show marked seasonal variations in precipitation.

An interdisciplinary working group of the Austrian Water and Waste Management Association (ÖWAV) and the Federal Ministry for Agriculture, Forestry, Environment and Water Management (BMLFUW), involving different stakeholders, was set up to collect multidisciplinary information on possible effects of climate change on Austrian water management and to estimate its significance. The final results of the working group were presented to the public and published as the report *'Effects of Climate Change on the Austrian water management'* at the end of 2008[9].

An example of the output of this working group is the assessment of climate change effects on heavy rainfall events and floods. The FLOOD Risk II project revealed that so far there have been no significant changes for medium and large catchment areas (> 250 km²) but indicated a need for action in smaller catchment areas, where the risk of heavy rainfall events already exists. Nevertheless the resolution of existing climate models is not yet high enough to get resilient results for these small areas. In high mountainous areas additional factors like increases in sediment yield because of a rising permafrost base would have to be considered. Possible measures for the future could include:

- Guidelines for the Federal hydraulic engineering administration 2006 (RIWA-T) are considering freeboards for dams as additional safety measure against higher water levels because of climate change.
- Protect retention areas to reduce the effect of heavy rainfall events on peak flows.
- Measures to reduce soil erosion and leaching of fertilizer
- Measures to impact of increased operation of storm overflows.

Example 4b – EU project ESPACE

The European project ESPACE (North West Europe INTERREG IIIB Programme) set out to influence the philosophy and practice of spatial planning. The focus of the ESPACE (European Spatial Planning Adapting to Climate Events) project was on how adaptation to climate change can be incorporated into spatial planning systems with a special focus on water management issues. It was the first project of its kind to focus on increasing the awareness of the need to adapt to the impacts of climate change and to begin to provide some of the necessary policy guidance, tools and mechanisms to incorporate adaptation into planning systems and processes.

ESPACE was founded by a transnational group of 10 Partners spanning four North West European countries and bringing together representatives from all levels of civic society. A range of actions were undertaken by Partners to identify how to best adapt to climate change. These include actions

[9] Source online: http://publikationen.lebensministerium.at/filemanager/download/44661

looking at the most effective ways of raising awareness, the role of behaviour change in adapting to climate change, policy review through the use of innovative techniques and the development of tools and models.

URL: http://www.klimaprojekt-espace.bayern.de/

4.2.3 Broadening the audience and increasing its capacities - Awareness-raising, education and training

Guiding principles

11. Include the issue of climate change impacts in the river basin in your RBD awareness-raising activities as part of the WFD public participation process.
12. Establish staff training and capacity building programmes on climate change issues, e.g. to introduce staff to climate change modelling, scenarios and projections.

An important side-effect of awareness can be the facilitation of acceptance of adaptation measures among the different stakeholders. All water-related sectors should be encouraged to become well-informed about possible impacts of climate change in their sector. The main result is ensuring preparedness, for instance through the implementation of own risk-management or adaptation measures as a consequence of increased awareness.

An additional prerequisite for building adaptive capacity for river basin management in a changing climate is learning and building up knowledge in the relevant organisations as well as the transfer of relevant knowledge.

4.2.4 Looking beyond the borders

Guiding principle

13. Develop joint or coordinated adaptation strategies in transboundary RBDs.

Transboundary basins pose particularly complex challenges with regard to the building of adaptive capacity for climate change. Joint bodies, such as international river basin commissions, should be responsible for the development of joint or coordinated adaptation strategies for transboundary basins and for following up their implementation and evaluating their effectiveness. The bodies need therefore to have the capacity and means to effectively undertake these tasks.

Further adaption to climate change might require actions outside the national part of a river basin e.g. some measure need to be taken upstream. This might require bilateral agreements based on common understanding.

Example 4c – Towards an adaptation strategy in the Rhine[10] river basin

The 1999 Rhine Convention, together with existing EU and national legislation and policies and a strong political commitment in all countries in the Rhine catchment, provide a sound basis for

[10] Switzerland, Germany, France, the Netherlands, Luxemburg, the European Commission.

developing and implementing an adaptation strategy pertaining to the impacts of climate change. Activities regarding adaptation to climate change have started with an assessment. However, already in the 1990s, important measures have been taken regarding flood risk management, increasing the basin's adaptive capacity to respond to future expected climate changes.

Following the severe flooding in the Rhine in the years 1993 and 1995, the International Commission for the Protection of the Rhine (ICPR) developed and adopted a comprehensive "1998 Action Plan on Floods" covering the period until 2020. In the context of the implementation of the 1998 Flood Action Plan, the flood damage risk (defined as the product of damage potential (€) and the probability of flooding (1/year)) have been assessed. In addition, possibilities for reducing flood levels by implementing measures in the catchment area have been identified. The resulting information was published in the "Rhine Atlas 2001" as one of the elements aiming at increasing the populations "flood awareness". Furthermore, the flood forecasting system has been improved, in particular by improved cooperation between water management administrations and weather services.

The Action Plan aims to improve the protection of people and goods against floods and at the same time to improve the floodplains of the Rhine. Great efforts have been made towards implementing the Action Plan and almost all measures to be implemented by 2005 have been undertaken. Their positive effect is demonstrable. In 2007, Rhine Ministers confirmed the need to develop adaptation strategies for water management in order to be able to address effects of climate change, which are clearly discernable.

The implementation of the 1998 Flood Action Plan over the period 1995-2005 was evaluated in 2007. The assessments will be repeated once every 5 years, for the first time over the period 1995-2010.

Adaptation strategy for climate change impacts

A cornerstone of the adaptation strategy will be the ability to forecast possible impacts of climate change on the hydrology of the Rhine (flood levels and durations, low water levels and durations and water temperature). As a first step, an assessment of available information revealed changes in these parameters over the last 3-4 decades. A second step, the development of common scenarios for these parameters, will be finalised in 2010.

The eventual adaptation strategy will take account of experiences gained with implementing the 1998 Flood Action Plan as well as the wider experience of the ICPR in protecting the Rhine. Synergies between flood protection and ecosystem and water quality improvements will be sought to the extent possible. Furthermore, problems, for e.g. drinking water supply and navigation due to low water levels, will also be addressed.

In this process, the ICPR has a coordinating and guiding role. The actual implementation of measures (including financing them) is a responsibility of the countries in the catchment area.

5 WATER FRAMEWORK DIRECTIVE AND ADAPTATION

5.1 Introduction

5.1.1 Aim and focus of this chapter

This chapter describes guiding principles for adaptation to climate change and relates them to each of the steps in River Basin Management (RBM) under the WFD. Although the guidance is focused on how to respond within the structure of, and the timetable for, WFD implementation (i.e. up to 2027), the principles proposed would be appropriate for application to other forms of river basin management or for a continuation of river basin management in the longer term.

The WFD RBM steps, which are the focus of this chapter, are:

1. Risk assessment - the summary of significant pressures and impacts of human activity on the status of surface water and groundwater (Article 5);
2. Monitoring and assessment of the status of surface water (ecological and chemical) and groundwater (chemical and quantitative) (Article 8 and Annex V);
3. Objective setting - under Article 4 for surface waters, groundwater and protected areas, including in particular identification of instances where use has been made of exemptions (Article 4(4), (5), (6) and (7));
4. Economic analysis - a summary of the economic analysis of water use as required by Article 5 and Annex III.
5. Programme of measures to achieve the environmental objectives (Article 11).

Please note: Although public consultation is an important step in the WFD management cycle, it is not specifically addressed in this chapter but it is dealt with in chapter 4. Please also consider the guidance provided in chapter 3 on how river basin managers should handle available information and uncertainty from climate change models, projections and scenarios.

5.1.2 Climate change and the Water Framework Directive

Although the WFD does not explicitly mention risks posed by climate change to the achievement of environmental objectives (see also WFD introduction in chapter 2.1), there is a strong case for incorporating climate change within the RBM process[11]. Furthermore, the underpinning rationale and processes of the WFD are amenable to delivery of adaptation (Figure 1). In particular, the integrated approaches to land, water and ecosystem

---

management, combined with the cyclical review of progress, are all consistent with the ideals of adaptive management. Focusing on the resilience of healthy aquatic ecosystems to changing and degrading conditions provide a cost-effective and relatively easy way to achieve adaptation. As the WFD contains several elements that will support the resilience of aquatic ecosystems and the rational use of water resources, achieving its objectives will support adapting to climate change.

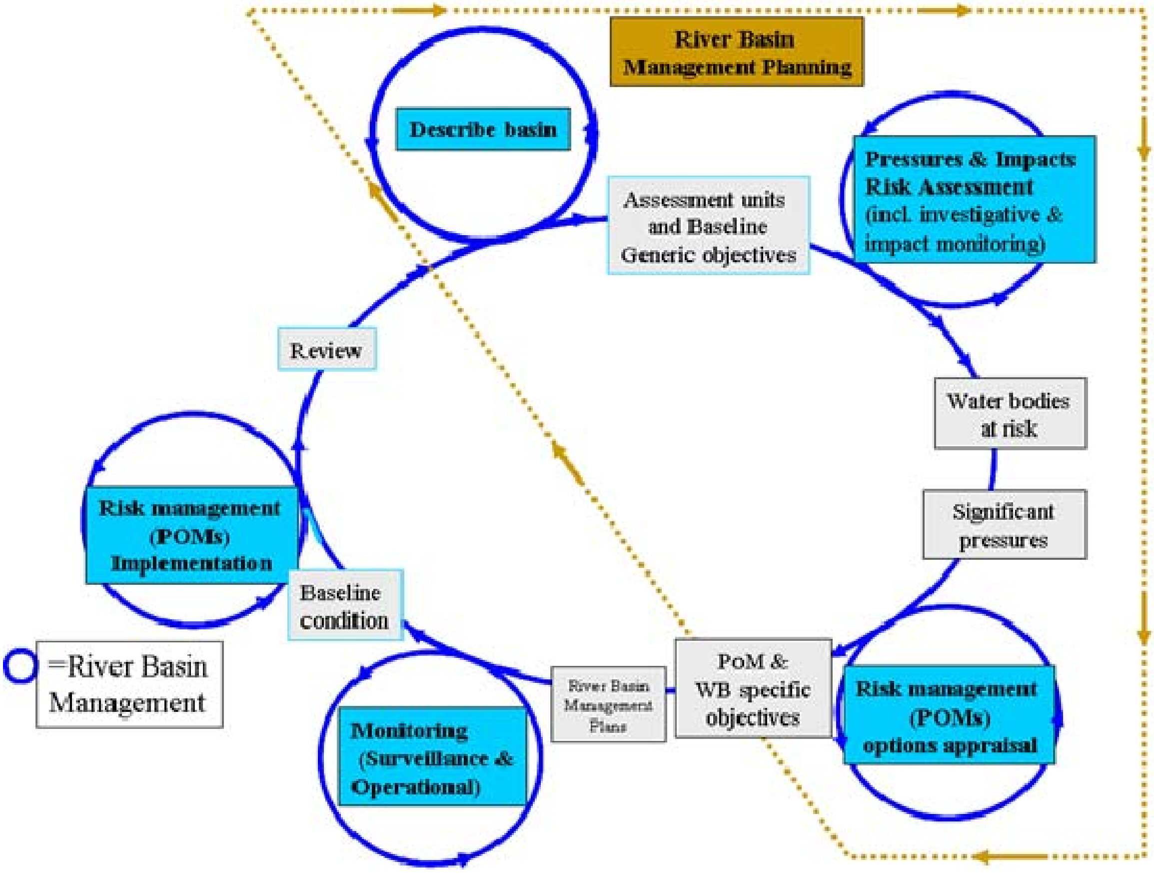

Figure 1 Schematic of RBM process and sub-processes under the WFD

Previous work has highlighted the climate sensitivity of:

- Anthropogenic pressures that affect likelihood of achieving good ecological status;
- Monitoring programmes;
- Water body typologies;
- Conditions at reference sites;
- Economic appraisal and cost-effectiveness of investments;
- Effectiveness of programmes of measures in achieving objectives;
- Synergies and conflicts due to mitigation and/or adaptation by other sectors;
- Stakeholder expectations and levels of engagement.

In addition, it should be kept in mind that climate change impacts upstream can have implications for the achievement of WFD objectives downstream, and therefore international cooperation as part of the WFD plays an important role. Please check recommendation of chapter 4 on the need to develop joint and coordinated adaptation strategies in the river basin management of international RBDs.

The guiding principles in this chapter are intended to help those with river basin management responsibilities address each of these sensitivities in a proportionate and robust manner, whilst acknowledging the inherent uncertainty of regional climate change projections. Where possible, "no-regret" or "win-win" measures are suggested; outcomes should be beneficial, regardless of the eventual nature of climate variability and change. Supporting activities are on-going to provide practical hints related to adaptation strategies, an example of which is the ClimateWater project (http://www.climatewater.org/) briefly described in Annex II.

5.1.3 Which steps in river basin management are most important in adaptation to climate change?

Some of the river basin management (RBM) steps are considered more critical than others in our ability to prepare for climate change, especially in the short term. Essential components for planning for climate change are judged to be:

- an ability to identify change as it happens through **monitoring;**
- ensuring that the likely scale of impacts of climate change on existing and projected future anthropogenic **pressures and risks** is understood, and
- developing and prioritising multiple-benefit catchment based solutions which restore or maintain the natural characteristics of catchments to build resilience to a range of possible climate futures. In this context, **measures** should be examined to ensure that they will not fail under future climatic conditions.

These parts of RBM should be the focus of Member States when considering how to deal with climate change.

It is thus expected that as a minimum, in the 2nd and 3rd cycle of RBM, Member States should clearly demonstrate:

- **how climate change projections have informed assessments of WFD pressures and impacts,**
- **how monitoring programmes are aligned to detect climate change impacts, and**
- **how choices of measures are as far as possible robust to future projected climate conditions.**

Apart from exceptional circumstances, **it is not expected that, within the timeframe of WFD implementation (i.e. up to 2027) and within the metrics used for status assessment, a climate change signal will be statistically distinguishable from the effects of other human pressures at a level requiring reclassification of sites**. It is more likely that indirect pressures arising from human responses to climate change will have a greater impact (such as elevated water abstractions for irrigated agriculture, or new flood defence infrastructure).

However, guidance is provided for cases where sufficient clarity from monitoring evidence shows this is the case. In most cases, climate change may add to existing human pressures and in case these pressures lead to a deterioration of status, this needs to be addressed via the Programme of Measures.

Likewise, climate change should not generally be used as a justification for exemptions, at least in the short term - it is considered that there will be few cases where sufficient scale and certainty in climate projections will combine with a lack of proportionate measures to require lower than default objectives to be set, but guidance is provided for where this is raised as an issue (see section 5.5). This is applicable to the upcoming RBM cycles.

5.2 Guiding principles for Water Framework Directive and adaptation

The principles set out in the table below provide guidance on how climate change adaptation should be considered in each of the steps of river basin management under the WFD.

Table 2 RBM steps and guiding principles for WFD implementation in a changing climate

RBM steps of WFD	Guiding principle	Summary of the guiding principles for the RBM steps
Assessing pressures and impacts on water bodies	1 Assess, over a range of timescales, direct influences of climate change and indirect influences where pressures are created due to human activities in adapting to climate change	*A more integrated approach to risk assessment is needed to counter changes in pressures that may arise from the direct impacts of climate change, as well as from autonomous and/or anticipatory measures taken by different groups to mitigate and adapt to climate change.*
Monitoring and status assessment	2 Maintain both surface and groundwater surveillance monitoring sites for long time series. Set up an investigative monitoring programme for climate change and for monitoring climate change "hot spots", and try to combine them as much as possible with the results from the operational monitoring programme. 3 Include reference sites in long term monitoring programmes to understand the extent and causes of natural variability and impact of climate change	*Good monitoring networks will be essential to identifying and reacting to climate change and so it is important that sites with long time series of data collection are not dropped from surveillance monitoring. In addition, knowledge of when and where climate change might be first detected could be used to target monitoring and reporting of effects in the most vulnerable water bodies, then to bring forward adaptation interventions as required. This is important for surface water and groundwater (including groundwater quantity monitoring).* *In order to detect climate change impacts early, the monitoring frequency needs to be higher than the WFD minimum for surveillance monitoring, as otherwise it will take a long time to gather robust time series.* *As climate change and human impacts at catchment scale may affect similarly the quality elements used for status assessment, information on coherent changes at reference sites, which by definition are sites with missing or very minor anthropogenic influence, is the primary proof that would enable disentangling the two kinds of impacts. So concurrent hydrometeorological data and data on quality elements are needed to better interpret mid and long-term changes in status.*
Objective setting	4 Avoid using climate change as a general justification for relaxing objectives, but follow the steps and conditions set out in the WFD	*There is a danger that anthropogenic climate change could be used as an excuse to set lower objectives for water bodies, even though formal attribution of a detected trend to anthropogenic climate change is unlikely at the scale of RBDs for several decades to come. Although the use of exemptions is an integral part of river basin management planning, applying exemptions without justification in line with the Directive cannot be seen as a general strategy to cope*

		with the consequences of climate change. In addition, there is need to assess the impacts of using exemptions for making water resources more resilient to climate change.
Economic analysis of water use	5 Consider climate change when taking account of long term forecasts of supply and demand and favour options that are robust to the uncertainty in climate projections	*Climate change will mean that the value of water will change as the balance between supply and demand is impacted. Economic analysis carried out in order to apply recovery of costs and judge the most cost-effective combination of measures should consider what these future conditions might be. However uncertainty surrounding projections means that we should look for solutions that will be able to perform over a wide bandwidth of climatic conditions.*
Measures for adaptation related to the WFD		
How to do a climate check of the Programme of Measures?	6 Take account of likely or possible future changes in climate when planning measures today, especially when these measures have a long lifetime and are cost-intensive, and assess whether these measures are still effective under the likely or possible future climate changes. 7 Favour measures that are robust and flexible to the uncertainty and cater for the range of potential variation related to future climate conditions. Design measures on the basis of the pressures assessment carried out previously including climate projections. 8 Choose sustainable adaptation measures, especially those with cross-sectoral benefits, and which have the least environmental impact, including GHG emissions.	
What to do if other responses to climate change are impacting on the WFD objective of good status?	9 Avoid measures that are counterproductive for the water environment or that decrease the resilience of water ecosystems 10 Apply WFD Article 4.7 to adaptation measures that are modifying the physical characteristics of water bodies (e.g. reservoirs, water abstractions, dykes) and may cause deterioration in water status 11 Take all practicable steps to mitigate adverse effects of counterproductive measures	

5.3 Pressure and impact assessment

Guiding principle

1. Assess, over a range of timescales, direct influences of climate change and indirect influences where pressures are created due to human activities adapting to climate change

European freshwaters are already being affected by many human activities, resulting in changes in land-use, pollution with nutrients and hazardous substances, and acid deposition. Healthy, free-flowing rivers respond to changes in land use and climate through dynamic movements and flow adjustments that buffer against impacts. However, many river basins are sufficiently impacted that their ability to absorb disturbances, such as changes in discharge and water stress, is severely limited.[12] Hence management of pressures and the restoration of natural functioning of river basins is an essential part of climate change adaptation.

Member States are required, under Article 5 of the WFD, to carry out a review of the impact of human activity (e.g. point and diffuse source pollution, abstraction) on the status of surface waters and on groundwater (see Annex II of WFD for technical specifications). Climatic change will have an influence on the extent of risk from these pressures. It will be essential not only to understand how the risk from these pressures will change over time without climate change but also to factor in how climate change will add to or reduce the level of risk in order to effectively plan appropriate measures. This will be particularly important where measures are planned that have a long lifespan or limited flexibility (for example large infrastructure projects such as reservoirs or water transfers).

Climate change should be integrated into the processes Member States use for assessing the risks from WFD pressures. As far as possible this should provide a quantitative assessment of the effect of climate change on the risks from pressures using European or Member State climate projection data. For the first cycle of river basin management the influence of climate change on the risks from WFD pressures (and the subsequent effectiveness of measures) may only be qualitative. However, quantitative analysis is needed to establish the severity and timescales over which changes may occur, and thereby improve risk assessments and prioritise adaptation work[13] in ongoing river basin management. More quantitative work is required prior to the implementation of measures which have a long lifespan and are inflexible to later adaptation. Although quantitative analysis may be needed and may take time, certain measures can already be taken that are likely to make a significant positive impact on the status of a water body: increasing the resilience of the water body is an important no-regret step in adapting to climate change (see section 5.7).

Potentially all of the WFD pressures will be sensitive to climate change. In this context, we need to distinguish between **"primary"** and **"secondary" pressures**. Primary pressures are linked to climatic impacts that affect natural systems or processes (e.g. temperature effects on metabolic rates, less precipitation due to climate change and, therefore, less water flow etc) and/or modify the effects of human pressures (e.g. more frequent flushing of combined sewer outflows). The following table summarises potential primary impacts of climate change

---

[12] Climate change and the world's river basins: anticipating management options. M A Palmer, C A Reidy Liermann, C Nilsson, M Flörke, J Alcamo, P S Lake, and N Bond. Front Ecol Environ 2008; 6, doi:10.1890/060148

[13] Environment Agency, 2008. *Water for life and livelihoods. Annex H – Adapting to climate change*. Rio House, Bristol, 24pp.

on water bodies. Secondary pressures are understood as pressures due to a human activity adapting to climate change, e.g. increased water storage, leading to a secondary effect of higher concentrations of pollutants downstream.

Table 3 Examples of primary climate change impacts on water status[14]

Parameters	Examples of primary impacts of climate change
Hydrological-hydromorphological	Changing river flows, lake levels and retention times, and sea levels lead to coastal erosion Hydrological connectivity of slopes, channels, and coastal zones Long-term bed-load and channel change Geomorphological processes creating dynamic/diverse habitats Sediment transport changes associated with climate change Changes in groundwater demand and recharge system induced or enhanced by climate change
Physico-chemical	Changes in water temperature and dissolved oxygen Decreased dilution capacity of receiving waters Increased erosion and diffuse pollution More frequent flushing of combined sewer outflows Potential remobilisation of sediment- and soil-associated historic contamination Photoactivation of toxicants Exceedence of water quality standards Salt water intrusion (both into groundwater and upstream into estuaries and tidal river systems)
Biological-ecological	Changing metabolic rates of organisms Changing ecosystem productivity and biodiversity Climate space of plant and animal distributions Fish migration patterns and dispersal corridors Increased eutrophication and occurrence of algal blooms Changes in aquatic fauna and flora including those at reference sites Changes in species assemblages in designated areas More rapid decline in faecal indicator organisms and pathogen populations Increased microbiological activity Decreasing groundwater levels may have adverse effects on depending terrestrial ecosystems

Note: Impacts may be considered at three levels: i) Hydrological/hydromorphological, ii) physico-chemical, and iii) biological-ecological. The power to attribute these impacts directly to climate change fades in the same order and will forever remain very weak at the biological level.

[14] Taken from Wilby, R.L., Orr, H.G., Hedger, M., et al. 2006. Risks posed by climate change to delivery of Water Framework Directive objectives. *Environmental International*, **32**, 1043-1055.

Management actions taken to address one pressure (or combinations of pressures) may increase the risks of not achieving WFD objectives for other pressures. Likewise, measures taken to mitigate emissions of greenhouse gases or to adapt to unavoidable climate change could indirectly affect or introduce new pressures to water bodies. Some actions may lessen pressures; others may increase pressures (as with greater water demand for bio-fuel production). **It is likely that such secondary pressures (i.e. pressures from human uses of water adapting to climate change) will have the biggest effect on water status on the short-term.** The following table lists possible secondary climate change impacts and effects on water quality.

Table 4 Examples of secondary climate change impacts and effects on water quality

Secondary climate change impacts	Effects
Reduced nitrogen emissions to air	Smaller area of acidic deposition and area of ecosystems adversely affected by excessive nitrogen (eutrophication).
Increased bio-fuel production	Increased groundwater acidification caused by enhanced acid deposition to forestry and removal of soil cations during harvesting; impacts on ground and surface water quality through increased fertilizer and pesticide use as well as more intensive agricultural practices on currently set-aside or extensively used agricultural land.
Increased water supply and storage	River regulation and inter-basin transfers change thermal and chemical composition of downstream waters. Dams modify river habitats and hamper fish migration. In the case of increased water recycling, higher concentrations of persistent pollutants due to water re-use.
Increased hydropower production	Changes in environmental flow of regulated rivers (secondary impacts from the Renewables Directive like proposals for new hydropower development and increased use of hydropeaking) Hydropower is an important renewable energy opportunity, but may impact on the achievement of good ecological status through changing flow patterns and modifying channel structures. Hydropower guidance should be followed to minimise these risks.
Longer growing seasons	Changing cropping patterns, increased agricultural pesticide and fertilizer use cause negative impacts on water quality; changes in soil tillage; diffuse runoff quality; increased water demand for irrigation; increased vegetation cutting and weed clearance in navigable water bodies.
Changing fire management regime	Controlled burns in headwaters; contamination of groundwater resources; increased export of organic carbon, sediments and toxics.
Measures to reduce flood risk	Improved urban water quality thanks to sustainable urban drainage systems, or upgrading of sewerage systems to cope with higher rainfall intensity; increased saline intrusion due to managed retreat of coastal defences.
Removal of obstacles to assist movement	Increased risk of spread of invasive species.

Risk assessments that are too narrowly focused on existing pressures within river basins may overlook important, but often remote or indirect, drivers of change. This underlines the need for a more integrated approach to river basin management and for engagement with a much broader constituency of stakeholders and planning processes (e.g. development planning, flood risk management planning). In many respects, indirect influences on pressures could be invoked (and therefore impact water body status) earlier than direct climate change impacts projected from, for example, higher temperatures or lower rainfall.

In general, however, this Guidance Document does not intend to summarise the large quantity of research evidence that is emerging and continuing to develop on the subject of climate change impacts on the water environment. It is recommended that those with responsibilities in river basin management familiarise themselves with the main sources of this information and keep up to date with relevant findings as they develop, in order to determine the likely impacts in their river basins. The findings of JRC and EEA, together with Member States own research institutions as well as results of key European projects (see Annex II of this Guidance) should be consulted.

Suggested actions

- Consult the findings of key research institutes (such as the EEA, JRC and national institutes (e.g. UK Climate Impacts Programme)) and of national and EU-funded research projects to develop your understanding of the potential climate change impacts on the water environment in your country or river basin.
- Identify direct climate change impacts on the risk from WFD pressures and, where possible, integrate into existing approaches for the quantitative risk assessment of pressures.
- Identify pressures that could be indirectly affected by climate change mitigation or adaptation policies considering also developments in other sectors, using expert opinion, local knowledge, literature reviews or targeted research.
- Estimate the time-scale(s) over which direct and indirect climate change factors might influence pressures on water bodies. Include consideration of longer term timescales (up to 2050 at the minimum) in order to understand and plan for longer term challenges.
- Report on how these pressures could influence achievement of WFD objectives and identify corresponding measures.

Example 5a – Direct climate change impacts on river water quality

An appraisal is undertaken to determine the potential impact of climate change on the water quality of rivers receiving consented discharges from sewage treatment works (STWs). Projected changes in monthly river flows for the 2020s are used to calculate final concentrations of phosphate, ammonia and dissolved oxygen via a simple mixing model applied to river reaches. The effects of water temperature on rates of reaction in rivers and on the solubility of dissolved oxygen, as well as effects on the flow and quality of discharges from STWs are also taken into account. The model then calculates the length of river falling into each of the five classes used for the WFD.

The modelling suggests only a small percentage of rivers should be downgraded when comparing river lengths in each water quality class in the 2020s with those in 2000. The reductions are due mainly to reduced dilution of current discharges from sewage treatment works, manifested by less desirable concentrations of phosphate and dissolved oxygen. Assuming the permanent loss of the river lengths downgraded from Good Status, the cost of the climate impacts can then be expressed as a Net Present Value. These damages can be weighed against the costs associated with programmes of measures to reduce pressures, such as more stringent consents for point discharges from STWs.

Example 5b – Decrease of the river flows within the Adour Garonne basin, France

Climate projections made by Météo France show that river flows could decrease by 25% as an annual average by 2050, for the entire Adour Garonne (AG) district. This decrease of the flows could reach 36% during spring and summer. The water status could be largely influenced, due to the combination of higher temperatures and decrease of the river flows. At the same time risks from anthropogenic pressures could increase. For example, projections by the "Statistics project for the population of AG district" showed a population increase of up to 20% by 2030. This could increase the conflict between water uses and users. New measures will be necessary to mitigate these effects and integrate climate change constraints.

Example 5c – Salmon already in "hot water"

Climate projections suggest most rapid warming in southern and eastern parts of the UK. The same regions are also expected to witness the earliest signs of depressed groundwater flows in summer. Indeed, rising air and water temperatures are already beginning to affect salmon distributions through changes in behaviour and physiological harm at different life-cycle stages. Synergistic effects of drought, over-abstraction, low dissolved oxygen concentrations, and higher salinity further reduce thermal tolerances of fish in estuaries.

Under the present conditions there is on average only one day per summer when water temperatures would deter migration upstream, but approximately one week during which conditions in the tidal river delay migration. As summer air temperatures increase the window of opportunity for fish to pass through the estuary becomes narrower, and hence the loss of fish rises. Without interventions, the viability of the salmon population is threatened in some "Low, Small/Medium Calcareous" rivers within a few decades.

Example 5d – Development of a numerical model in a transboundary aquifer

One of the objectives of the Scaldwin[15] project is the study and management of two transboundary groundwater layers or aquifers: the carboniferous limestone aquifer (shared between France and Belgium), which suffers from overexploitation, and the groundwater in the Dutch-Flemish polder area, which suffers from saltwater intrusion. The carboniferous limestone aquifer has a high economic value as a drinking water resource. The possible salinization in the Dutch-Flemish polder area will have a negative impact on the agricultural activities. For the latter, a joint numerical groundwater model will be developed, which will allow to us to gain an insight into the future distribution of fresh and saltwater under influence of climate change and sea level rise.

Example 5e – Increasing nitrogen loading in Southern Finland

A set of climate change scenarios suggest an increase of 2.8–4.7 ºC in annual mean temperature and 10.1–23.6 % increase in annual precipitation in southern Finland for period 2070–2100. The considerable increase in winter (December-February) temperatures (3.4–6.2 °C) and precipitation (26–56 %) predicted by the different scenarios influence strongly the hydrological regime, especially snow accumulation and snow melt in spring. According to model results such changes would increase the annual inorganic N load from catchments by 10–70 %. This is due to higher mineralization rate and increased water flow through the catchment soils. The predicted changes are more pronounced in an agricultural lowland catchment than in the forested one, particularly during the dormant period, from November to February. Efficient catchment scale mitigation measures are needed, especially on

[15] http://www.nweurope.eu/index.php?act=project_detail&id=3871

the agricultural sector, to prevent eutrophication of surface waters in future climate conditions.

Example 5f – River flow modelling in the Blsanka river basin, Czech Republic

Several rivers are located in a low precipitation region in the Czech Republic and their hydrological conditions have deteriorated during the last two decades, which are probably already affected by impacts of initial stages of climate change. The main problems occur during drought periods, when river discharges drop below minimum ecological flows, the river water is excessively polluted by waste water discharges from urban areas and the water resources are insufficient for meeting water use requirements for the purposes of agriculture, which is very important economic sector in this region.

In order to make decisions about effective measures, it was necessary to derive volumes of water, which are missing during drought events (deficit volumes) to ensure effective dilution of waste water and for maintaining the required ecological flows to keep the ecological function of the stream. Results of the application of deficit volume method (Tallaksen & Lannen, 2004) by using the EXDEV computer program showed that the storage capacity for ensuring ecological flows during the period 1969 – 2008 would be 510 megalitres (deficit in 2007). Including scenarios for climate change in the model suggests that the deficit volume will increase in range from 3260 megalitres (according to scenario RCAO B2) to 5750 megalitres (scenario HIRHAM A2) until the year 2085.

5.4 Monitoring and status assessment

Guiding principles

2. Maintain both surface and groundwater surveillance monitoring sites for long time series. Set up an investigative monitoring programme for climate change and for monitoring climate change "hot spots" and try to combine them as much as possible with the results from the operational monitoring programme.
3. Include reference sites in long term monitoring programmes to understand the extent and causes of natural variability and the impact of climate change

5.4.1 General remarks

Implementation of the WFD is based on objective and transparent criteria and procedures as agreed in the Common Implementation Strategy, e.g. for defining surface water body types, reference conditions, and quality class boundaries. Furthermore, it is based on robust monitoring data. Although climate change has the potential to impact on virtually all quality elements included in the definition of WFD ecological status, this does not affect the principles of water status assessment, which remain valid.

There is some evidence that anthropogenic climate change is having a significant impact on physical and biological systems globally and in some continents[16]. However, apart from exceptional circumstances, **it is not expected that, within the timeframe of WFD implementation (i.e. up to 2027) and within the metrics used for status**

[16] Cynthia Rosenzweig et al., Attributing physical and biological impacts to anthropogenic climate change, Nature, Vol 453| 15 May 2008

assessment, a climate change signal will be statistically distinguishable from the effects of other human pressures at a level requiring reclassification of sites.

In a few cases, climate change could impact status assessment in the relatively short term and influence the water body type and/or reference conditions. It is more likely that climate variability and change will work alongside pressures from human activities, which have to be addressed with measures to achieve good status. However, some general principles on how to deal with climate change induced changes, if they occur, are given below.

In the future, there will be certain areas in Europe that will be the first to clearly identify climate change impacts requiring an of assessment whether additional measures need to be taken to achieve good status. There are now a number of cases where tentative links to climate change are claimed (see examples below). It is essential that in these cases, sufficient monitoring is taking place that is linked to meteorological monitoring, and that both have a long enough time series reaching at least 20 years to avoid over-interpretation of any short term observed trends.

5.4.2 Monitoring

Monitoring will be essential to understanding and appropriately responding to climate change across Europe. After all, an appropriate river basin management response to climate change impacts can only be based on a **sufficiently robust long-term monitoring network of reference sites linked to meteorological data**. Otherwise, one may run the risk that designed measures may not tackle the real pressure.

Whilst monitoring programmes under the WFD are generally not designed for the need to identify and monitor climate impacts, all long-term monitoring programmes will inherently contribute to the detection and understanding of any climate change signals. It is very important to take a consistent and long term approach. Monitoring programs should be planned carefully with a long-term perspective and carried out consistently preventing major changes in the station network or methodologies such that comparisons can be made between years (this is the basic idea of any surveillance monitoring). It is very important to avoid abandoning monitoring stations which already have a long term consistent record, especially in the context of climate change. Notwithstanding the above, it may be possible when designing monitoring programmes to target reference sites (see 5.4.4) or "hot spots" of predicted climate change impact when adding new stations.

As a first approximation, climate change is expected to "squeeze" climate space occupied by high-elevation and coastal-zone ecosystems[17]. The former are already experiencing reduced snow/ice storage and amplification of extreme rainfall events; the latter rising sea levels and ocean temperatures. Other climate change impacts will be manifested through changes in disturbance regimes involving fire, pests, disease and competition from invasive species. These drivers will interact with existing pressures such as pollution, exploitation of natural resources, or land-cover change. Therefore, the resulting climate change "hot spots" might be regarded as a composite of the climate projection, distribution of existing pressures, and underlying pattern of vulnerable habitats and species.

Knowledge of *when* and *where* climate change might be first detected could be used to target monitoring, conservation efforts and resources[18,19]. Until now, attributable human-

induced climate change impacts have occurred in air and water temperature dependent responses (such as timing/volume of snowmelt, species' distribution and phenology)[20]. The risk of extreme heat-waves has already increased[21]; detectable changes in heavy precipitation could emerge by the third cycle of RBM under the WFD[6]. Where there are no economically or technically feasible means of countering such trends and their biological impacts, reducing other pressures to "buy time" may be the only rational option.

Please refer also to chapter 4 for further guiding principles on data collection to improve decision-making in river basin management under climate change as well as chapter 7.3 on monitoring for detecting climate change impacts on quantitative elements of water resources.

Suggested actions

- Do not systematically redesign monitoring programmes around climate change but, as part of general good practice, plan monitoring programmes carefully to take a long-term perspective, and apply consistently without changing the station network or methodologies. Do not abandon stations which already have a long-term consistent record.
- Notwithstanding the above:
- Where possible establish more intensive monitoring of vulnerable water bodies to better understand the pace and mechanisms of change, and use these sites as sentinels of climate change. In cases where the minimum WFD monitoring frequency is applied, assess whether this is sufficient; in order to early detect climate change impacts, the monitoring frequency needs to be higher than the WFD minimum for surveillance monitoring, as otherwise it will take a long time to gather robust time series.
- Encourage a monitoring programme that includes long-term, concurrent meteorological, water quality and biological monitoring of reference sites to improve evidence of causative links between climate variability and local ecological status.
- Compile register of species-dependent hydro-climatic thresholds and damage functions. Intensify monitoring of most vulnerable species/ecosystems to better understand the pace and mechanisms of change, and use indicator species to track impacts with/without adaptation.

Example 5g – Additional monitoring needed for detecting climate change induced changes to salt marshes

The salt marshes of the Dutch, German and Danish Wadden Sea, and the marshes of the British East Coast (classified as type K2 – polyhaline sheltered coastal waters) are highly dynamic natural ecosystems with tidal channels, sands, mud flats, salt marshes, beaches, dunes and a transition zone to the North Sea. They form the upper parts of the intertidal zone and are the interface between

---

mainland (the embankments) and the sea. Besides being highly valuable habitats, foreland marshes give a self-regulating protection of the embankments for coastal flood defence. The presence of a salt marsh in front of a seawall will thus improve safety of the hinterland and reduce the cost involved in seawall maintenance.

The Dutch have shown that the elevation of their foreland marshes is currently able keep pace with current 2.5 mm/yr rise in sea level. The threshold value for the intertidal flats seems to be a (relative) sea level rise of 6.0 mm/yr. Beyond this threshold intertidal flats start to disappear and even protection from erosion (e.g. by brushwood groynes) will no longer be sufficient. Although salt marshes may receive sufficient sediment to compensate for (relative) sea-level rise, lateral erosion of the salt-marsh edge can result in a net loss of salt-marsh area. A poor vegetation cover in the pioneer zone in front of the marsh can provide less protection of new sediment, with a subsequently lower net sedimentation. The effect leads to cliff erosion. This erosion can be intensified by strong winds, high tides and increased wave height, which in turn may be caused by climate change and human activities like land claim, dredging and canalization.

Because of possible large-scale climate change-induced effects it is important to use trilaterally (Denmark, Germany, Netherlands) harmonized criteria for monitoring the salt marshes. The following parameters are monitored every five years trilaterally: location and area, vegetation types, land use/management, geomorphology and drainage. Changes in geomorphology due to climate change will take at least decades to happen. But once a threshold has surpassed, after for instance a few decades, rapid changes in the vegetation cover can occur. It is likely that the common (WFD) monitoring will be sufficient to detect climate change-induced changes at the physical level (i.e. area of salt marsh and the relative soil levee), but additional monitoring may be required in order to establish the relation between ecological changes and climate change.

5.4.3 Surface water body types

Water bodies are "typed" by a set of obligatory (e.g., topographic, geological, physical, hydrological) and optional (e.g., water depth, mixing characteristic, nutrient status) descriptors. A number of these descriptors are climate sensitive. As any typology is a simplification compared to the natural continuum, some water bodies always remain on type boundaries and could, in theory, migrate from one type to another as a consequence of gradual climate change or sequence of extreme events. Over longer time horizons there is even the prospect that some sites could shift between different categories of water bodies, such as a lake to transitional water category. Any refresh of characterisations would have to be mindful of the fact that natural climate variability could result in temporary migrations between types. So there is an open question surrounding the length of the sampling period needed to confidently re-assign a water body from one type to another.

In order to keep the number of water bodies with ambiguous types at the minimum, typologies should be created as close as possible to the naturally occurring patterns using, e.g. clustering or other multivariate techniques. If the type of some water bodies will still change as a result of CC, these water bodies should be transferred to the appropriate type and the corresponding reference conditions applied to them.

Ecosystems of some types of water bodies, e.g. large shallow lakes, are more physically controlled and thus more sensitive to climate change.

Suggested actions

- Undertake a risk assessment to determine the extent to which climate change could trigger transitions between categories and types within rivers, lakes, transitional, coastal and artificial water bodies.
- Where possible establish more intensive monitoring of vulnerable water bodies to

better understand the pace and mechanisms of change, and use these sites as sentinels of climate change.

Example 5h – Change of water body type

A low-lying, near coastal lake was initially typed as "High alkalinity, Very shallow" because the $CaCO_3$ concentration is more than 50 mg/l, and the mean water body depth is less than 3 m. Certain objectives (and standards) apply to this type which help define its management.

According to the UKCP09 scenarios (http://ukclimateprojections.defra.gov.uk), between 61 and 87 mm of relative sea level rise is expected over the next 20 years (for high and low emissions scenarios respectively). Consequently, in this hypothetical case, after a series of stormy winters nearby coastal defences and dykes are permanently breached and sea water periodically enters the lake under very high tides. The morphology of the lake is unchanged but the water is now brackish. In the absence of new coastal defences, the site is now characterised as "Brackish, Very Shallow". Objectives and management may have to shift to suit this new type of lake.

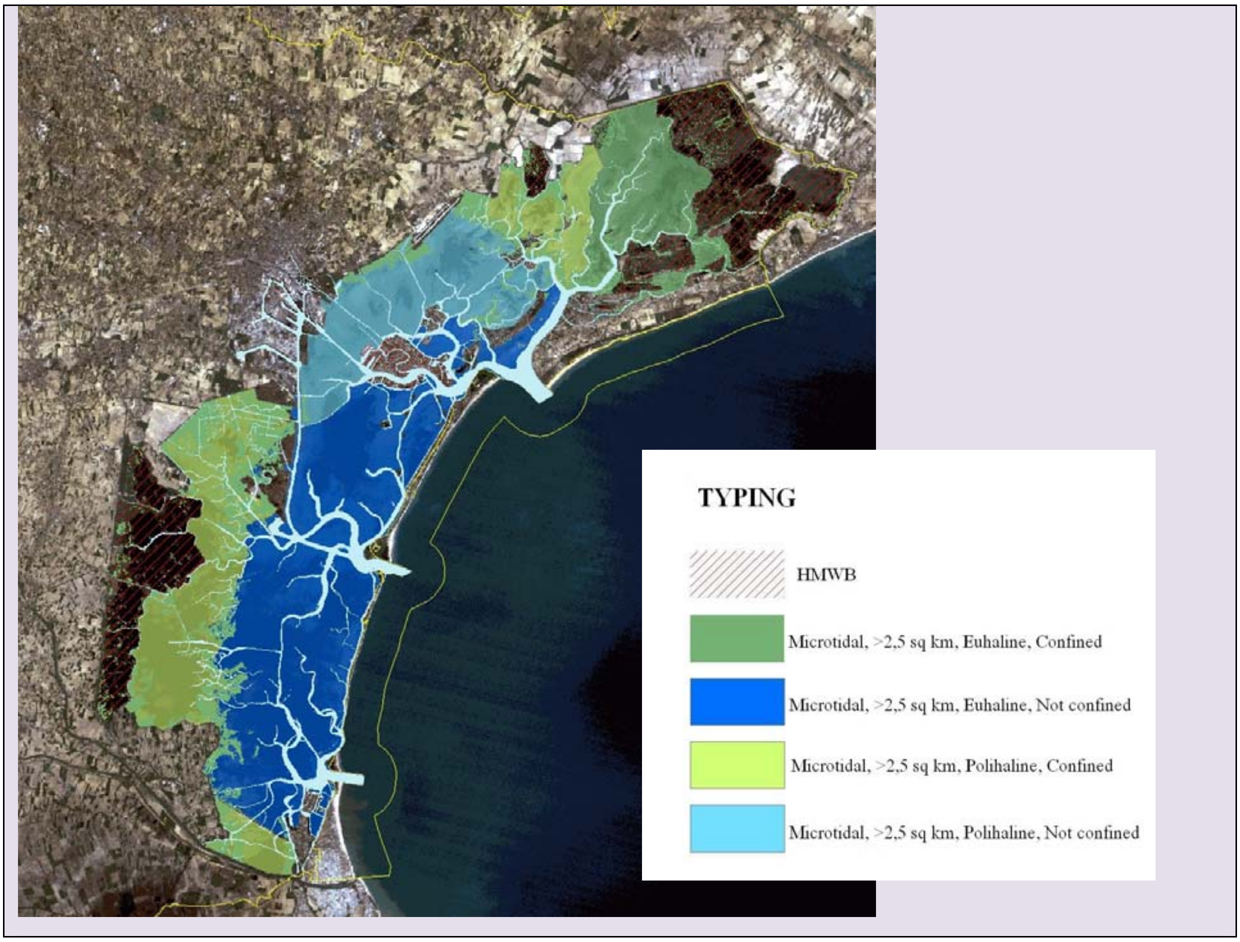
After a few more decades of net sea level rise, and near permanent connection to the sea, the water body is characterised as a "Transitional lagoon". Once again, objectives and management may have to shift to suit the new conditions.

Example 5i – transitional water in Mediterranean Ecoregion: the Venice lagoon (Italy)

Physical descriptors used for transitional water types in Italy are annual average salinity and tide range (the other descriptors are optional, such as the degree of confinement). In the Adriatic sea, three possible effects of climate change can be considered: rising mean sea level, increasing sea temperatures, and "tropicalisation" of temperatures and rainfall.

Tides and Sea level: The Venice lagoon is micro-tidal and it is not likely that the projected sea level rise will be more than 2 m (current tide range is around 1 m): therefore, there are not likely to be any migrations to a meso-tidal lagoon type. Furthermore, in the Mediterranean Ecoregion depth is not a descriptor for the transitional water typology, therefore any changes in the sea level will not cause any direct migration between types.

Salinity, sea level and rainfall: changes in salinity can be caused by an increasing sea level or by an increasing/decreasing rainfall. Venice lagoon (fig. 1) is now polyhaline around the edge (salinity: 20-30 psu) and euhaline close to the inlets (salinity: 30-40 psu) and the observed trend shows a marinisation process within the lagoon. The projected increase in sea level could increase this process and the polyhaline areas could shift to euhaline type. A reduction in mean rainfall over the basin could reduce fresh water inflows to the lagoon and cause the same migration between types. Conversely, increasing rainfall and fresh water inflows can favour migration toward polihaline types, despite the current marinisation process.



5.4.4 Reference sites

The objectives of the WFD include that water bodies should not deteriorate and that they should achieve "good status" by 2015[22]. For surface waters, "good ecological status" (or "good ecological potential" in the case of heavily modified and artificial water bodies) is defined by reference conditions for different water body types. Reference conditions should be set based on objective criteria, preferably by measuring ecological status in unimpacted sites (with agreed pressure criteria for what is unimpacted). Monitoring of reference sites will be essential to understanding and appropriately responding to climate change across Europe (see also section 5.4.2). In fact, a **sufficiently robust long-term monitoring network of reference sites, i.e. sites with missing or very minor anthropogenic impact, linked to meteorological data** will be the only direct way of detecting responses of water bodies to climate change impacts. Only if such monitoring reveals long term coherent changes in the status of reference water bodies over large geographical areas, it will be a proof of changing reference conditions. In practice, as the intercalibration exercise showed, MS use slightly different criteria for selecting reference sites. Use of best available sites instead of real reference sites should be marked as such and defined as an alternative benchmark (e.g. good status).[23] If the conditions at reference sites change, it will be really important to find

[22] Good chemical and ecological status for surface water bodies; good chemical and quantitative status for groundwater bodies.

[23] The procedure on how to define alternative benchmarks is described in CIS Guidance Document No. 14: Guidance on the Intercalibration Process 2008-2011.

out the causes and decide whether the site can still be used as a reference site or not. Such a decision should be supported by results of a sufficiently robust long-term monitoring network linked to meteorological data, including a demonstration of the specific impact of climate change.

Unless biological systems are already close to thermally and hydrologically induced "tipping points"[24], climate trends are expected to play a minor role in early WFD river basin management cycles; natural variability in annual and seasonal climate will be far more significant. Therefore, status definitions should be sufficiently wide ranging to accommodate natural variations within types. Given the brevity of many monitoring programmes, short-term trends in ecological status should be interpreted with extreme caution.

In general, reference conditions and default objectives should not be changed due to climate change projections over the timescales of initial WFD implementation (up to 2027) unless there is overwhelming evidence to do so.

Where there is judged to be significant risk that climate change (and possibly having regard for climate change related policy) would lead to failure to achieve the objectives set for 2015, 2021, 2027 or beyond, this should be noted in the river basin management plan since it is relevant information to the plan user and may assist in considerations of optimization of scarce resource use between locations and objectives earlier in the plan than when non-compliance projected to occur.

For the upcoming WFD cycles, the following actions are suggested in case monitoring data show strong evidence that conditions at reference sites are changing:

Suggested actions

- In order to achieve better distinction between climate change pressures and other human pressures, maintain robust long-term, concurrent meteorological, water quality and biological monitoring to improve evidence of causative links between climate variability and local ecological status. Maintain monitoring programmes at sites with a long history of monitoring in order to give the longest possible time series.
- Use homogeneous climate indices (for instance the NAO, Central England Temperatures or England and Wales Precipitation series) to contextualise biological samples taken under different conditions (i.e., hot-dry, cool-wet, etc). Use paleo-environmental reconstructions and other proxy evidence to represent the full range of conditions experienced at reference sites over multiple decades.
- Undertake periodic reviews of conditions and pressures at reference sites to assess whether the site can still be used as a reference site.
- Prioritise to distinguish climate change impacts from those caused by other anthropogenic pressures.
- Be aware of the challenges associated with attribution of environmental changes to anthropogenic climate change and avoid over-interpretation of observed trends.
- Focus on how climate variability and change will work alongside pressures from human activities and use the degraded water status because of these various pressures as the starting point for planning of measures.

[24] For example, increasing water temperatures combined with lower flows in summer could have lethal and non-lethal impacts on aquatic species such as salmon. See: Solomon, D.J. 2008. *The thermal biology of brown trout and Atlantic salmon: A literature review*. Environment Agency Southwest Region, 40pp.

Example 5j – Understanding biological changes[25]

Macro-invertebrate data for an upland region show declines in species diversity, inter-annual stability, and abundance since the 1980s at circumneutral (and to a lesser extent at acidic forest or moorland) sites. The declining biodiversity appears to coincide with reduced atmospheric deposition of acidifying substances, and rising stream pH at all sites. In other words, decades of industrial regulation and pollution control do not appear to have yielded intended environmental outcomes.

Further analyses of the macro-invertebrate data reveal strong correlations with winter air temperatures and the North Atlantic Oscillation (NAO) index. A long-term trend towards more positive phases of the NAO (typified by warmer wetter winters and increased runoff) since the 1960s is associated with lower abundance of macro-invertebrates in spring. It is too early to say whether such behaviour in the NAO is a manifestation of human-induced climate change. However, the data show the extent to which the "bandwidth" of invertebrate abundance can vary from year to year and decade to decade. The data further imply declining abundance (ignoring in-migration) under warmer future conditions. This example would justify further monitoring.

Example 5k – Impacts on fish distribution and abundance in the Baltic Sea

Changes in marine species observed in the Baltic Sea do not fit into the general pattern of northward shift due to increasing temperature. In this sea, salinity is one of the predominant factors that influence species presence. Salinity ranges from high (close to oceanic values) at the boundary of the North Sea to almost fresh water in the Bothnian Bay (northernmost part between Sweden and Finland). In general, the Baltic aquatic ecosystems are dominated by marine species in the western parts near the North Sea boundary, with predominantly brackish and freshwater species in the central parts. A small change in salinity could change the distribution of species. Changes in salinity are driven by climate-induced changes in precipitation and salt water inflow from the North Sea. It appears that changes have already been large enough to affect the composition of the Baltic Sea biota.[26]

Salinity in the Baltic has decreased steadily since the mid 1980s due to increased freshwater input (precipitation) and a reduction in the frequency of inflow events from the North Sea, which bring in more saline, oxygenated water. Projections for the future climate of the Baltic are for continuing increases in precipitation and decreases in inflows from the North Sea, therefore the distribution and abundance of cod and other marine species is likely to continue to diminish. Their position in the ecosystem may be taken over by more brackish and freshwater species, such as whitefish, pikeperch and perch[27].

Example 5l – Divergence in comparability to reference site for Lake Ijsselmeer

1. Characterisation: Lake Ijsselmeer is a large (114.000 ha), shallow lake (av. 4,6 m) in open connection with Lake Ketelmeer (3200 ha, 3,6 m) and Lake Zwarte Meer (1800 ha, 1,8 m). Lake Ijsselmeer was classified as M21 (large lakes > 10,000 ha, > 3 m depth, even though it is not

[25] Durance, I. and Ormerod, S. 2006. Climate change effects on upland stream invertebrates over a 25 year period. *Global Change Biology*, **13**, 942-957.

[26] A general description of effects caused by climate change are available at: Swedish Environmental Protection Agency (2005). Changes Beneath the Surface, Monitor 19. An In-Depth Look at Sweden's Marine Environment. 192 p. ISBN: 91-620-1246-0.

[27] MacKenzie et al., 2007 as cited in EEA Report No 4/2008 Impacts of Europe's changing climate - 2008 indicator-based assessment.

stratified), the others as M14 (<10,000 ha, < 3 m depth). Due to sea-level rise, the fixed water-levels used in the lakes at present will have to be raised in future, with a maximum raise of 1,5 m. This will change the average depth and the chances of stratification-like conditions occurring.

2. Reference conditions: The water level rise proposed changes the lakes to such an extent that the present reference lakes may become no longer applicable. Lake Peipsi in Estonia/Russia, is currently used as a reference site for Lake Ijsselmeer, however it is shallower and its discharge is not affected by sea-level rise because of the postglacial uplift (rebound) in its part of Europe. The change in water levels and stratification will be monitored to allow a change in reference site to take place if it is shown to become necessary in due course.

Example 5m – Impacts on biodiversity in the Adour Garonne River Basin, France

The following study is a study from "Groupement d'Experts Intergouvernementaux sur l'Evolution du Climat" (GIEC) this study was done by Cemagref (Eric Rochard 2008), which is an international body of research specialists of climate change. The Study realised for the Adour Garonne River basin is part of an overall study on impact of climate change over 200 European river basins. This study is providing reference conditions starting in 1900. The study shows that the major impacts of climate change on rivers and fish species are expected in the middle and long term. Models propose 4 scenarios till 2100. The study clearly highlights already existing impacts of climate change starting from the reference date 1900.

One case study demonstrates that the temperature of water has increased by 1°C over the last 20 years on the Garonne Estuary, due to climate change and associated events such as heat waves and droughts. The increase of the temperature has been monitored over a long period of time about 20 years. At the same time there was no increase of anthropogenic pressures (no additional abstractions, discharges etc.) in the same area. This increase of temperature has contributed to the disappearance of the fish "eperlan" in the estuary of the Garonne river and of the "Flet" the have been replaced by "anchois" due to the decrease of fresh water in the Estuary.

At the same time, a lot of invasive species (fauna and flora) are appearing in the Adour Garonne district, such as the "Bull frog", the "ecrevisse de Louisianne", the myrophilla from Brazil. All these species are modifying the biodiversity by the disappearing of local species (Eperlan, anchois,…) and the appearance of these invasive species. The quality indicator based on the endemic fishes and invertebrate species for the Garonne river will be modified in the years to come. The invasive species less valuable from an ecological point of view contribute to a diminishing biodiversity and at the same time have an impact on some parameters of GES (Fishes, invertebrates). A decrease of the biomass has also been identified by the CEMAGREF study.

The changes in species of fishes in invertebrate will have to be monitored carefully in the years to come in order to see if it could have an impact on the reference conditions of the Garonne river.

These impacts on biodiversity, GES and reference conditions are mainly due to the increase of the temperatures for the entire Garonne river and of the salinity in the Estuary and its progression up stream. Models driven by data starting in 1900 already show the impacts of climate change on the river basin which are expected to increase exponentially till 2100. At the same time the increase of the salinity combined with the ground water depletion is a factor of deterioration of the ecological status of the Garonne aquifer linked to the river. The salt intrusion is having an effect of the ecological status of this aquifer.

Reference: GIEC's study CEMAGREF 2008 case study of Adour Garonne river basin

5.5 Objectives setting

Guiding principle

4. Avoid using climate change as a general justification for relaxing objectives, but

follow the conditions set out in the WFD

Article 4 of the WFD expects Member States to achieve good surface water status and good groundwater status at the latest 15 years from the date of entry into force of the WFD, but provides for the possibility for exemptions to this rule. Paragraph 5 of Article 4 allows Member States to achieve less stringent standards where achievement of these objectives would be infeasible or disproportionately expensive. Paragraph 6 of Article 4 allows for temporary deterioration in the status of bodies of water only in circumstances where the extreme event is "exceptional or could not reasonably have been foreseen". Paragraph 7 of Article 4 allows for new modifications to the physical characteristics of water bodies leading to status deterioration under certain conditions.

Climate change has the potential to impact on the feasibility or expense of achievement of objectives. The EU Water Directors have endorsed that, whilst the use of exemptions is an integral part of river basin management under the WFD, exemptions without justification in line with the Directive cannot be seen as a general strategy to cope with the consequences of climate change. At the same time, the use of exemptions can have negative consequences for making water resources more resilient to climate change impacts.

Whilst it is expected from projections that there may at some point be unavoidable changes to water status due to climate change, there is still significant uncertainty (particularly relating to climate models) over the timing and nature of these changes. Largely it will still be difficult to distinguish the climate change signal from natural variability or other human impacts over the timeframe of the WFD (up to 2027). It is thus necessary to base decisions on the basis of clear monitoring evidence (see principle 2), and not to proactively aim for less stringent objectives based on modelled assumptions of future climate.

However, there may be cases where there is sufficient evidence that the expected scale of climate change impacts on pressures is large enough that the measures needed to meet default objectives would be too expensive or technically infeasible. Where climate change is brought forward as the underlying reason for exemption due to excessive cost or unfeasibility, a clear and robust evidence base as for exemptions in other cases and consistent with other aspects of the approach to climate change should be provided. Within this evidence, DETECTION of a trend alone will be insufficient to invoke a change of policy and process, and ATTRIBUTION of the trend to anthropogenic climate change will be required. Detail on the process and difficulties associated with attribution of changes to anthropogenic climate change are provided in the literature[28]. Put simply, for positive attribution to take place, the observed data should sit outside the range of natural climate variability and be inexplicable other than through the impact of anthropogenic climate change.

The evidence base should also be clear about the inherent uncertainty in climate projections and include consideration of costs and benefits over a range of timescales and potential climatic futures. The full range of potential measures and combinations of measures should be considered.

The process for assessing the need for less stringent environmental objectives should therefore link closely with the economic analysis of measures. Guidance on including adaptation to climate change in economic analysis is given below in section 5.6.

---

[28] Hegerl, G.C., Karl, T.R., Allen, M., Bindoff, N.L., Gillett, N., Karoly, D., Zhang, X.B. and Zwiers, F. 2006. Climate change detection and attribution: Beyond mean temperature signals. *Journal of Climate*, **19**, 5058-5077.

In addition, as extreme events, such as droughts, floods and surge tides may occur more frequently under a changing climate, robust scientific evidence should determine on a case-by-case basis whether they can be considered as exceptional or that they cannot reasonably be foreseen, as referred to in Article 4(6) of the WFD (see also relevant discussion on "exceptional floods" in chapter 0) and prolonged droughts in chapter 7.2.

Finally, the implementation of specific adaptation measures, for instance infrastructure projects, might invoke exemptions according to Article 4(7) of the WFD more often. As explained in section 5.7, certain adaptation measures to climate change can be counterproductive to WFD aims, e.g. storage basins. Such measures need to meet the conditions set in Article 4.7 of the WFD on new modifications (see CIS WFD policy paper on Article 4.7 exemptions).

Suggested actions

- Manage the expectations of stakeholders in terms of how significant an impact climate change will be in the timescale of the WFD.
- Closely monitor and at each cycle review characterisation for any specific water bodies for which lower than default objectives were considered due to climate change.
- When considering impacts of climate change as a basis for justifying exemptions, first establish climate change as the most probable cause of any observed changes.
- Under a changing climate, when disproportionate costs are used as a reason for an exemption, provide a robust evidence base that considers costs of measures and benefits over a range of timescales and climate projections.
- Assess the consequences of using exemptions on making water resources more resilient to climate change.

5.6 Economic analysis

Guiding principle

5. Consider climate change when taking account of long term forecasts of supply and demand and favour options that are robust to the uncertainty in climate projections

Changing climatic conditions do not change the requirements and steps in the implementation of the economic analysis of the WFD. There is still the need to follow the sequential steps for the economic analysis of the WFD, but with the integration of potential additional pressures, impacts and constraints due to climate change.

Annex III of the WFD sets out that economic analysis should be carried out for recovery of costs of water services (and that this should take account of long term forecasts in supply and demand for water in the RBD) and for judging cost effective combinations of measures. Figure 2 below gives a reminder of how economic analysis should be integrated into the RBM decision making; this approach remains the same under changing climate conditions.

Member States have taken markedly different approaches to economic analysis and so the way in which consideration of climate change might be incorporated will vary. However it is recommended that, whatever methodology is used, the required long term forecasts in supply and demand for water incorporate scenarios for climate change. In addition, in assessing combinations of measures, options should be sought that can be shown to perform (and be cost effective) under a wide bandwidth of scenarios for future climate change (see also chapter 5.7 of this Guidance).

Also the justification of lower objectives because of disproportionate cost should consider these long term climate changes. The cost-benefit ratio might change over time and not taking action at an early stage might increase the overall costs for adaptation, e.g. reducing water abstraction for irrigation might be seen as disproportionate because of the loss in income of farmers. However, if water becomes even more scarce, the costs for farmers quitting their business might be higher in the long run. Equally, requiring farmers to install winter storage reservoirs for irrigation could increase costs if they will not be allowed sufficient water to fill them within the payback period of the asset.

Suggested actions

- Carry out an assessment of the impact of climate change on the long term forecast on supply and demand in your river basin district. Integrate these projections into the economic assessment of water use.
- Carry out sensitivity testing based on climate change projections within cost benefit assessment of measures. Give preference to those measures that are robust or flexible to a range of possible climatic futures.

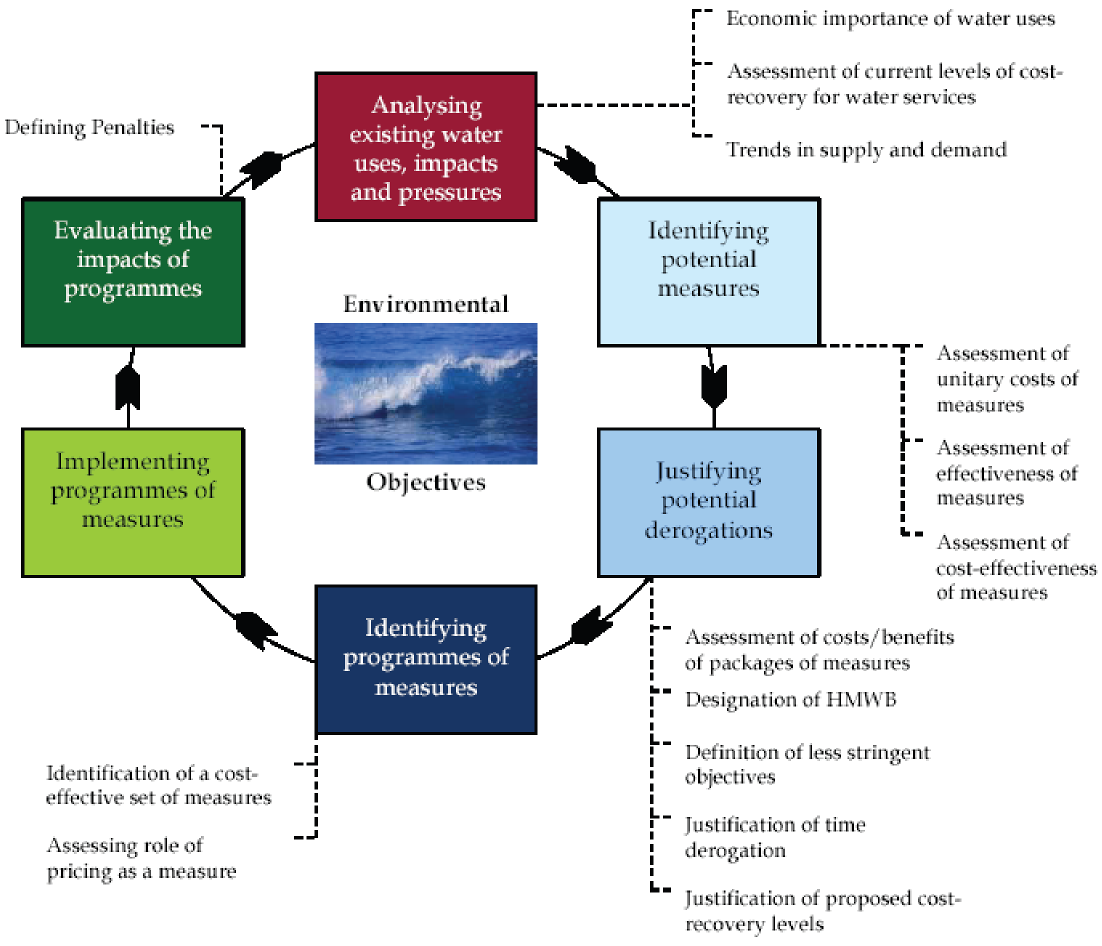


Figure 2 Integration of economic analysis in the RBM decision making process for WFD[29]

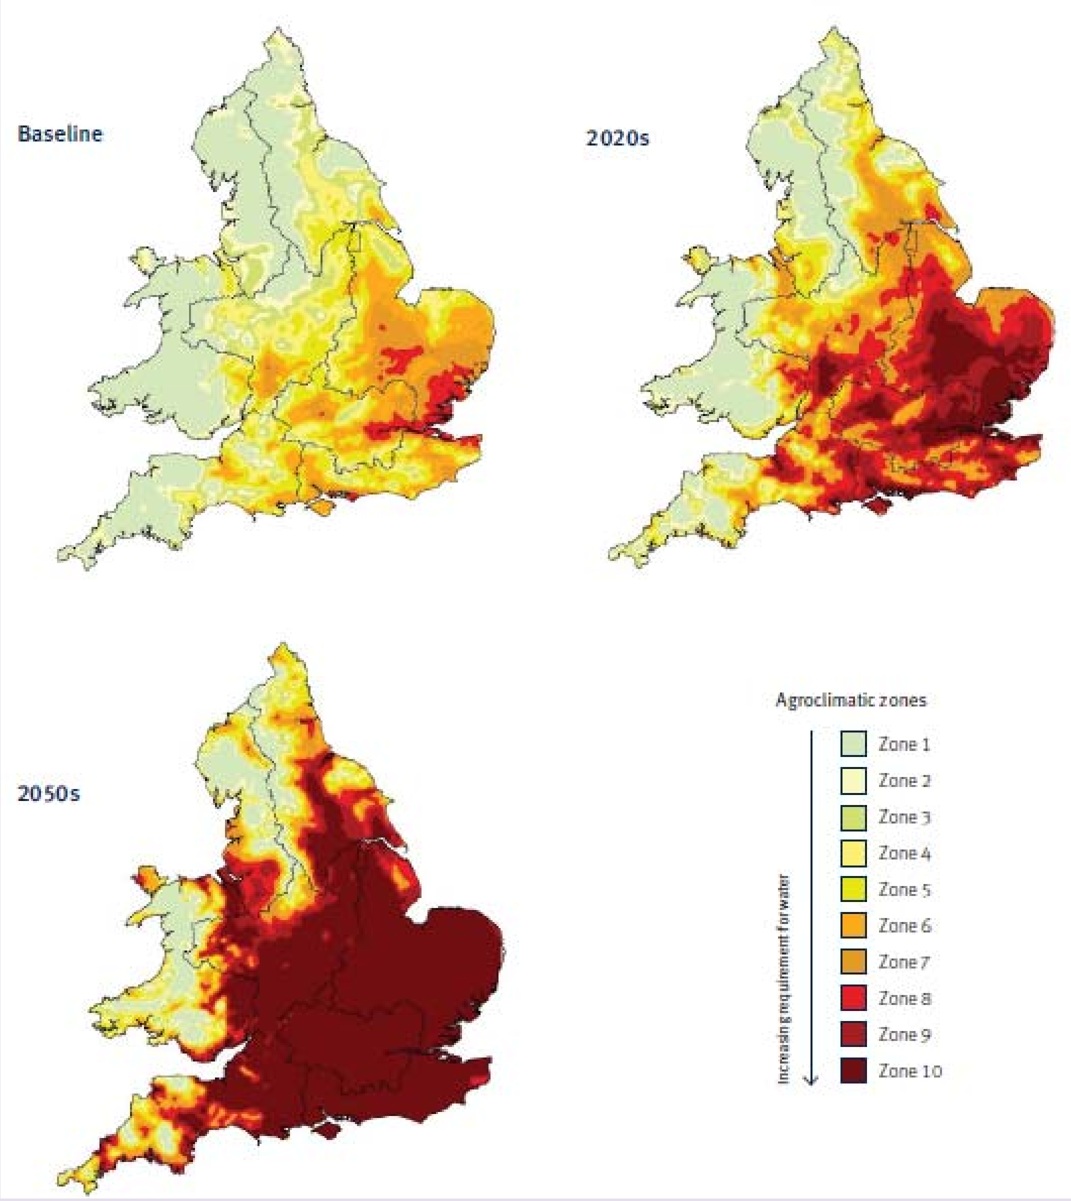
Example 5n – assessing future agricultural water use in England and Wales

The most significant use of water by the agricultural community is for irrigation. Demand for irrigation is concentrated mainly in East Anglia and parts of the Midlands. Despite currently only accounting for around one percent of total abstraction, irrigation is concentrated into a few months when water resources are most scarce, and little of the water is returned to the environment. On a hot dry day in summer, there can be more water abstracted for irrigation in some catchments than for public water supply.

For agriculture, the potential impact of climate change on increased demand is expected to be high. The figure below shows that potential irrigation requirements could increase dramatically, and could move northwards and westwards in the UK as a result of climate change. By the 2020s, central England and eastern margins of Wales could experience conditions similar to those currently typical of the south and east of England. By the 2050s we expect to see a substantial increase in the demand for agricultural irrigation under all of the scenarios we considered. These projections can be fed into economic analysis when considering the economic importance of water use and hence the cost effectiveness of future measures (e.g. winter storage reservoirs or efficient irrigation) to avoid environmental deterioration.

[29] CIS WATECO Guidance Document 1 on the Economics Supporting the WFD.



Example 5o – Comparison of options for managing abstraction pressures

Under current conditions abstraction pressures within a particular river basin district mean that good ecological status is not being achieved and measures are needed in response. Both development of new water supplies and introduction of new demand management measures are being considered. Incorporating climate change scenarios in the water resources zone model gives that by 2050 the river basin district is likely to become between 10 and 30% drier. Combinations of measures are developed on the basis of current pressures. There is a marginal difference in cost between the two least cost options - a) a new reservoir and introduction of metering, and b) the slightly cheaper possibility of a new reservoir and leakage reduction in the supply network. These are then sensitivity tested against the projected future water resources availability. Whilst both have flexibility to be adjusted through time to enable them to perform over the full range of projected climatic futures, the costs for adjusting option b) rise much more sharply than for option a). On this basis option a) is chosen.

In cases with metering already introduced and/or relatively high leakage rates, the choice would be different. Leakage reduction can be an important instrument worthwhile for realizing sustainable water use.

5.7 Measures for adaptation related to the WFD

5.7.1 Introduction

What to find in the following sections on measures?

After laying down principles for taking climate change into account in other steps of river basin management (RBM) under the WFD (see previous sections in this chapter), let us focus on related adaptation measures, including the role climate change may have on the WFD programmes of measures.

In a first step (section 5.7.2), we will discuss the need to assess the WFD programmes of measures or individual measures with regard to the impact changing climate conditions may have on their effectiveness for achieving the WFD objectives. The aim should be to enhance the robustness of the programmes of measures against changing climate conditions.

Beyond ensuring the robustness of individual measures and programmes of measures, there might be a need to take specific actions to achieve good water status.

Although, as already explained, it is unlikely that climate change has such impacts on water bodies that it will jeopardise the achievement of the WFD objectives on the short term and that related measures have to be taken, some guidance at general level will be provided in case this may happen.

In addition, when the Programme of Measures (for the 2nd and 3rd cycle) contains major investments for the long term (e.g. building new or upgrading urban waste water plants), climate change needs to be incorporated, even when it is unlikely that significant climate change impacts will occur in the next river basin management cycles. But climate change projections for the longer term may show significant impacts, thus it may be beneficial to already adjust the measures that are taken now (or in 2020) to the long-term predicted changes.

In section 5.7.3, we will discuss the influence of adaptation measures which serve other purposes related to water (e.g. guarantee water supply, flood protection, sustain tourism, etc.) which may impact on achieving WFD objectives. These measures are more and more being planned. Also water management measures for mitigating climate change may have an influence on achieving WFD objectives. These potential impacts and influences have at least to be considered in the planning process.

The following sections do not aim at collecting all measures that are available for adapting to climate change related to the WFD, but rather focus on the consideration of adaptation measures by those with river basin management responsibilities based on current knowledge and tools, and on measures resulting from the principles set out in the previous sections of this chapter. Instead of being overambitious about the details of adaptation achievements in the long-term, this chapter **concentrates on measures and actions that can be taken already in the 2nd and 3rd RBM cycles of the WFD to start adapting our water resource environment to climate change.**

Please note...

The pressures and impact analysis as required by WFD and mentioned in previous sections of this chapter provides relevant input to the climate change vulnerability of a given area, especially on the short term (i.e. the 6 years WFD planning cycle). However, a longer term vulnerability assessment is needed to assess the effectiveness of the Programme of Measures (5.7.2).

As stated earlier, the WFD offers important tools for adapting to climate change impacts, but sometimes it is not easy to distinguish regular water management issues and measures from adaptation measures.

Specific measures related to flood protection and drought management and the interlinkages with the WFD are addressed in Chapters 0 and 7.

Check also Annex I of this Guidance for a non-exhaustive list of key sources of information on adaptation measures and actions with regard to water in Europe.

5.7.2 How to do a climate check of the Programme of Measures?

Guiding principles

6. Take account of likely or possible future changes in climate when planning measures today, especially when these measures have a long lifetime and are cost-intensive, and assess whether these measures are still effective under the likely or possible future climate changes.
7. Favour measures that are robust and flexible to the uncertainty and cater for the range of potential variation related to future climate conditions. Design measures on the basis of the pressures assessment carried out previously including climate projections (as explained in section 5.3).
8. Choose sustainable adaptation measures, especially those with cross-sectoral benefits, and which have the least environmental impact, including greenhouse gas emissions.

Due to the fact that substantial financial resources will be invested within the next river basin management cycles, and that many measures and investments will have a long lifespan and will not necessarily include the possibility of adjustments, Member States/RBD authorities have to screen the potential effects of climate change and to undertake a "climate check" of the Programmes of Measures (PoMs).

The overall aim of the climate check is to ensure that the PoMs are sufficiently adaptive to future climate conditions. The climate check should provide a form of sensitivity analysis for the selection of measures that are effective, robust and cost-efficient under changing conditions. Additionally, it should ensure that the measures are beneficial to the objectives of the river basin management plans both now and in the future.[30] See example 5t for assessing measures for adaptation, identifying advantages and disadvantages and defining whether and under which circumstances a measure could be classified as relevant for water management in RBMPs.

In the subsequent RBM cycles, the Programme of Measures needs to undergo a climate check as a default and firmly based on scientific evidence, notwithstanding the fact that knowledge and new data are constantly evolving (CIS-WFD, 2008-3).

Generally, only measures that are robust to climate change impacts and do not increase the burden of climate change should pass the climate check and should be considered in future RBMPs. The flow chart of climate checking measures is illustrated in Figure 3.

---

[30] Already in the first RBMPs, there have been some activities in the Member States on climate checking of PoMs. A survey with responses from 21 EU Member States plus Norway during the summer 2008 is available. See report CIS WFD (2008). Progress report on incorporating climate change in the first River Basin Management Plans. November 2008.

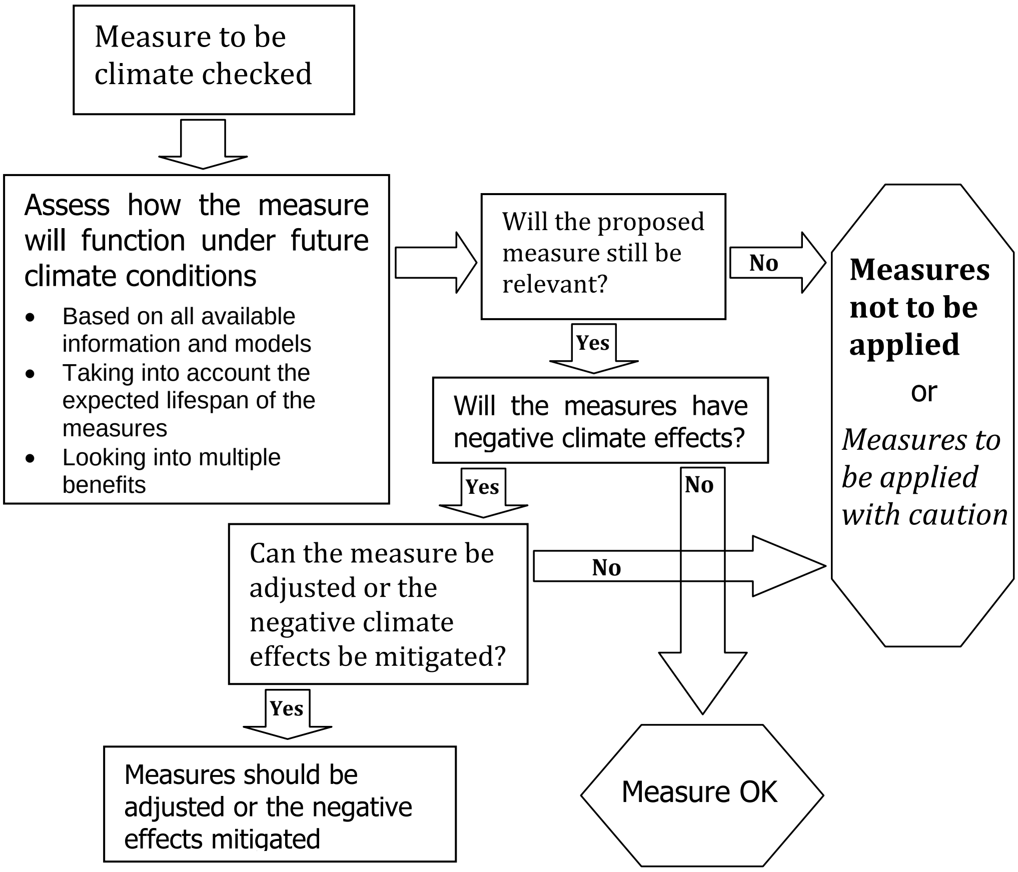


Figure 3 Climate checking of measures

Each climate checking of PoMs should involve an evaluation on the level of individual measures, or on categories of measures, so as to determine if the respective measures are robust to future changes.

First, the sensitivity of the measure should be evaluated against the anticipated future climate conditions as each measure or group of measures has its own sensitivity. In cases where the measure is sensitive to the anticipated future climate conditions, it has to be re-evaluated and potentially adjusted so that it is more robust to future climate conditions.

Because of often limited knowledge and a certain level of uncertainty concerning the impacts of climate change on the water bodies, **the best option is to favour measures that can cope with a range of future climate conditions and are sufficiently adaptive to these.** This will minimise risks associated with implementing measures whose effectiveness at achieving WFD objectives could be compromised by climate change even in the face of high uncertainties.

If the sensitivity/vulnerability of a measure with respect to its intended effectiveness is **high**, it has to be checked, whether this vulnerability affects the overall advantageousness of the measure. To ease the process, more detailed analysis should concentrate on measures that are likely to be affected by climate change.

It is crucial to document the process and methodology of the climate check of measures in the RBMPs. This allows repeating the check at a later stage when more or better projections become available. The documentation of the climate check should be followed by appropriate monitoring to evaluate the results of the check.

Suggested actions

- Evaluate sensitivity of measure against future climate conditions
- Use an appropriate range of future climate projections when checking measures, including uncertainties. The limitation of the range of projections is given by the feasibility of the sensitivity assessment.
- Document the process and methodology of the climate check of measures in the RBMPs.

5.7.3 What to do if other responses to climate change are impacting on the WFD objective of good status?

Guiding principles

9. Avoid measures that are counterproductive for the water environment or that decrease the resilience of water ecosystems.
10. Apply WFD Article 4.7 to adaptation measures that are modifying the physical characteristics of water bodies (e.g. reservoirs, water abstractions, dykes) and may cause deterioration in water status.
11. Take all practicable steps to mitigate adverse effects of counterproductive measures.

There is an opportunity for many adaptation measures to support the achievement of WFD objectives. These are for example measures that give room for the river for flood protection which also will improve hydromorphological conditions (see Example 5r for more examples).

There are however some adaptation measures that will actually be counterproductive for the water environment, and these should be avoided as much as possible. **In case there is no chance to avoid those measures, they need to meet the conditions set in Article 4.7 of the WFD on new modifications** (see CIS WFD policy paper on Article 4.7 exemptions). Application of the Article 4.7 conditions may still lead to the conclusion that better environmental options exist for the planned measures, which have to be undertaken instead of the planned measure.

In case no better environmental options exist, all practicable steps to mitigate the adverse effect of the concerned adaptation measure have to be taken. Article 4.7 (WFD) provides a possibility to be exempt from achieving good status because of a new physical alteration of a water body, when the benefits of, for instance, taking measures to improve public safety are deemed more important than the benefits for the environment.

It may also occur that certain climate mitigation measures have adverse effects on the water environment, and then the same guiding principles apply. This may be the case for e.g. hydropower development, improved inland waterway transport and biomass cultivation.

Example 5p – Modelling measures and climate change impact in Sweden

Various measures for reducing nutrient load have been modelled using the HBV-NP model in the Rönneå catchment (1900 km^2) of Southern Sweden. It was stated that water quality objectives can be reached by different strategies, which will affect different polluters and social sectors. However, no single measure to reduce the nutrient load was enough in itself, but a combination of measures would be necessary. The cost-effective strategy could reach the goals at 20% of the cost compared to the most expensive strategy examined (Arheimer et al., 2005). The cheapest measures were then allocated where they were simulated to be most effective, and included changes in farming practices (with an increased use of spring crops, catch crops, fertilization in spring and buffer strips), construction of wetlands on arable land close to large point sources, and upgraded waste water treatment facilities in rural private households.

The impact of climate change was examined for the phosphorus load and for the implementation of the examined present cost-effective combination of measures. The modelling was based on the ECHAM4/OPYC3 B2 scenario, downscaled with the RCA3 model and a complementary scaling procedure. Hydrology and phosphorus concentrations were simulated for the time period 1961–2100, using the ICECREAM model for arable leaching and HBV-NP model for integrated catchment analysis including all sources, erosion and major turnover processes at the catchment scale. The results show a 10% increase in phosphorus load with present land use and emissions in a future climate (Fig. 1). When incorporating the cost-effective measures in the model, the total transport is reduced by 28% compared to the present situation, but as climate change impact evolves, the effect of the measures is significantly reduced (Rosberg and Arheimer, 2007). In 2090, only 12% of the reducing effect remains, and it can be concluded that the chosen measures are rather climate dependent. Thus, climate change must be considered when establishing future objectives and programmes of measures according to the Water Framework Directive. Climate-proof measures should be high-lighted.

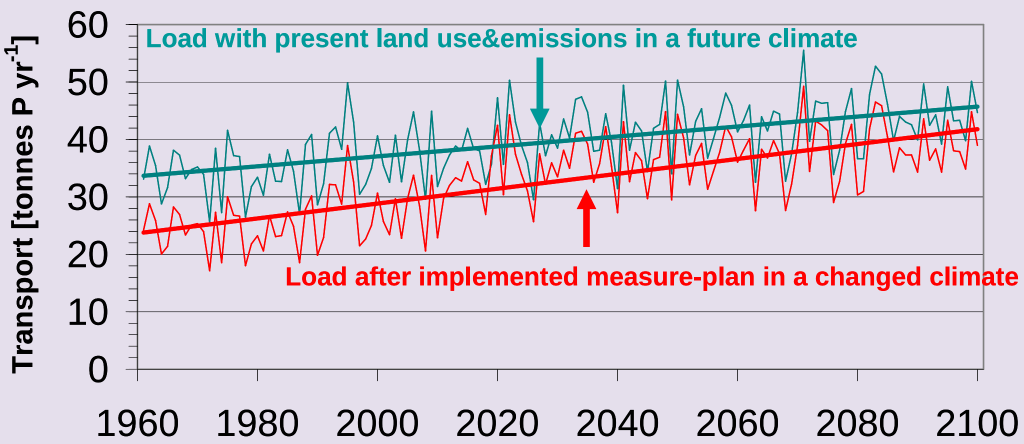

Figure 1. *Simulated phosphorus load in the Rönneå River in a changed climate based on present land use and emissions, and a cost-effective programme of measures, respectively. Trend lines are given (from Rosberg and Arheimer, 2007).*

Example 5r - Sectoral adaptation measures that may positively interact with the WFD environmental objectives

Sector	Adaptation measures/actions
Flooding	*Strengthening existing protection, construction of new protection structures* e.g. construction of new dykes and dams or tidal barriers; enhancing capacity of sluices and weirs and adapting the design

	factor for flood protection measures
	Making room for water/increasing natural retention and storage capacity e.g. construction of artificial side channels, reconnection of old river arms: and increasing water transport and retention capacity of floodplains
	Risk-based planning and building resilience
	Forecasting and early warning systems
	Protection against urban flooding including upgrading of storm drain capacity; increasing soil infiltration and water retention use of wetlands
Water scarcity and droughts	*Water demand management* e.g. putting price tag on water; improving water conservation and water efficiency, raising public awareness of water-saving behaviour
	Supply management and increase reuse and alternative sources e.g. development of water infrastructure, rainwater and greywater harvesting, appropriate use of irrigation reservoirs, matching different water qualities to different uses
	Water allocation and planning including making new housing development water neutral, drought management plans (DMPs) and ensuring environmental flow
Other sectoral adaptation measures	*Spatial planning, land use changes and urban development e.g.* Water assessment for new spatial development and transboundary flood management through spatial planning
	Agriculture e.g. reducing water demand and improving water use efficiency: changing farm practices on irrigation, soil moisture conservation practices; reducing fertiliser and pesticide use.
	Water services in water resource planning the impact of climate change on water availability and water demand have to be taking into account and demand management measures on water conservation and saving may need to be strengthened.
	Energy e.g. different location for power plants (cooling water) and evaluation of the impact of climate change on hydropower production and dam safety
	Navigation e.g. providing sufficient water depth in times of low water flow. But also navigation use might in turn benefit certain aquatic species; any requirement for increased water storage to support navigation infrastructure might similarly be combined with habitat creation initiatives; integrated sediment management planning could aim to offset any potential new dredging requirements by identifying measures, such as buffer strips, which aim to prevent additional sediment (and associated nutrients, pesticides, etc.) entering the watercourse.

Example 5s – Mitigation and adaptation to climate change in the Seine Nord Europe Canal Project

The Seine Nord Europe Canal is to be the link of the Central European Seine Scheldt Waterway. The high-capacity river network in northern France is to be connected to 20,000 km of European high capacity waterways, in particular in Belgium, the Netherlands and Germany.

The Seine Nord Europe project has been specifically designed to cope with the possible challenges created by changes in meteorogical and climate conditions. Possible trends in water and temperatures parameters have been integrated in the design, building and exploitation phases of the project, including:

- adaptation to water availability (e.g. waterproofness; optimisation of water management;

water storage)

- adaptation to extreme temperature changes, impact on infrastructures quality (e.g. dams)
- adopting mitigation measures on the canal building project (e.g. life cycle carbon footprint; reduced road emissions; energy neutrality or energy positive through renewable generation).

Example 5t – Criteria to help selecting adaptation measures

Criterion	Sub-criteria	Guiding questions to be asked
Effectiveness of adaptation	Adaptation function	Does the measure provide adaptation in terms of reducing impacts, reducing exposure, enhancing resilience or enhancing opportunities?
	Robustness to uncertainty	Is the measure effective under different climate scenarios and different socio-economic scenarios?
	Flexibility	Can adjustments be made later if conditions change again or if changes are different from those expected today?
Side-effects	No regret	Does the measure contribute to more sustainable water management and bring benefits in terms of also alleviating already existing problems?
	Win-win (or win-lose)?	Does the measure entail side-benefits for other social, environmental or economic objectives? E.g. does it • contribute to closing the gap between water availability and demand? • affect the delivery of other WFD objectives (e.g. river flow)? • create synergies with mitigation (e.g. does it lead to decreased GHG emissions)?
	Spill-over effects	Does the measure affect other sectors or agents in terms of their adaptive capacity? Does the measure cause or exacerbate other environmental pressures?
Efficiency/ costs and benefits	Low-regret	Are the benefits the measure will bring high relative to the costs? (If possible, consider also distributional effects (e.g. balance between public and private costs), as well as non-market values and adverse impacts on other policy goals)
Framework conditions for decision-making	Equity and legitimacy	Who wins and who loses from adaptation? Who decides about adaptation? Are decision-making procedures accepted by those affected and do they involve stakeholders? Are there any distributional impacts of the climate change impacts or of the adaptation measures?
	Feasibility of implementation	What barriers are there to implementation? • Technical • Social (number of stakeholders, diversity of values and interests, level of resistance) • Institutional (conflicts between regulations, degree of cooperation, necessary changes to current administrative arrangements)

		Priority and urgency	How vulnerable are the water uses, the ecosystem and the region? Are there other trends to consider, e.g. demographic trends? When are the climate change impacts expected to occur? At what timescales does action need to be taken?	

6 FLOOD RISK MANAGEMENT AND ADAPTATION

6.1 Introduction

Why is it important to take climate change into account in flood risk management?

Although no significant general climate-related trend in extreme high river flows that induce floods has yet been detected[31], **there seems to have been an upward trend in flood occurrence in at least some European rivers in the recent past**. For instance, in Europe twice as many river flow maxima occurred between 1981 and 2000 than between 1961 and 1980[32]. In the Nordic countries, snowmelt floods have occurred earlier because of warmer winters[33]. In Portugal, changes in precipitation patterns have resulted in larger and more frequent floods during autumn, but also to a decline in the number of floods in winter and spring[34].

In general, the upward trend in flood occurrence is not ubiquitous and certainly cannot be unambiguously related to climatic changes[35], as long-term trends in hydrological variables are often masked by the significant inter-annual to decadal variability. Also, confounding factors such as land-use change and water management practices have considerably changed the natural flows of water, making it difficult to detect climate change-induced trends in the occurrence and intensity of floods. Even high flows in the rivers combined with high or higher levels in the sea have led to higher frequencies of flooding in coastal areas. Moreover, in the case of extreme floods, given the small probability of occurrence, it is necessary to use long time series to detect trends.

Nonetheless, **future changes in the intensity and frequency of extreme precipitation events combined with different land use policies are likely to cause an increase in flood hazard across much of Europe**, although in the more northern and mountainous areas the risk of snowmelt floods and ice jams in spring may actually be reduced owing to rising temperatures[36] (EEA/JRC/WHO 2008). Due to intensified precipitation patterns, the likelihood of larger intensity of flash floods and pluvial floods across Europe is becoming bigger. The nature of flood hazards may also change; for instance, it is foreseen that in Finland flood risk related to lakes and reservoirs may increase in the South, whilst fluvial floods may decrease. In many places the expected impacts on large river systems are still very uncertain. A number of studies have attempted a quantitative assessment of changes in flood hazard due to climate change in a number of European river catchments[37].

Despite these uncertainties, for countries such as Sweden, Finland and UK, where more in-depth vulnerability studies on climate change impacts on flood risk have been carried out, the conclusion is often that although the information is uncertain it is robust enough to warrant that adaptation action can already be started.

33 Hisdal et al., 2007

34 Ramos and Reis, 2002

35 Kundzewicz et al., 2005

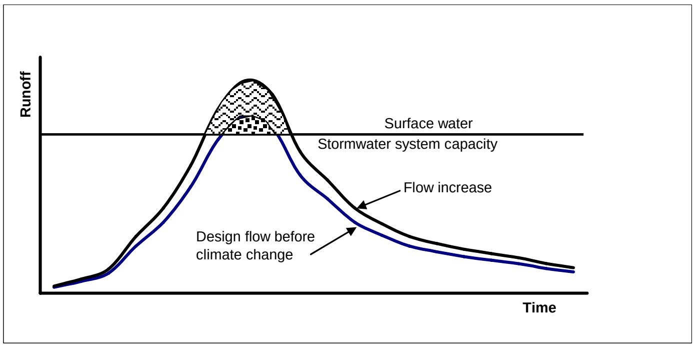
36 Dankers and Feyen, 2008; Dankers and Feyen, 2009

37 e.g., Booij, 2005; Dankers et al., 2007; Graham et al., 2007; Kay et al., 2006; Lehner et al., 2006; Lenderink et al., 2007; Shabalova et al., 2003; Dankers and Feyen, 2008

Since there are major variations from year to year, studies are required over long time periods in order to be able to draw relatively reliable comparisons. The scenarios may also differ both in impact and certainty depending on whether the timeframe is mid-term (e.g. 2030) or long term (e.g. 2100). It is necessary to use reference periods while interpreting and validating the scenarios. The effects of climate change on the probability of floods can furthermore only be calculated in detail based on a river basin approach.

Due to climate change, the probability of different types of floods is likely to change, and it may lead to increased flood risk if additional measures are not taken. Due to marked differences between different types of floods - e.g. coastal floods, flash floods and urban floods - measures to be considered throughout the flood risk management cycle should correspond to the challenges of these distinct types (see Annex III for details on these challenges).

An illustration of the uncertainties of changed flood risk with climate change is that although precipitation may change by a certain percentage, the associated increase in flood damage may be even more difficult to assess.



A small change may end up...

Heavy rain in the city of Fredrikstad: Number of houses flooded after 15 % increase in precipitation nearly doubles!

Historical 20 yr-rain June 25, 1988
Historical 50 yr-rain July 10, 1979

Rain	Number of houses	Change (number)	Change (%)
20-yr	22		
20-yr + 15 %	41	19	86
50-yr	62		
50-yr + 15 %	115	53	85

Modelled by Halvor Hardang
Master thesis 2007, UMB

Figure 4 Relationship between increase in runoff and potential damage.

When engineers plan the stormwater/sewage system, part of the stormwater is designed to run on the ground surface under heavy precipitation, because it is too expensive to include rare precipitation episodes in the drainage system. As a result, a small increase in rainfall intensity may increase surface runoff several times. Hence, inundation of houses is likely as the climate changes (Figure: O. Lindholm and B.C. Braskerud). For instance, in a part of the Norwegian city Fredrikstad (close to the Swedish border) a 50-year rain usually floods 62 houses. With an increase in precipitation of only 15%, 115 houses will be flooded due to overload of the combined stormwater/sewer system (Modelled by Halvor Hardang, Master thesis 2007, Norwegian Univ. of Life Sciences).

What can you find in this chapter?

As explained in chapter 2, the key steps of the flood risk management cycle in the Floods Directive are preliminary flood risk assessment, flood hazard and risk maps, and flood risk management plans.[38]

---

[38] Note that the PFRA does not necessarily have to be carried out where an area is already subject to mapping and planning (Art 13.1.b).

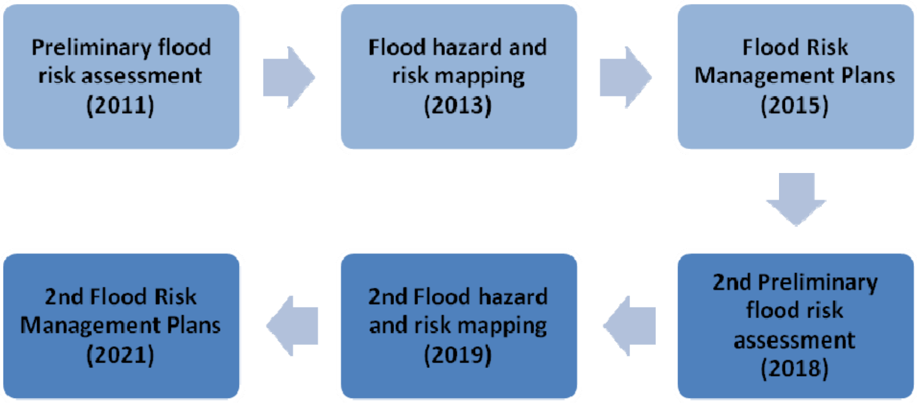


Figure 5 Steps of flood risk management cycle in Floods Directive

Climate change also needs to be taken into account throughout the full flood risk management cycle. Different examples are given below. The Floods Directive furthermore needs to integrate risk management throughout the implementation cycle, which among other things requires a multi-hazard approach, and for instance that the risk assessment places safety issues at its core.

This chapter of the Guidance follows these main steps of the Floods Directive to explain how climate change should be incorporated. The Floods Directive states that the preliminary flood risk assessment (Article 4, FD) shall be based on, among other things, the "impact of climate change on the occurrence of floods" from the first cycle, and article 14.4 (FD) states that the "likely impact on climate change on the occurrence of floods shall be taken into account in the reviews [of the preliminary flood risk assessment and the flood risk management plans]".

The need for EU and MS action to ensure that climate change is taken into account in the implementation of the Floods Directive was emphasised in the EC White Paper on Adaptation.

The purpose of this informal document is to provide guidance to river basin managers and flood risk managers on how best to take climate change into account in river basin management, already from the 1st implementation cycle of the Floods Directive.

In addition to the guiding principles in the sections below, one overall guiding principle covering all steps of the implementation of the Directive, as well as the full flood risk management cycle, can be highlighted:

Overall guiding principle

1. Start adapting flood risk management to potential climate change as soon as possible, when information is robust enough, since full certainty will never be the case. Follow the guiding principles set out for the WFD.

A general question to be considered in the implementation of the Floods Directive is if the potential changes to flood risks induced by climate change require a changed flood risk management approach. Examples are: changes of duration, intensity and frequency of floods, intensified coastal flood risks (related to both sea level rise and increased storm surges), floods in ephemeral rivers (in particular in drying regions), changed patterns in snowmelt, ice-jam floods and more regulated rivers due to hydropower production. Flood risk management should take into account the impact of climate change on the hydrological behaviour of the catchment, both in natural (reference) and altered (modified) conditions -

for instance rivers regulated for hydropower production or with flood defences - since it may change the floods regime; this requires the integration with the river planning process under the WFD. Risk reduction responses may also include different approaches to land use planning, the role of climate change in civil protection policies, and learning to live with and adapt to floods preventing them is not possible.

6.2 Preliminary Flood Risk Assessment

Guiding principles

2. Understand and anticipate as far as possible climate change impact on flood patterns
3. Use best available information and data
4. Homogenize time series, and remove bias as far as possible.
5. Understand and anticipate as far as possible increased exposure, vulnerability, and flood risk due to climate change, for establishing areas of potential significant flood risk.

The FD established that the potential impacts of climate change must be considered within the preliminary flood risk assessment from the first planning cycle, based on the available information.

There are likely to be challenges and limitations on the degree of consideration of climate change in undertaking the preliminary flood risk assessment (PFRA), particularly in the first cycle, given the qualitative rather than quantitative information that may be available or readily derivable. This knowledge is foreseen to be improved in the second cycle (after the first flood maps and flood risk management plans).

Working with models, scenarios and projections

Chapter 3 of this Guidance discussed the use of different climate models, scenarios and projections. A set of guiding principles on decision-making and management of the water environment under uncertainty of models and projections was put forward. Those guiding principles are also valid for flood risk management.

Improving trends detection

One of the most difficult things to predict is changes in trends. Based on available information, scenarios are built with a significant amount of uncertainty around them. For climate change, the horizon of the scenarios is often 50 to 100 years, while climatologists even look at 2300. On the other hand, no or little information about land use scenarios more than 30 years ahead is available and geographically the scale is rather rough. Maps with arrows and shaded zones indicating where changes are expected are difficult to put into GIS-systems for scenario calculations. The same is valid for demographic changes: long term perspectives indicate birth, death and migration rates but local evolutions find only very limited expression in these tables. The issue of field significance and regional consistency for trend detection in hydrological extremes is addressed in one of the examples below.

In general, it is proposed to improve trend detection methods, using the information gathered over the Floods Directive implementation cycles detecting trends of changing flood patterns.

To enable improved trend detection it is also important to continue monitoring of occurring floods in the coming years. The PFRA requires that past floods be taken into account.

Existing information on past floods (as of today) is one important component, but it will also be important to collect information on new floods that will occur, and which will be considered as "new old" floods in the next implementation cycle. In this context, it is proposed to develop a structure for gathering information on past floods, to enable a large, consistent and comparable set of data to be used for the detection of climate change signals concerning all types of floods and adapted to the rules and guidelines of INSPIRE (2007/2/EC).

It is also important to work further on homogenizing and removing bias from timeseries of past floods, in order to detect climate change signals. One example is an increase of high probability floods (low return rates) in certain Austrian rivers since the 1960s, which is however attributed to structural measures related to the straightening of rivers rather than climate change.[39] It is also important to use time series that are as long as possible as well as relevant for the type of flood event investigated.

Using information availability under WFD

In particular, the following information derived under the WFD is of particular relevance for the purpose of assessing climate change related aspects of the Floods Directive:

- Flow levels to assess changes in normal flow regimes.
- Physical modification of water bodies, sediment transport, etc.
- Characteristics & impacts of human activities, e.g. information on polluted soil, identification of point and diffuse sources, etc.

In particular, all those signs and signals due to climate change, such as spatio-temporal irregularity of flow regime and available water resources, can be used to improve flood knowledge, and must be taken into account in the preliminary flood risk assessment.

Furthermore, coordinated implementation of the two directives will enable information exchange and use to be optimized and for relevant information gaps to be identified.

Working with "readily available information" on climate change impacts on flood risk

Article 4.2 of the Floods Directive states that the PFRA shall be carried out "based on available or readily derivable information, such as records and studies on long term developments, in particular impacts of climate change on the occurrence of floods". The identification of such information at different scales (RBD/UoM, national, EU) is therefore important.

In addition, identifying the kind of information which it would be beneficial to develop at different scales, can help guiding research projects in the timescales relevant:

- more information on "paleo" floods/past floods to support long-term trend assessments.
- further information to be made available via GMES, notably for reviews.
- elevation maps needed for both maps/PFRA.

Using best available information - links to insurance industry

[39] Blöschl G., Merz R. (2008). Bestimmung von Bemessungshochwässern gegebener Jährlichkeit – Aspekte einer zeitgemäßen Strategie (Estimating Design Floods of a Given Return Period – Facets of a Contemporary Strategy). Wasserwirtschaft 11 (2008): 2-11.

In the view of climate change increasing flood risk-related pressures, it is in everyone's benefit to share data, and from the insurance industry's perspective there is no competitive advantage in not sharing data with all stakeholders involved. Transparency of information therefore needs to be improved, not the least from the side of the insurance sector. The role of insurance in the recovery phase of the flood risk management cycle is important in several countries. Despite several good examples of information exchange, changes to the insurance culture may be needed and the information needs to be made available to local authorities as well as flood risk managers. The detailed and high quality information of insurance and reinsurance industries gathered during the recovery phase of a flood is of help for water managers and local authorities to improve their plans for the prevention, preparation and protection phase, which is important for all stakeholders.

Information exchange with the insurance industry should therefore be reinforced, for the purpose of using the expertise available for risk assessment throughout the flood risk management cycle, including collection of data for hazard mapping, and improving prognosis and decision making under uncertain conditions, including economic development.

Example 6a: HORA – Flood Risk Zoning Austria

HORA is an Austria-wide risk zoning system (www.hochwasserrisiko.at) for natural disasters, presently prioritising floods and earthquakes. This project has been jointly implemented by the Federal Ministry for Agriculture, Forestry, Environment and Water Management and the Association of Austrian Insurance Companies (Verband der Versicherungsunternehmen Österreich VVO) on more than 25,000 river kilometres. A central finding of the 2002 flood, caught up from the study "FloodRisk", was that besides raising people's risk awareness, indicating the limits of active measures of risk protection and the necessity of the adapted use of endangered areas, a "risk partnership" between state, insurance companies and individuals would play an even greater role in the future. HORA is playing an important part in this cooperation and is a unique project in Europe in the cooperation between the state and the private sector. The beneficiaries of this cooperation are to be the citizens of this country when it comes to providing important information, for example on the risk of flooding of one's home or of an industrial enterprise, an infrastructure facility, etc. In addition to obtaining easy and quick information about any risk of flood via a digital internet hazard map, which serves as a first risk assessment as well, this tool can also be used to optimise and set priorities in the required flood control at the municipal, provincial and federal levels.

For the Federal Ministry for Agriculture, Forestry, Environment and Water Management, the project is not only a milestone in the field of risk communication, but also reflects Austria's leading role in the water sector. HORA advances parts of the EU Flood Framework Directive which require more information for the public. What counts for the insurance companies is, apart from higher risk awareness of the people, improved realisation and assessment of potential dangers as a basis of insurability.

Making most of the review of the preliminary flood risk assessment in view of climate change

According to the Floods Directive, there is a need to review the PFRA (Art. 4 and 5) every 6 years. All relevant data should be made use of, with a view of identifying potential changes or trends induced by climate change.

To ensure climate change is properly considered in the reviews of the preliminary flood risk assessment, including the subsequent identification of areas of potential significant flood risk, it is recommended to:

- always use latest available (yet robust) information
- identify "climate change hot spots" which should be subject to more detailed checks and which can serve as trend detection areas and indicators of the vulnerability of certain regions. The need for reassessments shall be considered in each review

period.

- exchange information between MS on climate change impacts, not just between MS sharing water courses but also at a wider scale, so as to raise awareness on changes noted.

Transparency on how to deal with "worst case" scenarios in assessment of potential significant flood risk

In general, when acting under uncertainty it is recommended that many scenarios are investigated and considered. An assessment of potential significant flood risk requires that some kind of "worst case scenario" be considered as a point of reference regarding the worst situation that can be expected, although the measures taken in the planning process may be based on more realistic scenarios. However, for flood risk management planning it may not be practicable to use the worst case climate scenarios as considered by IPCC (such as new ice age, 18 m SLR etc), and the term should be used with care and in such a way that is still useful for planning purposes. Flood risk assessment should typically use a scenario comprising river discharges, sea levels and weather conditions that are considered to have a small though realistic possibility within 100 to 200 years. The extreme discharges, sea levels, etc. may be higher than the design conditions of man-made flood defences.

The latest available climate change information should be taken into consideration. The "worst case" scenario should be clearly described. The periodic review cycles required by the Floods Directive will provide an opportunity to take into account new scientific results regarding climate change.

The term scenario in this context is used for climate change issues and must not be confused with scenarios according to Article 6 (3) FD, which cannot be considered under PFRA.

Taking climate change into account when assessing the effectiveness of existing man-made flood defense structures

The Preliminary Flood Risk Assessment requires both an assessment of the effectiveness of existing man-made flood defence structures and taking into account climate change related impacts on floods, depending on the need of the Member States.

The "worst case" scenario mentioned in the previous paragraph should be one basis for assessing man-made flood defence structures, depending on how this term is defined and assessed. It should be noted that also without climate change there is a potential risk in areas behind man-made structures.

Suggested actions

Understand and anticipate as far as possible climate change impact on floods

- Monitor changes to flood patterns by gathering comprehensive information on past floods - consider development of a "past floods database at European level"
- Develop a structure for gathering information on past and new floods
- Improve trends detection, using the information gathered over the implementation cycles detecting trends of changing flood patterns

Use best available information

- Anticipate and improve readily available information

- Use monitoring under WFD on flows, physical modifications, pressures and impacts, etc.
- Consider what is "available and readily derivable information" today and what is foreseen to be "available and readily derivable information" in 2011, 2018, etc. (taking into account for instance the forthcoming 5th IPCC AR).
- Exchange information with the insurance industry, as well as land use and spatial planners
- Make the best use of review cycles of PFRA
- Continue further best practice exchange on how to incorporate climate change information in the PFRA at European level

Homogenize time series, and remove bias as far as possible

- Remove bias from timeseries and use timeseries that are as long as possible

Understand and anticipate as far as possible increased vulnerability and flood risk due to climate change

- Take climate change into account when assessing the effectiveness of existing man-made flood defence structures
- Be transparent in the use of "worst case" scenarios – take latest available climate change information into consideration

Example 6b: Trend detection in France

Regional methods for assessing field significance and regional consistency for trend detection in hydrological extremes have been developed and applied to France (Renard et al, 2008). The impact of climate change on hydrological regimes is still an open question: one possible cause of this could be the lack of statistical methods to detect trends in data affected by a very high variability. The results of the study emphasize some of the challenges related to the detection of changes in a non-stationary climate. For example, preliminary analyses showed that many stations from the initial data set were affected by significant changes, but most of these changes could be explained by non-climatic factors, principally measurement problems. Such biases are unlikely to be specific to France and might be encountered in any river flow series.

Example 6c – Detecting and attributing flow changes in southern Germany

The KLIWA project (www.kliwa.de) was set up to look at adaptation strategies for flood protection in southern Germany. As first step, long-term meteorological and hydrological measurement data from Bavarian and Baden-Württemberg weather stations were analysed and trends were determined. The climate conditions in Southern Germany, which have an impact on the entire water balance, have changed noticeably in the past century, especially during the last three decades. In specific regions the trends that have been observed through monitoring exceed the natural margin of deviation, derived from long measurement time series, for some of the variables examined (air temperature, precipitation (regional precipitation, heavy-precipitation 24h and more)). The results agree with the explanation that the global and regional climate is human-induced, but do not yet provide certainty of attribution of changes in extreme floods of river flows to anthropogenic climate change.

Example 6d: Available and readily derivable information in Finland

The Finnish Environment Institute (SYKE) has abundant hydrological data files, e.g. several daily discharge series which have started in the 19th century. These data series have been used in statistical analyses to find out trends in a large set of hydrological variables, including those related to floods. In general, the flood regime in Finland has not yet changed significantly, although the spring peaks have moved to an earlier date on many locations.

SYKE has also developed The Watershed Simulation and Forecasting System (WSFS), which is operationally used for forecasting various hydrological variables for all river basins in Finland. The inputs of the model are precipitation and temperature, the simulated components include snow accumulation and melt, soil moisture, evaporation, groundwater, runoff and water levels of the main rivers and lakes.

Extensive data files and advanced modelling tools give good possibilities to study also the impacts of climate change to floods. These kind of studies have already been performed, and the work is continuing.

In the present stage of these studies, climate change impacts on floods in Finland by 2010-39 and 2070-99 have been evaluated on 67 sites to get a general overview of changes in floods on national scale. This assessment was done with WSFS modelling tools using climate scenarios from both global and regional models. The flood magnitudes of 20 and 100 year floods and their changes were estimated with frequency analysis. The results can be used to identify areas where climate change may potentially increase the flood risk. (According to these results the floods in Finland may decrease in many areas but increase especially on large central lakes and their outflow rivers.)

The general trend of the effects of climate change will be taken into account when the flood risk in the watershed is assessed in the first PFRA. Not just the change in the peak flow but also the change in the seasonal distribution of floods has to be taken into account. In some watersheds the increase of winter floods may rise the flood risk significantly. More detailed studies may be used later during the following rounds of the implementation of the directive.

6.3 Flood Hazard and Risk Maps

Guiding principles

6. When identifying the different flood scenarios, incorporate information on climate change
7. Present uncertainties surrounding climate change in maps transparently.
8. Use the 6-year review of flood maps to incorporate climate change information

The Floods Directive requires 6-yearly reviews of the flood mapping. Probabilities may change in that timeframe, partly because of climate change but also because of other drivers (mostly shifting probabilities; see further explanations below); the 6-year planning cycle allows for the incorporation of these changes. An extra effort is needed to deal with uncertainties in the mapping phase. By taking on board the changes in flood extent of the different scenarios, the management response as set out in the plans should change accordingly, thus providing a sign on how the cyclical implementation of the directive is useful for climate change adaptation.

It is highly recommended to include additional information which Member States consider useful (see Article 6.5.d) for flood prone zones regarding climate change and its effects, for example water velocity maps, water depth, and possible fast occurring changes of stream routes in plan view, as well as slower changes resulting of meander migration. With reference to Article 6.5.d (FD), Member States may consider it useful to analyze and map the role of sediment load, especially in flash floods and taking into account possible increases in soil erosion in watersheds.

Further development of analytical methods to assess flood hazards in a changing climate and cartographic methods may help to display probabilities and uncertainty in flood-mapping products. Further development of mapping methodologies will also be important for different types of floods where flood patterns are expected to change with climate change: pluvial floods (urban/rural), coastal floods, extreme river floods, flash floods, ephemeral floods, ground water floods, ice jam and frazil ice floods, etc. (see Annex III for further information of different types of floods).

For all scenarios it is important to inform map users about the uncertainties. In electronic format maps, this could for instance be done by means of pop-up text. Further information exchange is needed on how to best do this in a consistent manner across the RBD. For instance in transboundary RBDs, it is also important to inform map users about the uncertainties.

Medium probability (at least 100 years return periods)

Due to the effects of climate change, within a period of 6 years there may be changes in intensity and extent of floods and potential changes; what constitutes a medium scenario flood, for instance a 100-year probability flood, may change within the 6 year cycle. Flood maps should take account of this as much as possible if conditions and scenarios change.

Low-probability or extreme events

Most probably, in some parts of Europe, this kind of events may increase in severity; in consequence, considering climate change impact on this scenario is crucial. As high return periods may become more uncertain, this uncertainty needs to be managed.

Low probability events are mainly extrapolations of measurements outside the range of events that occurred in recent history (read: since beginning of measurements). In most simulations and scenarios the extreme events seem to become more severe regarding their consequences. Combinations of uncertain conditions under future circumstances combined with the uncertainty in the scenarios describing future conditions (climate change, land use, etc.) make it difficult to include them in the risk approach (what probability do they get?). While protection against more or less frequent events is a largely adopted solution, a cost-benefit analysis may prove that this approach is not efficient for worst-case scenarios. Measures to minimize the consequences will be different for these worst-case events.

With the flexibility provided by the Floods Directive, the possibility is given to choose between "extreme event" and low-probability scenario. This implies that, for instance in the description of a worst case scenario, ignoring the 'exact' probability avoids discussions focusing on this kind of detail and allows to address the issue of real importance: how to deal with such an event when it happens?

It is thus proposed that the extreme event scenario could be used for anticipating changes to floods related to climate change, in the case that it is not possible to estimate with any accuracy the expected flow changes corresponding to low probability.

High probability flood events

Depending on local / regional circumstances it may be appropriate to include high probability floods in the maps, on the grounds that climate change is also likely to increase the frequency and intensity of events in this category. In some areas they may not differ much from 100-year flood in extent.

One reason for this is the added communication value of hazards and risks related to for instance 20- or 5-year floods.

It is very important that the information from the high probability event scenarios be taken into consideration in the water resources management and disaster risk reduction adaptation efforts. The more frequently a flood event occurs, the more important it is to take robust flood management measures to ensure the increased resilience of society against frequently upcoming events.

It is recommended to review the need for including mapping of high probability events, where this is not already done - in each review cycle, in the light of the possible impact of climate change.

Suggested action

- Make sure best available information (see above under Preliminary Flood Risk Assessment) is taken into account when flood scenarios are reviewed every 6 years.
- Present uncertainty related to climate change in a transparent manner in flood maps.

6.4 Flood Risk Management Plans

6.4.1 Flood Risk Management Objectives

Guiding principles

9. Incorporate climate change in setting flood risk management objectives
10. Ensure coordination at catchment level, also respecting the Directive's coordination requirements at RBD/unit of management level.

The Floods Directive requires Member States to set the flood risk management objectives, "focussing on the reduction of potential adverse consequences of flooding and, if considered appropriate, on non-structural initiatives and/or the reduction of the likelihood of flooding". The Flood Risk Management Plans shall in consequence include measures to achieve these objectives. The objectives of the WFD shall also be taken into account when establishing measures. The likely impact of climate change on floods shall also be taken into account in the review of the plans (FD Article 14 (4)). Member States will decide which types of objectives are set. In the light of the importance of potential impacts of climate change on floods, and the need to anticipate these as far as possible, it is recommended that climate change is taken into account already in setting the objectives for the first cycle of implementation of the FD, and some recommendations be given in the context of further information exchange in relation to the development of Flood Risk Management Plans.

In addition, it is necessary to pay special attention to the environmental objectives of WFD Article 4.1 to see how to best ensure the positive synergies between the two Directive, as some types of floods as well as some types of flood management measures (such as wet land restoration) can also have beneficial aspects for increasing the climate change resilience of ecosystems such as the ecology of the river and floodplain, soil fertility, groundwater recharge, and biodiversity.

When setting the objectives, the safety aspects of flood risk management need to be emphasised in view of climate change, in particular as regards civil protection measures.

Comprehensive policy frameworks exist for planning and decision making, such as Integrated Flood Management[40]. Those are based on risk management principles that recognize explicitly the residual risks on the floodplains while taking a comprehensive perspective of floods, river health, as well as benefits and risks of floodplain use.

Suggested actions

- Indicate how climate change plays a role in setting flood risk management objectives.

6.4.2 Awareness raising, early warning, preparedness

Guiding principle

11. Include climate change scenarios in ongoing initiatives and in planning processes.

Chapter 4 of this Guidance put forward a set of guiding principles that may help those with responsibilities in river basin management in building adaptive capacity for coping with climate change in the upcoming river basin management plans. These principles are also valid for flood risk management and are here complemented with recommendations specific to the flood risk management process.

Education and awareness raising

With climate change, flood awareness is likely to increase, and this needs to be managed in a constructive way, to make sure the right level of concern leads to the right management decisions. Awareness-raising campaigns can be considered as addressed to the public, to local authorities and politicians, and to other sectors influencing flood risk management. Increasing the awareness of increased flood risks, and how to cope with floods, in the education system is also important.

The awareness about the fact that the public can expect less ordinary events coupled with more extreme flood events needs to be raised. This should include education about: the source – pathway – receptor chain and all aspects of safety from prevention to recovery.

Education and other public awareness-raising measures would therefore be crucial for preparedness, prevention and protection, and as such can be important measures in future FRMPs.

Involvement of stakeholders

A holistic approach needs all public and private stakeholders to be involved. It is important to raise awareness, but also to help identify acceptable optimal flood risk management measures. An important example is to involve local planning authorities in the process (see further text on land use).

[40] Refer: http://www.apfm.info/pdf/concept_paper_e.pdf

Full use should therefore be made of the consultation mechanism (Article. 9) to ensure active involvement of interested parties in the river basin and flood risk management process, regarding the climate change related role of significant drivers and risk receptors.

Make sure potential changes to flood risk are built into multi-hazard disaster risk reduction civil protection/emergency measures

Climate change may in many areas lead to an increase in number and intensity of hydrometeorological hazards, including weather-driven events like floods. This will create situations where urgent response civil protection interventions will become more necessary. Improving early warning systems, enhancing preparedness on EU and Member State level of simultaneous events, improved preparedness of population and further climate proofing of civil protection, including coordination and funding, will be important to take into account in the planning for future civil protection. Flood risk management therefore also needs to take increased pressures on civil protection due to climate change more into account in planning. Cooperation between flood risk management authorities, water management authorities and emergency response authorities may need to be improved in some cases.

Suggested actions

- Include climate change related flood risk changes in ongoing education initiatives to improve flood risk awareness and preparedness.
- Improve institutional awareness of potential climate change related impacts on flood risk, for instance ensure that authorities responsible for climate change adaptation and flood risk management coordinate with river basin management.
- Ensure all interested parties are involved in the consultation process for the Flood Risk Management Plans.
- Increase the resilience of civil protection and disaster management infrastructure in view of climate change.

Example 6e: "Early warning and preparedness"

It is better to be prepared by preventing floods and other consequences caused by climate change. **Early warning** is one important complementary measure to take, but it does not replace the need for preventing climate change in the first place. Early warning is also one of the measures that are efficient under current and all possible future climate change conditions: a no-regret measure. The effect of early warning increases when floods can be predicted earlier. Flash floods and cloudbursts cannot be predicted very accurately, neither their geographical occurrence or their time scale. The rise on larger European rivers can be predicted further in advance, thus allowing for a larger range of actions. Coastal water levels are in general predictable a few days in advance, but a determining factor for flooding to happen is usually the behaviour of defences (dunes, dikes, quay walls, etc.), as it is the case for dike-protected areas along rivers. Breaching causes an immense volume of water flowing into the hinterland with high flow velocities close to the breach.

Preparedness means that all plans and procedures are ready and usable on any moment, that inspections of the current situation are carried out and reparations are done when necessary. In the emergency and response stages, all effort needed to minimize loss of life and damage and that can be considered realistic should be prepared and carried out. The review is adapting the procedures and improving the preparedness phase because the question, with and without considering climate change, is never: "will there be a next event?" but "when will the next event occur?". A red line through all these phases is communication: communication about preparations made by public authorities and about what people can (or have to) do during the preparation phase; communication as 'take action' commands in the emergency and response phase; and explanation of lessons learned and new insight (e.g. in the severity of climate change) in the review. Communication is not a matter of specialists only and is, in the preparedness and review phase, more a dialogue with all stakeholders than one-way-communication about model results.

6.4.3 Measures

Summary of guiding principles

12. Perform a climate check of flood risk measures

13. Favour options that are robust to the uncertainty in climate projections
    a. Focus on pollution risk in flood prone zones
    b. Focus on non-structural measures when possible
    c. Focus on "no-regret" and "win-win" measures
    d. Focus on a mix of measures

14. Favour prevention through the catchment approach

15. Take account of a long term perspective in defining flood risk measures (e.g. with respect to land use, structural measures efficiency, protection of buildings, critical infrastructure, etc).
    e. Include long-term climate change scenarios in land-use planning
    f. Develop robust cost-benefit methods which enable taking into account longer term costs and benefits in view of climate change.
    g. Use economic incentives to influence land use [Link insurance]

16. Assess other climate change adaptation (and even mitigation) measures on their impact on flood risks:
    h. Hydropower and flow regulation
    i. Link with water scarcity

The guiding principles are explained one-by-one in more detail in the following paragraphs. Please check also section 5.7 for guiding principles and elaboration on measures for adaptation related to the WFD.

Guiding principle

12. Perform a climate check of flood risk measures

As for other aspects of water management referred to in this guidance, climate change checking of flood risk management measures is crucial. No-regret or low-regret measures should be favoured when considering options (see also guidance provided in chapter 5.7 on measures in general). It will be crucial to consider questions such as "Are planned measures to be taken by 2015 still the best to be taken, knowing that the situation may change in 2050 (especially when a dyke has a lifetime of 50 years)?"

Although changes may not appear in the planning period (2015-2021 for instance) but for instance in 2050, the effects of the mitigation and prevention measures often have a longer lifetime, and all measures included in the flood risk management plans should therefore be climate checked.

Further examples are given below.

Guiding principle
13. Favour options that are robust to the uncertainty in climate projections

Assessing potential future flood risk is a core task of flood risk management, and the process carries many inherent uncertainties. As climate change only forms part of the flood risk, which also comes from a range of other drivers that have uncertainty attached to them, an assessment of the various factors causing such uncertainty, including climate change, is necessary to manage uncertainties.

The assessment of flood risks and planning to reduce them in view of climate change impacts must be done in an uncertain context. In this particular context, the precautionary principle has to be applied.

Pollution risk in flood prone zones

An area which is heavily polluted requires that the FRMP includes a management response if the area is in a flood zone. Today the hypothesis may be that the area will not be flooded so often, and the management response may be limited as knowledge exists on how to handle the situation under such a hypothesis.

The flood risk management should take into account, however, that the area might flood much more often due to climate change, therefore possibly increasing the flood hazard, and the choice of management mechanisms may be different. This may for instance affect the choices made between building permanent defences, relocating the installation out of the floodable area, or even remove the polluted soil.

Non-structural measures

In recent years, flood management policy has shifted from defensive action towards management of risk and enhancing societies' ability to live with floods via increased use of non-structural flood protection measures. Spatial planning, including regulation of floodplain development and relocation, can consider more 'room for rivers' and could have effects for both floods and low water. Non-structural measures, which do not involve large structural components, can be rated as more flexible, less committing and more sustainable than hard measures. Yet, the latter may be indispensable in certain circumstances[41]. Technical flood protection measures are often necessary to handle the effects of rare major events. Water managers are thus faced with the challenge to **design a site-specific mix of both types of measures, which may be altered or are robust to changing conditions**.

No regret and win-win measures

Another way of dealing with uncertain impacts of climate change is to prioritise "no regret" or "win-win" measures. In this context the flexibility of measures is an important criteria. Dykes that can be increased in height during a flood event are one example.

Example 6f: Promoting "no-regrets" options in view of climate change

During the pilot Catchment Flood Risk Assessment and Management (CFRAM) studies in Ireland, analysis was undertaken, including flood mapping, of two possible future scenarios based on

[41] Kundzewicz, 2002

projections of the impacts of changes in climate and land use. An objective was set within the option appraisal framework to promote adaptability to the effects of such changes within any measures under consideration for adoption within the Flood Risk Management Plan, and the temporal coherence of the Plan was evaluated to promote a 'no-regrets' approach. While the process implemented during the pilot stage will be refined, it is considered that the approach promoted adaptability to climate change within flood risk management.

A win-win measure may furthermore be a measure that at the same time reduces flood risk and has other positive aspects such as improvement of the quality of the aquatic environment, which is the case of wetlands or sustainable urban drainage. Other examples are flood reducing measures having positive effects on generating green energy, recreation, landscape quality etc.

A tool-box of for instance different good practices on sustainable urban drainage could be usefully developed.

The development of a 'catalogue' of possible "no-regret" measures (measure feasible under actual climate conditions and different climate scenarios) at the European level with examples from different parts of Europe, could facilitate the identification of such options.

Mix of measures

Faced with the situation that adaptation activities are necessary, but scenarios are still uncertain, the best option may be to identify the most optimal mix of measures. The catchment approach section below indicates one such example, but this can also entail a mix of non-structural measures such as education, change of private property owners' responsibilities, economic incentives, better forecasting, improved collaboration, as well as improvement/introduction of structural measures.

Guiding principle

14. Favouring prevention through the catchment approach including the need for transboundary cooperation on prevention

The so called "catchment approach" to flood risk management may be favoured in the face of climate change to ensure all possible flood hazard reduction measures are taken across the catchment, so as to decrease the pressures on structural flood defences downstream. An explanation of what is meant by the "catchment" approach, and why this approach is beneficial in view of climate change as no-regret options, is given below.

The catchment approach to flood risk management can offer real benefits and advantages to flood risk managers. The catchment approach provides the appropriate spatial unit of management: the basin or sub-basin. The catchment forms the arena for risk and hazard mapping and enables the causes and effects of flooding to be examined and linked. This, in turn, helps identify where and how floods arise and have their impacts. Ultimately, this supports the identification and selection of measures for reducing flood risk to people and business and the environment.

For example, river flooding may occur in communities because of a combination of local and upstream factors. By identifying and describing the flood processes within the catchment, these factors can be revealed. Examples of measures that can be combined to reduce flood risk included planning to avoid flood risk areas; building flood resilient properties; better flood warning systems; soft and hard engineering in highly urbanised areas; natural flood management techniques such as wetland restoration and renaturalisation of river flows; sustainable urban drainage schemes and at-risk property removal.

The process is particularly suitable for climate change adaptation measures and water resource management plans, both strongly linked to economic, social and environmental sustainability. For example, some flood risk management is likely to consider natural flood management, i.e. the restoration of natural features of the environment that contribute to storing or slowing flood waters. Several of these measures, such as the reconnection of rivers to flood plains or the restoration of wetlands, slow the flow of water downstream and lead to a more natural flow regime within a catchment. In addition to the flood risk benefits, these approaches can deliver a wide range of environmental and biodiversity benefits, assist the climate change adaptation agenda, contribute to electricity production from hydro developments and support industries reliant on a regular supply of clean water.

By improving understanding of flooding processes and the links between rural and urban areas, as well as those between neighbouring and distant member states, a catchment approach can help direct resources to cost effective options so as to reduce flood risk, which can also have the potential to deliver a wide range of coincident benefits.

Guiding principle:

15. Take account of a long term perspective in defining flood risk measures (e.g. with respect to land use, structural measures efficiency, protection of buildings, critical infrastructure, etc).

Ensure land use / spatial planning is robust in view of climate change

In view of climate change, more efforts are needed to ensure flood risk is considered in spatial planning and in other local land use management. Locating a new housing project close to a lake or river which is likely to become flooded even more often in the future may not be a way of reducing potential flood damage in the future, and it may be very costly. Such decisions are taken today, and even if the increased floods of increased sea/water levels are not a threat today, the project is clearly supposed to be located at that place also in 2050 or 2080, when climate change is expected to have more severe effects. Relocation of such assets at a later date may not necessarily be a cost-effective option. Likewise, the decision on whether to give more room to the river (by moving dykes for instance) instead of increasing the height of a dyke - which also involves a land use decision - is a measure with a long expected life time. Also in the shorter term, if building in a flood-prone area cannot be avoided, then the importance of building flood resilient buildings is an example of a measure with long term effects.

It is therefore crucial that flood risk management and spatial planning should even today closely take into account climate change scenarios, and for these links to be legally strengthened. Flood Risk Management Plans shall furthermore take into account spatial planning and land use, and may include promotion of sustainable land use practices.

Member States may include measures towards this aim in the FRMPs:

- MS may include changes or clarifications of the legal situation regarding building in flood-prone areas (in some cases stronger legislative basis for spatial planning),
- New buildings or new infrastructure should be built so that already built-up areas will be safer and protected against floods.
- Considerations of moving assets (economic, humans, critical infrastructure…) away from high flood risk areas – relocation.

Short-term vs. long-term considerations in cost-benefit assessment

Identifying long-term changes in the climate patterns now can help prevent that "regret decisions" are taken that will increase vulnerability in the future. These actions will benefit in the long-term perspective. One example is land-use decisions (see above).

When taking climate change into account in the consideration of measures, it is also important to consider the uncertainty associated with climate change objectives, and also the temporal planning of measures (i.e., sequenced projections of measures to be implemented over time).

This is also the case when carrying out cost-benefit assessment for flood risk management measures. It is furthermore important to properly take into account (and evaluate) the long term costs and benefits, and not just consider the short term, especially since benefits will be long term but costs short term. An important example relates to loss of agricultural land, where the benefits to society of long-term food security should be included rather than simply using the market (private) value of land.

Use of economic incentives

Risk awareness can be increased with the help of economic instruments, including the use of insurance premiums to send the right incentive price signals regarding the potential flood risk of an individual property in flood zones. Apart from giving an incentive for building in a flood-resilient manner, insurance policies are of course an important instrument at the end of the "safety chain", as they help to restore flood damage. Therefore, the future role of insurance in view of climate change and floods needs to be considered.

Guiding principle
16. Assess other climate change adaptation (and even mitigation) measures on their impact on flood risks

Hydropower and flow regulations

New modifications to water bodies (hydropower dams for instance) may change flood risks and there is a need to coordinate and exchange information between WFD and FD management.

Existing dams can also contribute to flood risk management. This should be recognised in flood risk assessment and management.

Dams and reservoirs, if properly planned and managed, can be considered as an important part of integrated water management schemes under climate change conditions. Multifunctional dams may contribute to water storage (for drinking water supply), flood protection, hydropower, stabilisation of discharge downstream in times of drought for ecological purposes, maintenance of water abstraction and discharge for power plants, navigation, recreation, fishery and nature protection."

Such dams are subject to operation licenses (also called concessions in some countries) for hydropower schemes in which the regulating national authorities establish the conditions under which a power plant shall be operated at different moments of the year and sometimes even of the day. This license/permit contains detailed conditions for river flow regimes and minimum and maximum water levels to respect according to the season, so that for example enough storage space is in the reservoir to absorb the spring flood. The WFD also requires that such permitting regime of impoundments are regularly reviewed.

Storage power plants have an important effect in reducing local floods, but run-off-river power plants can also have a positive effect, especially on smaller and medium flood events. The way the water flows are regulated in such rivers should take potential changed flood patterns into account, to make sure flood risk isn't increased, but rather decrease in the way the flow is managed.

Example 6g: Hydropower in Sweden

In most of the major rivers in Sweden there are cascades of dams and hydro power plants built for electricity production. The dams and the hydropower plants are owned by the electricity producers. Permission for the facilities and for the water regulation is given by environmental courts after a trial where concerned interests are scrutinized and balanced. The power plants are run in cooperation with other dam and other plant owners within the river. A secondary effect of the river regulations has been that floods and inundations occur less frequently, especially in spring time (related to snow melt).

A committee, with representatives from authorities and the power and mining industries, has been established with the assignment to study the vulnerability of the existing dams to climate change. Comprehensive work is ongoing with development of methods and analysis of effects on the magnitude of the 100-year flood and the design flood for dams based on data from several regional climate simulations from different European research institutes. The committee work increases the understanding of possible effects on the magnitude of floods in a changing climate as well as the related uncertainties.

Example 6h: Hydropower in Norway

In Norway, regulated rivers often host several dams and power plants which are operated by different owners. The operation license granted by the government for each power plant (including the related dams and dikes) regulates a coordinated flow regime for the whole river basin according to various needs, such as flood mitigation and protection of fish, to ensure safe ice conditions on the river for transport in winter, appropriate water volume in waterfalls for tourists, and so as to keep the fjords as much as possible ice-free. In the context of climate change, the melting glaciers combined with more intensive precipitations in winter increase the risk of winter and spring floods. Increasing the storage capacity of water will hence become a key issue, since the security of the electricity supply could be compromised if the reservoir levels have to be kept low in order to absorb winter and spring floods, while people need electricity to heat their houses during the cold winter season, 99 % of which comes from hydropower. Therefore in Norway water management is the responsibility of a special governmental agency, the Norwegian Water Resources and Energy Directorate, which assumes the integration of various water needs into an adequate operation licenses for all hydropower plants.

Example 6i: Managing multifunctional dams

The Czech Republic and Germany are sharing inter alia the transnational Elbe River Basin. As a consequence of the severe flood event in summer 2002, both countries agreed to assess and better integrate the Vltava / Moldau Dam Cascade and the Dams in Germany into the transnational flood protection scheme as stipulated in the Flood Protection Action Plan of the International Commission for the Protection of the Elbe. The snow melt flood in early spring 2006 bolstered the strategic approach to adaptively manage multifunctional dams in a national and transnational setting.

Link with water scarcity

For those areas where the hydrological regime might become more irregular and for which therefore more extreme droughts and floods are expected, two opposed responses can follow: volume increase of retained water resources behind dams to reduce drought severity, and greater free volume available behind dams to reduce flood discharges. Reservoir safety and management will in these situations require further attention.

Specific attention to this is therefore needed in flood risk management plans, including in different awareness-raising and preparedness measures.

Suggested actions

- Further development and exchange of good practices on adaptation measures related to flood management.
- Ensure land use / spatial planning is robust in view of climate change.
- Improve economic models to enable taking into account long-term costs and benefits in planning.
- Increased use of economic incentives, such as the cost of insurance being linked to flood risk of individual properties.
- Review permits for impoundments (see WFD) to make sure possible climate change related flood risks can be mitigated.
- Consider occurrence of multiple hazards in flood risk management, example of increased incidents of ephemeral floods.
- Develop tool-boxes and examples of "no-regret" and "win-win" measures, and exchange this information across the EU.

6.4.4 Links to WFD

Guiding principles

17. Pay special attention to the requirements of WFD Article 4.7 when developing flood protection measures
18. Determine on the basis of robust scientific evidence and on a case-by-case basis whether an extreme flood allows for the application of WFD Article 4.6.
19. Pay special attention to the vulnerability of protected areas in view of changed flood patterns

WFD Article 4.7 New modifications

As mentioned in chapters 5 and 5.7 of this Guidance, the implementation of specific adaptation measures, for instance infrastructure projects, might invoke WFD Article 4(7) (exemption for new modifications) more often in the view of climate change. Article 4(7) requires the identification and consideration of alternatives, i.e. "significantly better environmental options".

Proper consideration of the possible impact of climate change in the implementation of the Floods Directive will benefit the application of these objectives. The Flood Risk Management Plans should make reference to the application of these provisions in the WFD, in view of the need to take into account the environmental objectives in the FRMP (Article. 7, FD).

WFD Article 4.6 Temporary deterioration

The Guidance Document No. 20 on Exemptions to Environmental Objectives states that "It is most likely that "extreme flood" events falling under category (a) [low probability or extreme events] will require the application of a 'temporary deterioration'. However, floods with a higher probability of occurrence may also be regarded as "extreme floods" in circumstances where the impacts of such floods are equally exceptional or reasonably unforeseen."

What is an "exceptional flood" may change as a result of climate change, and flood risk managers must anticipate more extreme events. When use is made of Article 4.6 to justify temporary deterioration of status following a flood event, it is therefore important that all required conditions of Article 4.6 (WFD) are complied with, and that the implementation of the Floods Directive takes into account climate change in a way that facilitates the compliance with these provisions. As agreed by Water Directors in the same Guidance document, "In no way does the application of exemptions under the WFD give a Member State a possibility to make an exemption from the obligation of implementing all aspects of the Directive on the assessment and management of flood risks."

Further guidance on what constitutes exceptional floods in the context of climate change, changing the patterns of floods as regards location, intensity, and duration may be developed, as well as a practical guidance on how to comply with the conditions set out in Article 4.6 as regards for instance taking all practicable steps to avoid further deterioration.

The Flood Risk Management Plans shall make reference to the application of these provisions in the WFD, in view of the need of taking into account the environmental objectives in the FRMP (Article. 7, FD).

Protected areas and drinking water abstraction areas (WFD Articles 6-7)

The WFD protected areas are indicators in the Floods Directive for environmental impacts, and need to be considered in mapping and planning. The relevance for climate change is the impacts of more frequent flooding or flooding over longer periods of time of drinking water abstraction areas. It is therefore recommended that the FRMP includes measures such as:

- Increased incidents of high probability floods could help cleaning up; however the normally beneficial effects of floods could be reduced. There are uncertainties on the effects which need to be considered in flood risk management plans.
- There may however be a higher likelihood of contamination due to flood events of water bodies used for drinking water abstraction; the safety and availability of drinking water needs to be taken into account in FRMP. Subsequently, more resilience against the negative effects of floods is needed with climate change.
- There is also a higher likelihood of contamination of ready-to-eat fruit and vegetable crops, both directly from flooding and indirectly from less extreme events which cause contamination of irrigation water, due to increased sewer overflows for example.
- This is a learning process and this issue needs to be addressed in particular in the update of plans.

How to deal with uncertainties of flood risks needs to be fully taken into account when managing the protected areas and a process of joint/holistic management needs to be built, involving both water quality and flood risk managers.

Suggested actions

- Take into account guidance and expertise on catchment approach and non-structural measures when investigating "better environmental options" according to Article 4.7

WFD.

- Include information on exceptional floods giving rise to the use of Article 4.6 WFD, which is consistent and coherent with the information and measures included in FRMP.

7 DROUGHT MANAGEMENT AND WATER SCARCITY AND ADAPTATION

7.1 Introduction

This chapter deals with addressing specific effects of climate change in areas exposed to water scarcity and drought. In these regions, water is an essential and scarce resource. Many economic sectors are strongly dependent on water availability, and therefore a major challenge of water management is to balance water supply[42] and demand; this challenge will be aggravated by climate change.

Water scarcity and drought have been broadly documented as phenomena which are likely to be impacted by climate change in European countries (EC 2007a, IPCC 2008, EEA 2008), but climate change is only one of many pressures which must be faced by water management in these areas. If climate change produces a further reduction in water availability, the impacts in these regions may be very strong; therefore special consideration should be given to including climate change in hydrological planning.

As explained in chapter 2, an official Communication was issued regarding water scarcity and droughts (EC 2007b), which is one of the bases for the guidance provided in this chapter. As well as being in the focus of policy, water scarcity and droughts are also the subject of several European research projects concerning, for instance, management options under water stress (see Annex II).

In order to discuss adaptation in water management, it is essential to differentiate between the terms "drought" and "water scarcity".

The term "**drought**" refers to a temporary deviation from long-term average or normal conditions in a hydrological context with regard to water supply. It usually originates in a considerable reduction in precipitation over a significant period of time and with a substantial spatial extent. Through interconnection within the natural water cycle, changes in other climate or land surface conditions can also cause droughts, e.g. through an increase in ambient air temperature and consequently higher evapotranspiration rates. The propagation of droughts through the water cycle may cause temporary shortages in water supply; their impacts depend on vulnerability and coping capacities on the demand side. Climate change can affect the gradual change of average conditions, as well as the frequency and magnitude of deviations from them, thus affecting the occurrence of drought events.

The term "**water scarcity**" indicates a long-term imbalance between water supply and demand in a region (or in a water supply system) possibly characterized by a semi-arid or arid climate and/or enhanced by a fast increase of water demand, associated with population growth and/or an extension of irrigated agriculture. Climate change may create or intensify water scarcity problems in a region, either through a reduction in water supply or through an increase in water demand.

7.2 River Basin Management Plans as a tool for addressing water scarcity and droughts

In addition to the guiding principles in the sections below, one overall guiding principle covering drought management, water scarcity and adaptation can be highlighted:

---

[42] Water supply refers to the quantity of water generally available and not only to water supply for a specific use, e.g. urban water supply.

Overall guiding principle

1. Use the Water Framework Directive as the basic methodological framework to achieve climate change adaptation in water-scarce areas and to reduce the impacts of droughts.

Guiding principles

2. Make full use of the Water Framework Directive environmental objectives, e.g. by the requirement to achieve good groundwater quantitative status to ensure a robust water system, which is more resilient to climate change impacts.
3. Determine, on the basis of robust scientific evidence and on a case-by-case basis, whether a prolonged drought allows for the application of WFD Article 4.6, and take into account climate change predictions in this case-by-case approach.
4. Pay special attention to the requirements of WFD Article 4.7 when developing measures to tackle water scarcity under a changing climate and which may cause deterioration of water status.

The River Basin Management Plans required by the WFD offer considerable potential to address drought consequences and water scarcity issues. This becomes even more valid under a changing climate, in which additional stress is put on water resources.

First of all, the planning process required by the WFD provides the right way of analysing pressures, setting objectives and putting cost-effective measures in place. There are many links between climate change adaptation measures related to water scarcity and droughts and the WFD environmental objectives, such as good groundwater quantitative status, sufficient surface water quantity to sustain ecological status, and also broader objectives such as rational water use. Specifically, the WFD requirement to achieve good groundwater quantitative status includes ensuring a balance between abstraction and recharge of groundwater. Also by the requirement of achieving good ecological status for surface waters, a river site-specific minimum flow needs to be established, which sustains the achievement of the site-specific objectives with respect to aquatic life. Measures to achieve these objectives have to be reported in the River Basin Management Plans. Such measures include the economic tools mentioned in Article 9 of the WFD (e.g. water pricing policies providing adequate incentives to use water resources efficiently).

It is recommended to consider the option of developing a specific drought management plan (DMP) to prevent and alleviate drought impacts (see CIS guidance on this topic[43]). The main objective of drought management planning is to minimize the adverse impacts on the economy, social life and environment when drought occurs, but also to provide prevention strategies for avoiding those impacts in the first place.

In case of exceptional or unforeseen prolonged droughts, the WFD allows for a temporary deterioration of water status. This should be reported in the river basin management plans, including related measures that will be taken in such situations, as well as restoration measures. Specifically, Article 4.6 of the WFD defines that "Temporary deterioration in the status of bodies of water shall not be in breach of the requirements of this Directive if this is the result of circumstances of natural cause or force majeure which are exceptional or could

43 http://circa.europa.eu/Public/irc/env/wfd/library?l=/framework_directive/scarcity_droughts/version_report_fvpdf/_EN_1.0_&a=d

not reasonably have been foreseen, in particular extreme floods and prolonged droughts, ...", provided that the conditions of Article 4.6 are met including among others taking all practicable steps to prevent further deterioration in status.

In addition, the requirements of the WFD Article 4.7 should be applied to any adaptation measures that modify the physical characteristics of water bodies, especially measures related to the development of new water infrastructure to tackle scarcity in a changing climate (see chapter 5.7.3 for guidance on the application of Article 4.7).

7.3 Monitoring and Detecting Climate Change Effects

Guiding principles

5. Diagnose the causes that led to water scarcity in the past and/or may lead to it in the future.
6. Monitor water demand closely and forecast it, based on improved knowledge about demands and trends.
7. Collect as much high quality information as possible to anticipate changes to water supply reliability, which may be imposed by climate change, in order to detect water scarcity early.
8. Distinguish climate change signals from natural variability and other human impacts with sufficiently long monitoring time series.

Water scarcity relates to long-term imbalances, hence it is not something that comes and goes and changes fast. Climate change may aggravate existing problems of scarcity and may raise problems that are just below surface (e.g. areas in which the demand/availability balance is close to friction). Water scarcity should therefore be "diagnosed" based on past and future water demands. Given the high degree of uncertainty of climate projections and the relevance of challenges imposed by climate change in semi-arid regions, it is essential that the climate change adaptation process be based on high quality information.

The monitoring of precipitation and its transformation into available resources should be used as starting point for monitoring water scarcity under climate change. In this context, it is also necessary to establish monitoring of water uses as well as monitoring of demand. The early detection of droughts requires an advanced monitoring system based on high-resolution hydrometric networks and a system of objective indicators.

The hydrometric networks will have to be adapted to track the impact of climate change on water resources (see also guidance on monitoring under the WFD in chapter 5.4). Hydrometric networks were designed primarily to obtain average values and seasonal and interannual variability of precipitation and streamflow series on the assumption of stationarity. Currently, it is difficult to obtain even those average values, given the deep human intervention on the hydrological cycle in water scarce regions. However, it is critical to identify the impact of climate change on water resources in a natural regime for the gradual establishment of adaptation policies and for monitoring their implementation.

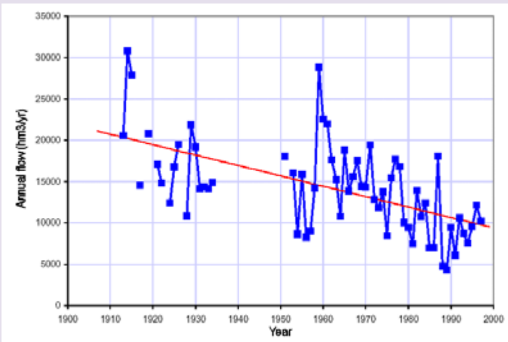
In areas suffering from water scarcity, the balance between demand and supply is already broken. When this current unsustainable balance between water supply and demand is aggravated by climate change, more areas or more catchments will be subject to water scarcity. Therefore, the intensification of monitoring should be accompanied by the development of a comprehensive set of indicators, which can assess the impacts of water scarcity and of eventually increased droughts.

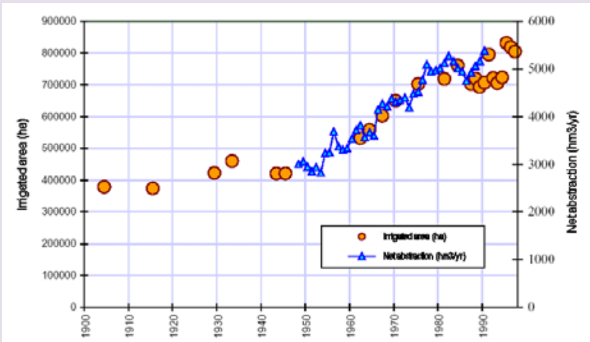
Suggested actions

- Adapt the hydrometric networks to track the impact of climate change on water resources, providing enough redundancy to obtain accurate estimations of naturalised streamflow series from observation, closing the water balance in each sub-basin.
- Establish already now a monitoring system of water uses as well as demand monitoring.
- Develop a comprehensive set of indicators at appropriate temporal and spatial scale which can link phenomena in order to predict drought and water scarcity impacts.
- Diagnose water scarcity based on past water demands and improve knowledge about past and current water demands and on future trends, incorporating climate change projections.
- Analyze how predicted changes in mean annual runoff will change supply reliability and how those changes will affect the socioeconomic system behind the water resources system.

Example 7a – Trend detection in the lower Ebro river

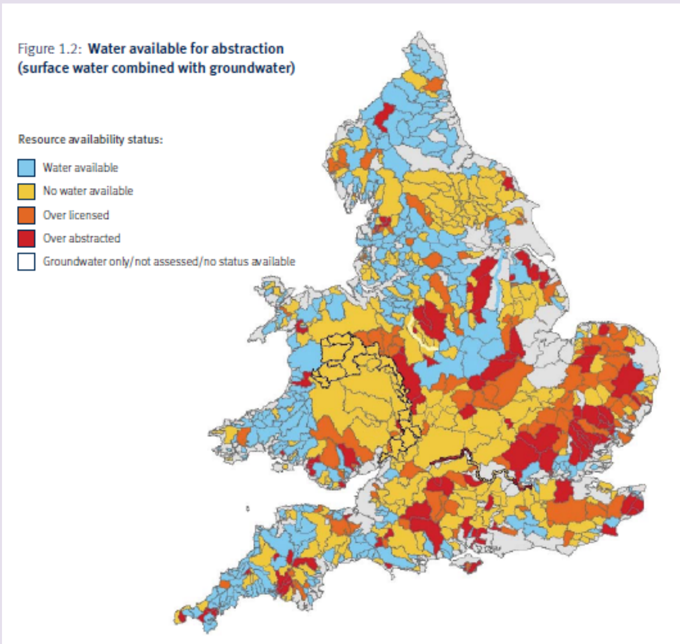
The subject of natural flows in the lower Ebro has been one of intense controversy throughout the years. The observed flows at the most downstream station of the Ebro river in Tortosa (figure on the left) show a decreasing trend which has been attributed to climate change. However, the analysis of a series of natural flows obtained through rainfall-runoff modelling, combined with the observed record at Tortosa and the storage fluctuations in the reservoirs allows an estimation of water consumption in the basin, which correlates quite well with the historic development of irrigated areas in the basin as shown in the figure on the right. Only a very dense monitoring network would be able to assess whether a decreasing trend of natural flows in the Ebro river is really occurring.





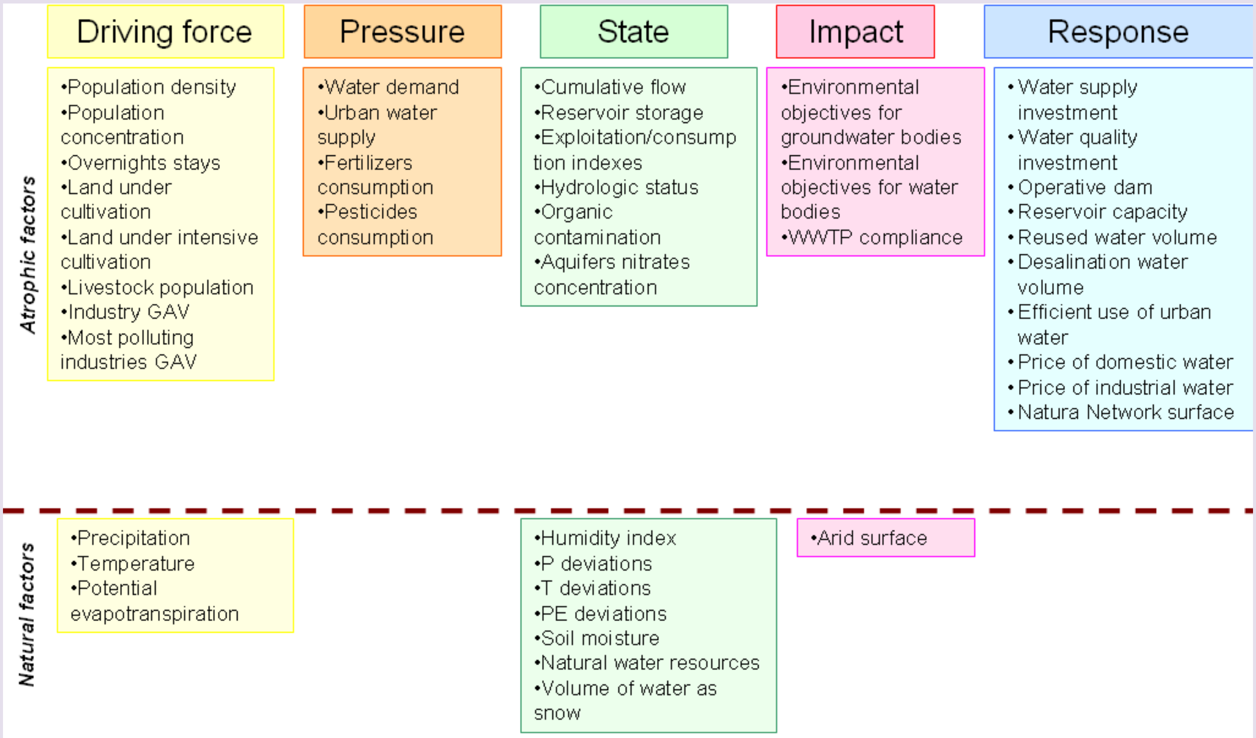
Example 7b – Monitoring of water availability for abstraction developed for the U.K.

We assess the availability of water resources for licensing as part of a programme of Catchment Abstraction Management Strategies (CAMS). CAMS consider the rainfall reliably received, the water requirements of the environment and the amount of water licensed for abstraction. They show us where water is potentially available for abstraction. In 2008, we completed assessments for 119 CAMS, and for the first time, we now have consistent information on potential resource availability on a catchment scale for all of England and Wales (Figure below):



Example 7c – Structure of indicators developed by Spain

The Integrated System for Water Information developed by Spain provides support for the system of drought indicators which are used to detect and declare risk of water shortage in water supply systems. The figure below shows the complexity of the structure of the system of indicators, which combines natural and anthropogenic factors.



7.4 Adaptation measures related to water scarcity & droughts

Guiding principles

9. Take additional efforts to prevent water scarcity and be better prepared to tackle the impacts of droughts.
10. Incorporate climate change adaptation in water management by continuing the focus on sustainability (sustainable balance between water availability and demand).
11. Follow an integrated approach based on a combination of measures (compared to alternatives based on water supply or economic instruments only).
12. Build adaptive capacity through robust water resources systems.
13. Involve stakeholders for engagement to realise decisive measures to tackle water scarcity.
14. Assess other climate change adaptation and mitigation measures on their impact on water scarcity and drought risks.

Most problems anticipated as a result of climate change are in fact an aggravation of current structural problems due to already existing imbalances between water supply and demand. Climate change will imply more radical measures than those already necessary without climate change. Climate change adaptation policies are targeted to prevent or correct these problems, and therefore they will be equally effective in addressing currently existing water management problems. Accordingly, the determined implementation of adaptation strategies will produce beneficial results in a wide range of climate change scenarios. In particular, efforts to prevent water scarcity (including actions on water user awareness raising) and to be better prepared to tackle impacts of occurring droughts should be further intensified.

From the viewpoint of the development of the program of measures (POMs) in RBMPs, taking climate change into account in regions with limited natural water availability should lead to an intensification of policies for demand management as a way to more efficient water management. It is important to always keep the long term in perspective. Some solutions which are perceived as adequate for a stationary scenario may not be so in the long term, under climate change effect.

The first option should always be to intensify actions on demand management to reduce pressure on the water supply sources, especially in times of drought. The greatest scope for action is in irrigation demands, which usually account for the largest fraction of total demand in water scarcity regions. The POMs should include the information and education of citizens to promote or impose the use of domestic water-saving techniques and the intensification of programs for avoiding leakage in water distribution networks and reducing public demand. In a scenario of potential reduction of natural resources, supply-enhancement measures could also be used, promoting non-conventional water resources including wastewater recycling. Under the possible changing conditions in climate change scenarios, it is essential to diagnose the causes that led to water scarcity in the past or may lead to it in the future (see section 7.3) and to set up appropriate regulations to restore a sustainable balance. For this task, the use of market-based instruments should be assessed to address problems caused by water scarcity. It is essential to perform an economic assessment of water use and water value, promoting the efficient use of water by installing individual meters and establishing a pricing policy that penalizes excessive water consumption. But most importantly, monitoring of demand is needed to inform the decisions on supply measures versus water demand management measures.

Suggested actions

- Use the social awareness of the climate change problem as an opportunity to identify the best solution to current challenges in the management of water resources and to correct major environmental problems
- Continue with the options proposed in the Communication on WS&D of 2007: putting the right price tag on water, allocating water and water-related funding more efficiently, improving drought risk management, considering additional water supply infrastructures, fostering water efficient technologies and practices, fostering the emergence of a water-saving culture in Europe, improving knowledge and data collection, etc.

Climate change adaptation will require the progressive reduction of water consumption and the reallocation of water availability to those uses that are deemed socially as more appropriate. These changes cannot be improvised and water managers and decision-makers in water scarcity regions should not wait until the effects are evident to start building adaptive capacity in their river basins (see also chapter 4 for guiding principles on building adaptive capacity).

In a climate change context, the traditional concept of water resources planning should be revised. It will no longer be an activity primarily aimed at increasing the availability of water resources to meet growing demands. **Water resources planning should rather strive to develop effective ways of managing the growing scarcity of the resource, mostly through demand management measures**.

Moreover, synergies with other fields of water management have to be used more consistently. For example, maintaining certain minimum water flows also under changing (climate) conditions is necessary for both achieving the environmental objectives as well as ensuring the function of rivers as waterways for transportation. Early co-ordination in selecting and planning of adaptation measures could therefore serve both purposes.

Water use efficiency varies tremendously across regions and across different users (i.e. agriculture, households, industry). Some member states already successfully reduced domestic and industrial water use through water-saving policies. Demand management needs to consider that cost-efficiency of additional measures therefore differs for different user groups and regions.

It is also important to enhance the performance of water supply systems by increasing their robustness. Robustness can be built into water resources systems through the expansion and diversification of supply sources and their integration in combined systems. The sources of water supply from different origin can have very different characteristics. Resources of different nature (e.g. surface and groundwater) show highly significant differences in terms of variability and reliability. Even the same kind of resources (such as the regulation of surface water), but for different locations, will show the logic differences in terms of hydrological conditions on each site and the characteristics of their hydraulic systems. Systems that integrate a large number of supply sources can best respond to situations of scarcity through integrated water resources management, using every resource for the purposes that is more appropriate depending on its amount, regularity and reliability. The integration of different kinds of water demands in conjunctive systems allows the satisfaction of the most important demands through the use of strategic reserves or the exchange of water rights. In the long term, investment in improving the performance of water supply systems delivers adaptation benefits.

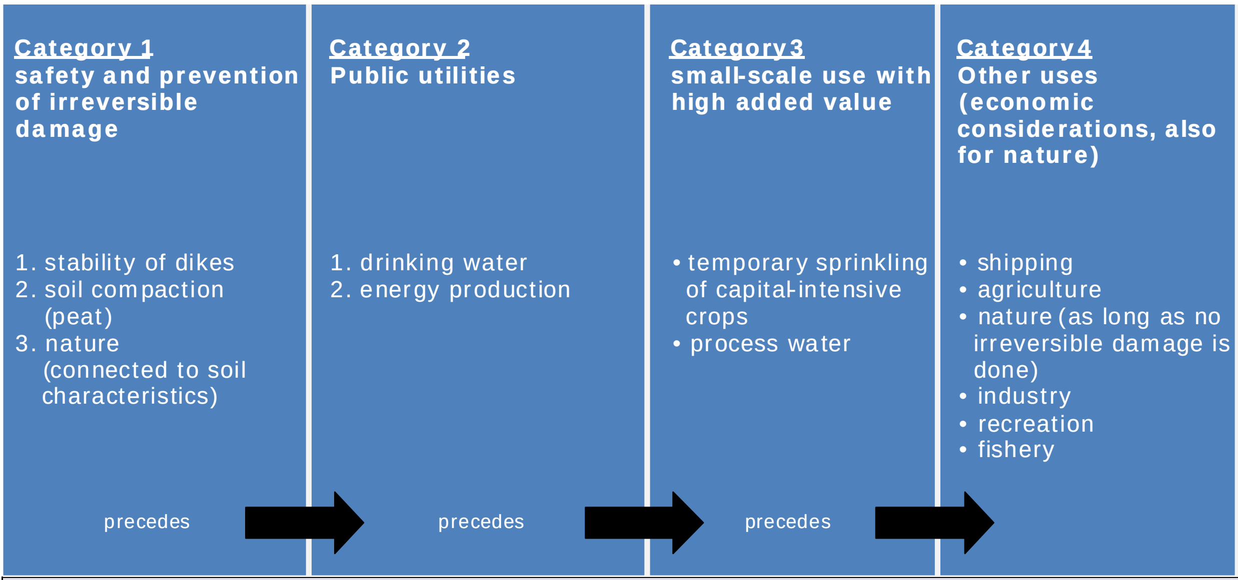
Suggested actions

- Strengthen the institutions in charge of water management to prepare them for the challenges that lay ahead. If necessary, adjust their role from traditional water supply to water demand management
- Build robustness into your water resources system by integrating multiple sources of supply and water demands in conjunctive systems and by improving and enlarging water transportation and distribution infrastructure to achieve the best possible allocation of available resources in future water markets
- Discuss adaptation measures related to water scarcity and droughts in a transboundary and interdisciplinary context

Example 7d: Two-track approach for sustainable freshwater supply in the Netherlands

Existing freshwater supply agreements in the Netherlands will remain in force until 2015. Under normal circumstances, policy is geared towards meeting users' needs wherever possible; as yet, no big problems are expected until 2015, again under normal circumstances. In periods of water shortage (in warm and dry summers), water will be distributed on the basis of the list of priorities and the damage to be contained.

In the planning period 2009 - 2015, the central government will be making long-term decisions on freshwater supplies and salinisation control, including any infrastructure measures and land use planning this may require (see chart below). In the coming planning period, possible solution



strategies are to be worked out with the regions. The key aspects of this new strategy are greater levels of regional self-sufficiency and optimisation of the freshwater distribution in the main and regional water systems. For this too, the central government, the regions and the users will be hammering out solutions in the coming planning period. With the help of long term scenarios, it will be investigated what can be achieved with current policy. In case of a tipping point, a broad range of possible measures is looked at, including moving specific functions as agriculture or nature to water abundant areas. Solutions and areas will be considered as a cohesive whole and the (spatial) consequences for regional systems and functions (drinking water, agriculture, nature and shipping) made transparent.

Example 7e: Successful water demand management in Germany

Domestic drinking water use has been reduced by about 30% in Germany since the 1980ies due to changes in consumer behaviour and technological innovations. This was realized through a combination of various factors:

- A number of studies on future water demand published in the 1970s predicted a tremendous increase in water use for the upcoming decades
- This information was acknowledged by a growing public concern about environmental issues during the 1980s
- In a lose but nevertheless close interaction different actors, i.e. governmental bodies and public authorities, NGOs and water utilities promoted water saving and provided consumers with information about water saving
- A water-saving culture became part of day-to-day life and changed people's habits ranging from lawn watering and rainwater harvesting to tooth brushing.
- Obligatory water meters and water pricing according to consumption were already in place, forming water-saving incentives for private households.
- Manufacturers responded quickly with water-saving innovations for washing machines, dish washers, toilet flushers, shower taps, etc.

Meanwhile, the success of water saving causes extra costs and efforts in drinking water supply and wastewater disposal, e.g. for additional disinfection in case of longer residence times of drinking water in mains, more frequent flushing of sewers, or increased treatment efforts in case of higher concentrations of wastewater contaminants.

Annex I: Adaptation actions/measures – Sources of information

The evidence base for adaptation is not wide, as work is still at an early stage. However, with the establishment of national adaptation strategies and in many cases webportals on climate change adaptation, there is a increasing amount of information and case studies that may be used for establishing an overview of relevant adaption actions/measures for the specific RBD and the specific pressures.

There are a number of inventory gathering adaptation case studies which, to some extent, describe the experience with implementation:

- **EEA and its Topic Centre on Water** have in 2008 and 2009 worked on a report describing good practice examples in relation to adaption in water management (to be published in the second half of 2009). The report's main objective is to compile examples of measures/actions that are relevant for WFD purposes and that can be considered good-practice for adaptation to climate change. It aims to support the efforts of incorporate climate change aspects into their river basin management planning.
- Other **databases for adaptation measures** and concepts are:
  - UNFCC Database of submissions on adaptation planning and practices under the Nairobi work programme: The database provides a query mask to select measures according to country, geographical scale, sector and type of measure http://maindb.unfccc.int/public/adaptation_planning/
  - AMICA-CLIMATE is a European Interreg IIIC initiative which has tried to make the adaptation process more transparent http://www.amica-climate.net/online_tool.html
  - UKCIP Adaptation action case studies. National approach which is a good example of hands-on guidance to become active http://www.ukcip.org.uk/index.php?option=com_content&task=view&id=286&Itemid=423

Annex II: Summary of information resources and relevant research

EXAMPLES OF INFORMATION NETWORKS IN EUROPE

This section gives indications to those with river basin management responsibilities of key sources of further guidance and information concerning adaptation to climate change in Europe, especially with regard to water issues.

Common Implementation Strategy of the WFD (WFD-CIS)

The European Commission and Member States established a Strategic Steering Group (SSG) on Climate Change and Water under the Common Implementation Strategy. The SSG convened in Sep 2007 for the first time. Since then it aimed at integrating adaptation to climate change into the WFD implementation process. The guidance at hand is a product of the preparatory work of the SSG.

UNECE

The United Nations Economic Commission for Europe established a Task Force on Water and Climate under the Convention on the Protection and Use of Transboundary Water courses and International Lakes. The Task Force produced Guidance on Water and Climate Adaptation[44] for decision makers and water managers, in particular at the transboundary level. The Guidance provides a framework to develop step-by-step an adaptation strategy taking into account usual barriers. It provides also an overview of potential adaptation measures. In addition, a Task Force on Extreme Weather Events has been established, which prepares Guidelines on Water Supply and Sanitation in Extreme Weather Events (deals with extreme weather events due to Climate Change and their impact on drinking water supply and waste water treatment).

EWP

The European Water Partnership (EWP) is in the process of setting up a European Dialogue on Climate Change Adaptation and Water[45]. This Dialogue will focus on raising awareness, exchanging experiences and best practices between all stakeholders and the set up of concrete projects to help make sure Europe is safe from climate change. It will be a focal point for coordination in Europe, as well as towards the outside world.

Clearing House

The European Commission is for the moment exploring the possibilities of establishing a Clearinghouse on climate impacts and adaptation. The aim is to develop both the software and information architecture for a planned repository ('Clearinghouse') on adaptation. In the future this could be one of the major sources of information on adaptation measures.

ADAM Digital Compendium on Adaptation

This Digital Compendium[46] acts as a portal for the dissemination of the transdisciplinary analysis results carried out in the EU ADAM project[47] (see also section on relevant research projects below). It comprises an adaptation catalogue with possible adaptation measures including information on the extent, feasibility, efficiency, and cost effectiveness of these

measures. It is accompanied by key messages about what supports and what hinders adaptation together with a set of learning examples, and a macro-economic analysis estimating the monetary effects of climate change and adaptation for different European countries.

RELEVANT RESEARCH PROJECTS

Integrated research on the functioning of climate and on understanding climate change impacts represents a key component of decision-making regarding adaptation and mitigation. This includes studies on the past evolution of the earth and marine system, including polar regions, and prediction of their future evolution including observations, experimental studies and advanced modelling and taking into account the anthropogenic forcing. Scientific outputs are recognised to be essential for the development of effective adaptation and mitigation measures to climate change and its impacts. For examples, advanced climate change models at the global and regional scales are developed and used to better design measures at various scales. In relation to climate change impacts on water, these models enable study of changes in atmospheric composition for all components of the water cycle. Different approaches are being investigated to translate the output from the climate models to the river basin scale, for example to design risk based approaches to tackle climate related hazards such as droughts, storms and floods.

Research on climate change is closely linked to policy developments at EU level as highlighted in the White Paper on adaptation to climate change and on-going discussions about integration of adaptation and mitigation measures in the river basin management planning of the Water Framework Directive. Scientific outputs are also contributing to international policies and debates, in particular through inputs to IPCC assessment reports and UNFCCC documents. In this context, projects of the 6th Framework Programme (2002-2006)[48] and of the on-going 7th Framework Programme (2007-2013)[49] largely contributed to gathering knowledge relevant to climate change adaptation in the context of the WFD river basin management planning. Research areas are exemplified by projects described below (the list is obviously far from being exhaustive – an updated list of projects in support of climate change research is available[50]), highlighting their potential to be linked to policy developments.

Research into climate change scenarios

PRUDENCE and ENSEMBLES projects

Research on climate change scenarios and predictions have been ongoing and expanding in the last few decades. For example, the PRUDENCE project (2001-2004)[51] has provided a series of high-resolution climate change scenarios for 2071-2100, including an analysis of the variability and level of confidence in these scenarios as a function of uncertainties in model formulation, natural/internal climate variability, and alternative scenarios of future atmospheric composition. A continuation of this research line is illustrated by the ENSEMBLES project (2004-2009)[52], which integrates climate change impact studies into an ensemble prediction system, quantifies the uncertainty in long-term predictions of climate change and

---

[48] In particular projects funded under the 'Global Change and Ecosystems' sub-priority

[49] In particular projects funded under the 'Environment (including climate change)' theme

[51] Prediction of Regional scenarios and Uncertainties for Defining EuropeaN Climate change risks and Effects - http://prudence.dmi.dk

[52] ENSEMBLE- based Predictions of Climate Changes and their Impacts - http://www.ensembles-eu.org/

provides a reliable quantitative risk assessment of long term climate change and its impacts. It includes the production of Regional Climate Scenarios for Impact Assessments and the formulation of very high resolution Regional Climate Model Ensembles for Europe.

STARDEX project

"Statistical and Regional dynamical Downscaling of Extremes for European regions" (STARDEX, 2002-2005)[53] has given a rigorous and systematic inter-comparison and evaluation of statistical, dynamical and statistical-dynamical downscaling methods for the construction of regional scenarios of extremes. The aim was to identify the more robust techniques and used these to produce future scenarios of extremes for European case-study regions for the end of the 21st century. Large amounts of progress were made to answering the vital question as to whether extremes will occur more frequently in the future.

CECILIA project

The FP6 project CECILIA (Central and Eastern Europe Climate Change Impact and Vulnerability Assessment)[54] has as primary mission to improve the understanding of local climate change in Central and Eastern Europe and its impacts into forestry, agriculture, hydrology and air quality. It thus provides detailed regional climate projections (and impact assessments) for Central and Eastern Europe.

CLAVIER project

The FP6 project CLAVIER (CLimate ChAnge and Variability: Impact on Central and Eastern EuRope)[55] aims to make a contribution to successfully coping with climate change challenges, by studying in detail three representative CEE Countries: Hungary, Romania, and Bulgaria.

CIRCA ERA-Net

Climate impact analysis and adaptation response must be informed by a coherent body of research and it is CIRCLE´s prime objective to contribute to such efforts by networking and aligning national research programmes in the 19 CIRCLE partner countries.[56] The Implementation of a European Research Area (ERA) for climate change is CIRCLE's final goal. The objectives include learning from each other, exchange knowledge and experience, planning and most important establishing transnational research programmes and joint calls. There were 3 regional calls: Nordic, Mediterranean, and Mountainous areas.

Research into climate change impacts on the aquatic environment and water cycle

CLIME project

Research on climate change impacts on aquatic ecosystems has already started within the 5th Framework Programme, e.g. the CLIME[57] project developed a suite of methods and models for improved management of lakes and catchments under future as well as current climatic conditions. The most up-to-date regional climate scenarios, and existing catchment and lake models were used in the project to address issues that were central to the implementation of the Water Framework Directive. Particular attention was paid to two water quality issues that are likely to become increasingly important, namely leaching of highly coloured water from

peatland catchments and increased productivity of some lakes and the increasing frequency of algal blooms.

KLIWAS project

With focus on larger central European rivers including the Elbe, Rhine and the Danube, the interdisciplinary research programme KLIWAS[58] started in 2007. It integrates ecological, economical, water quality and water quantity aspects of climate change for rivers and coastal waters which are used as waterways. KLIWAS strictly follows a multi-model-approach. It uses and evaluates all available climate model runs (including those of the EU-FP6-Project ENSEMBLES and new runs provided by the KLIWAS group) as well as different hydrological models in order to provide a reliable basis for the assessment of various adaptation options. With the purpose of model validation and monitoring of climate change effects, historical data bases are extended, too. A model chain is established, which couples climate models to hydrological/oceanographic, hydrodynamical/sedimentological, water quality and ecosystem models. At each step, uncertainty is analysed in detail to assess the level of understanding of the aquatic systems and their sensitivity to low flow, floods and other aspects of "historical" and future climate change. Changes and possible adaptation measures of the waterways are evaluated taking all functions of rivers and coastal waters into account. Thus, various WFD relevant information is provided.

EURO-LIMPACS project

Research to understand and quantify the impact of climate change (CC) on freshwater ecosystems at the catchment scale has been active through the EURO-LIMPACS[59] project, which examined CC interactions with other key drivers and pressures related to aquatic systems at multiple time scales up to secular trends. The project provided a high level of expertise on CC impacts on aquatic ecosystems which is reflected in a Position Paper (addressed to policy-makers) on "Impact of climate change on European freshwater ecosystems: consequences, adaptation and policy". Scientific achievements combined analyses of long term data sets, the reconstruction of past trajectories from sediment archives, experimental approaches in the laboratory and in mesoscosms, model and scenario developments, and the development and testing of Decision Support Systems (DSS). The results from this research are expected to assist in: (1) assessing the potential impacts of global change at the local to regional scales freshwater lakes, rivers and wetlands across the wide range of European climates, geomorphology types, land-use, and human impact; (2) developing a unified system of ecosystem health indicators related to the impact of CC; (3) reviewing the effect of CC on restoration strategies for freshwater ecosystems and (4) understanding the interaction of CC with key water quality problems such as hydromorphological change, eutrophication, acidification, and long range atmospheric transfer of toxic pollutants. A new FP7 project (REFRESH) will follow on from Euro-limpacs and focus on an assessment of the practical measures that might be taken by managers to mitigate or adapt to the impacts of CC on freshwater ecosystems.

WATCH project

Specific research on climate change impacts on the global water cycle is carried out under the WATCH project[60] which unites different expertises (hydrologists, climatologists, water use experts) to examine the components of the current and future global water cycles, evaluate

[58] KLIWAS (www.kliwas.de)

[59] http://www.eurolimpacs.ucl.ac.uk

[60] www.eu-watch.org

their uncertainties and clarify the overall vulnerability of global water resources related to the main societal and economic sectors. The project is developing a number of global and regional datasets to facilitate the assessment of changes in the water cycle, including case studies in river basins located in the EU. In parallel a conceptual modelling framework is being developed to provide consistent modelling results and transfer information between scientists and stakeholders. This will include methodologies to handle biases in climate model output and quantify the resulting uncertainties in estimates of future components of the global water cycle. WATCH aims to increase our understanding of drought and large scale flood development and their propagation for the past and future climates through studies at different scales (global, regional, river basin). Five test basins, within Europe, are being used to translate water resources applications from the global water cycle system to river basins.

CIRCE project

The assessment of climate change impacts on water resources is also being studied in focused aquatic environment, e.g. the Mediterranean area through the CIRCE project[61]. In particular, research is carried out to investigate how strongly climate variations induce significant changes in the hydrological cycle, e.g. increasing atmospheric water vapor, chancing precipitation patterns and intensity, and changes in soil moisture and runoff. The project collects data from observations to quantify those changes and to develop a regional climate model able to analyze the conditions in the Mediterranean area. The investigations concern surface water, groundwater, coastal aquifers and the interactions between them. Both water quantity and quality issues are taken into account. The final goal of this project is to produce an assessment (RACCM – Regional Assessment of Climate Change in Mediterranean) to be used to deepen the understanding of the impact of climate change on water resources and to suggest potential adaptation measures.

ACQWA project

A more focused research is reflected by the on-going ACQWA Project[62] which investigates the consequences of climate change in mountain regions where snow and ice is currently an important part of the hydrological cycle. Numerical models are used to predict shifts in water amount by 2050, and how these changes will impact upon socio-economic sector such as energy, tourism and agriculture. There will be focused studies on governance issues and ways of alleviating possible conflicts of interests between economic actors competing for dwindling water resources. Following a first phase of research in the data-rich European Alps, the models and methods will be applied to non-European regions such as the Andes and the Central Asian mountains, where climatic change and changing snow, ice and water resources will be a source of concern but also of opportunity in the future.

CES project

In the Nordic Region a specific research program has been set up to further investigate the risks, potentials and adaptation measures for the renewable energy resources in the context of climate change, the CES standing for Climate and Energy Systems (http://www.os.is/page/ces_forsida). It is including hydropower, wind power, bio-fuels and solar energy and is in many ways a follow up on the Climate and Energy (CE) Nordic-Baltic research project (2003-2006), both funded by Nordic Energy Research (www.nordicenergy.net) and the Nordic energy sector.

The goal of the CES project is to look at climate impacts closer in time and assess the development of the Nordic electricity system for the next 20-30 years. It will address how the

---

[61] http://www.circeproject.eu

[62] Assessing Climate change impacts on the Quantity and quality of Water – www.acqwa.ch

conditions for production of renewable energy in the Nordic area might change due to global warming. It will focus on the potential production and the future safety of the production systems as well as uncertainties. The key objectives are summarized as:

- Understanding of the natural variability and predictability of climate and renewable energy systems at different scales in space and time.
- Assessment of the risks due to changes in probabilities and nature of extreme events.
- Assessment of the risks and opportunities due to changes in production of renewable energy.
- Development of guiding principles for decisions under climate variability and change.
- Development of adaptation strategies.
- A structured dialog with stakeholders.

Research into mitigation / adaptation options and costs

AquaStress project

Mitigation / adaptation options to respond to climate change conditions have been developed, tested and evaluated within the AquaStress integrated project[63], leading to the definition of mitigation options exploiting new interfaces between technologies and social approaches, as well as economical and institutional settings. Particular emphasis has been given to methods, tools and guidelines – e.g. for groundwater modelling, groundwater recharge, improved crop policies - to facilitate a holistic approach to manage water supply and water demand. Several lessons can be derived from the AquaStress experience on improved approaches to integrated and participative water management, which is considered fundamental for adaptation to changing conditions.

ADAM project

Adaptation and mitigation strategies in support of European Climate Policy have also been investigated within the framework of the ADAM project[64] which developed long-term policy options / scenarios that could contribute to the EU's 2°C target and targets for adaptation. The project made significant contributions to climate change policy developments through regular policy briefs, highlighting that Green House Gas emissions could be technically reduced in Europe by up to 80% by 2050. This is obviously only indirectly linked to river basin management developments but it has nevertheless consequences on the way integrated water resource management will have to evolve over the forthcoming decades.

NeWater project

Increasing uncertainties due to the accelerating pace and greater dimension of changes (e.g. climatic and demographic changes) and their impact on water resource management have been investigated by the NeWater Integrated project[65]. The central issue of the NeWater project was the requirement for a transition from currently prevailing regimes of river basin water management to more adaptive regimes in the future. NeWater identified several key elements of the water management system, amongst others governance, sectoral integration, information management, and risk mitigation. Research focused on processes of transition of these elements to more adaptive processes of Integrated Water Resources

[63] http://www.aquastress.net

[64] ADAM website

[65] NEWATER: adaptive integrated water resources management - www.newater.info

Management (IWRM). Seven river basins (Amudarya, Elbe, Guadiana, Nile, Orange, Rhine and Tisza) were selected as case study areas to establish the link between practical activities and advances in thematic research and tool development. The project has developed a book on Climate Change Adaptation in the Water Sector and twelve publicly available synthesis products which are of direct interest to policy implementation and development, including databases, guidelines on uncertainty in adaptive management, , evaluation of water resources scenarios in the case studies, a guidebook on adaptive water management, etc. All the reports and tools are available on the project webpage.

AQUAMONEY project

Besides the development of mitigation/adaptation strategies, an important element is the economic valuation of identified measures. In this respect, research has contributed to develop scenarios and quantify environmental and resource costs and benefits linked to adaptation to climate change within the framework of the AQUAMONEY project[66].

ClimateCost project

Efforts are being pursued with the recently launched ClimateCost project[67] which builds up on results of AQUAMONEY and ADAM to further develop climate change and socio-economic scenarios with quantification of related costs, including an assessment of physical effects and economic damages of major catastrophic events.

ClimateWater project

Specific inputs for the identification of gaps that would have possible effects on the implementation of the WFD in combating climate impacts on water are being studied by the ClimateWater project[68]. Based on an analysis and synthesis of data on the likely water related climate change impacts, the project will identify adaptation strategies that were developed in Europe and globally for dealing with the CC impacts on water resources and aquatic ecosystems (preventing, eliminating, combating, mitigating). Research needs in the field of 'climate impact on the water cycle and water users' will be identified with special regard to enable the ranking of adaptation action in the light of the magnitude of impact on water resources and the urgency of the action needed.

Scoping report on Climate Change in Inland Waterways

In 2009, the UK's Inland Waterways Advisory Council published a 'scoping report' on how inland waterways in England and Wales can assist in mitigating for and adapting to the effects of climate change – in particular, greater winter rainfall, drier summers, higher temperatures and more frequent extreme weather events. Secondary effects also examined included adaptation to changes in sediment run-off, transport and accumulation and changes in flora and fauna. The report highlights the most likely impacts of climate change and the potential consequences for inland waterways in England and Wales. It then identifies and assesses a range of potentially appropriate measures through which changes in use of the waterways could contribute to reducing the extent of climate change (mitigation) and management of waterways can be modified to prepare for the anticipated or recorded effects of climate change (adaptation). The report is available at:

http://www.iwac.org.uk/downloads/reports/IWAC_Climate_Change_Inland_Waterways_Apr09.pdf

Research on droughts and water scarcity

XEROCHORE project

Besides research on management options addressed by AquaStress (see above section), specific research needs on droughts are being discussed in the XEROCHORE Support Action[69] which is currently establishing the state of the art of drought related national and regional policies and plans and will lay down a roadmap that will identify research gaps on various drought aspects (climate, hydrology, impacts, management, policy) and steps to take in order to fill them. In particular, support to European Drought Policy will be provided through expert recommendations about impact assessment, policy-making, drought in the context of integrated water resources management and guidance on appropriate responses for stakeholders. The large consortium (over 80 organisations) is closely linked to the European Drought Centre and the CIS Working Group on Water Scarcity and Drought, which has basically led to the development of an internationally recognised exchange platform on drought issues between the research and policy communities. This is strengthened by links established with relevant RTD projects which include drought components, e.g. WATCH, CIRCE, as well as the recently launched MIRAGE project on Intermittent River Management[70]. It is expected that the exchange platform, now established and developed within the XEROCHORE project, will be further strengthened by the European Commission through the clustering of projects dealing with climate change and water security (including drought aspects) from 2010 onward.

European Drought Observatory

The Joint Research Centre of the European Commission is developing a prototype of the European Drought Observatory (EDO) in the frame of the Seventh Framework Programme for Research, Technological Development and Demonstration. EDO will provide information on drought monitoring, detection, forecasting, and assessment in a multi-scale approach, integrating various information systems that provide information on droughts on international, national, regional, and local level in Europe through interoperability arrangements based on INSPIRE principles. EDO will enable a consistent assessment of droughts in Europe, allow for inter-comparison of different methodologies applied throughout the continent, and foster exchange and collaboration among partners in research and application.

Research on floods

FLOODsite project

The project most relevant to flood research carried out within the years 2004-2009 at EU level in support of the Flood Directive is certainly the FLOODsite Integrated Project[71]. The project was interdisciplinary integrating expertise from across the environmental and social sciences, as well as technology, spatial planning and management. The notion of 'integrated' flood risk management now goes towards a change of policy from one of flood defence to flood risks being managed, but not eliminated. The project has developed robust methods of flood risk assessment and management and decision support systems which have been largely tested in pilot sites. Regular contacts with the CIS Working Group on Floods have enabled to inform the policy community about progress on flood risk management. Over than 100 research reports are available for public upload on the project website.

[70] Ref. MIRAGE

[71] FLOODsite project 'Integrated Flood Risk Analysis and Management Methodologies' - http://www.floodsite.net

FLASH project

Flash flood events and predictive scenarios have been studied by the FLASH[72] project in five countries (Israel, Italy, Greece, Spain and Cyprus) on the basis of the collection and analysis of lightning data and precipitation observations. Research is continuing on how to reduce loss of life and economic damage through the improvement of the preparedness and the operational risk management for flash floods and debris flow generating events as currently undertaken by the IMPRINTS project[73], which also studies how to contribute to sustainable development through reducing damages to the environment. The project will produce methods and tools to be used by emergency agencies and utility companies responsible for the management of these extreme events and associated effects. Impacts of future changes, including climatic, land use and socioeconomic will be analysed in order to provide guidelines for mitigation and adaptation measures.

CRUE ERA-Net

CRUE ERA-Net[74] has also completed 7 projects about "Risk assessment and risk management: effectiveness and efficiency of non-structural flood risk management measures", while a second call is related to flood resilient communities.

Research perspectives

Modelling capabilities should be improved and appropriate tools should be developed to advance the capability to assess climate effects on water resources and uses. New research areas (resulting from the 2009 FP7 call for proposals) will investigate novel observation methods / techniques and modelling and socioeconomic factor analyses to reduce existing uncertainties in climate change impact analysis and to create an integrated quantitative risk and vulnerability assessment tool. In particular, impacts on key strategic sectors such as agriculture and tourism will be investigated as well as macroeconomic implications of water availability in terms of regional income, consumption, investment, trade flows, industrial structure and competitiveness with focus on Southern Europe, North Africa and the Middle East.

In terms of perspectives, research should look into the evaluation of climate change adaptation and mitigation measures across multiple water-dependent sectors, and investigate interactions among water and other environmental compartments (sediment, soil, air). At present, scientific information about water-related impacts of climate change is not sufficient, especially with respect to translation of climate model output to river basin scale (matching the scale of the WFD River Basin Management Plans), water quality, aquatic ecosystems and groundwater, including their socio-economic dimensions. Research into climate change impacts on the water cycle from the global to the regional scale is essential to improve the understanding and assessment of key drivers and their interactions, in order to better manage and mitigate risks affecting the water cycle and to reduce uncertainties in policy responses. This also includes research related to disaster risk reduction to improve understanding and modelling of extreme events related to the hydrological cycles at scales that are relevant to decision making (possibly linked to policy).

[73] Improving Preparedness and Risk Management for Flash Floods and Debris Flow Events - http://www.imprints-fp7.eu/

[74] CRUE ERA-Net (www.crue-eranet.net)

ANNEX III: Challenges of selected types of floods

The specific challenges of coastal floods and sea level rise

Due to climate change and the resulting sea level rise, the actual probabilities of coastal flooding will increase without additional measures. Compared to many other sources of flooding, the probabilities will remain rather low but the consequences when it happens are enormous. Only in the North Sea region, about 16 million people live behind coastal flood defences. Especially for estuaries, the combined effects of high discharge probability and storm tides at sea are both influenced by climate change. A moderate exceptional storm tide and discharge can lead to really exceptional water levels in estuaries. Such flood events can also have additional effects of changes in salt/fresh water boundaries. Some studies, for instance in Norway[75], also show that the tsunami risk is also increasing with climate change, as climate change increases risk of landslides which could trigger floods in coastal areas.

To reduce the flood risk in coastal areas, different measures could be considered in the flood risk management plans and an adapted approach to coastal flood risk management may be required. Issues that may need more consideration are::

- Non-structural (spatial planning) measures like restrictions for new developments in coastal flood-prone lowlands and building regulations to reduce the vulnerability against flooding
- Multifunctional uses of flood defences (e.g., the Dutch "Delta-Dike-Approach")
- Not "black/white" solutions, but important trade-off and balances of objectives to be found
- Win/win areas for instance for industrial activities to be sought
- Relocation of highly vulnerable activities.

Dealing with flash floods, torrent floods, debris flows and land slides/erosion due to floods

The 4th IPCC assessment report predicts that climate change will increase the occurrence of flash floods across the EU. This leads to a number of new challenges to flood risk management. For instance different or reinforced protective measures against sediment and debris deposits may be needed. Flash floods can rapidly change river flows and debris flows. Those very dynamic hydromorphological processes are well known in the alpine catchments. But as these processes are difficult to foresee on the one hand and may cause major damages on the other hand, they are complicating flood risk management. Flash floods with debris flow and sediment deposits may change river course permanently or temporarily, which will have an impact on hydromorphological condition of rivers and lakes. In practice there may not be any boundary between torrential flood (usually transporting solid material), debris flows and land slides as far as risk management is concerned. The above mentioned increases risk of landslides which could trigger tsunamis. This is another issue which may require attention (see also information on research related to flash floods in Annex II).

Measures that should be included in the flood risk management plans:

- Reinforced awareness raising among politicians of land slide hazards
- Identification of flash floods "hot spots" such as fans (alluvial fans, dejection cones, etc), and rapid changes in plan view of active channels (avulsions and sediment deposition or erosion related processes) to raise awareness of flood risk managements and land use planners.

Urban floods

It is broadly recognised that climate change will result in an increase in peak rainfall intensities and the frequency with which high intensity rainfall events will occur. Heavy rain and snow induced by climate change could cause significant damage in urban areas. A recent model study estimates the impact on a Swedish city and suggests there could be an increase in the number of surface floods by 25-45 % during this century. There may also be a non-linear response increase of precipitation vs increase in surface run-off (see example introduction chapter 6). If this rainfall is combined with thunderstorms, additional problems such as electrical failures could worsen the consequences because pumping facilities may stop. For example, low intensity rainfall events would cause no direct harm to the urban drainage system. However, they may worsen the effect of events that follow due to saturation of the area. Very high intensity and extreme rainfall events would be likely to cause increased basement floods and surface floods, as well as sewer overflow. The prediction of future flooding could help its implementation, particularly in urban areas where risks are higher. [76]

The impact of increased surface water flood risk in urban areas is likely to be compounded by urban creep (which results in faster runoff from impermeable areas and less infiltration) and the increasing value of the assets likely to be affected. Techniques to enable the identification of areas susceptible to 'pluvial' flooding are evolving as well as management approaches to deal with surface water flood risk but awareness of the potential problem needs to be raised across Member States underpinned for instance by guidance on appropriate responses.

Surface water flooding can also occur in conjunction with fluvial or tidal flooding affecting urban areas and the risk of these types of flooding is also likely to increase with climate change. It is therefore necessary to try to **identify the different sources of likely flood risk in any urban area and their likely interaction**. Such an understanding of flooding mechanisms is often the key to identifying appropriate and cost-effective solutions.

Flood risk management of urban floods should include taking climate change projections into account when identifying where urban water systems have a low capacity and identifying their most vulnerable locations. To manage urban floods in view of climate change, specific consideration are required in relation to the design and dimensions of water run off systems, and management of reservoirs and infrastructure such as underground parkings.

Suggested actions

- Assessment of the likely variation in projected increase in peak rainfall intensity across Member States due to climate change.
- Recognition of the potential significance of surface water flooding in urban areas in terms of damage potential and risk to life to promote awareness raising within Member States.
- Guidance or examples of good practice on appropriate techniques to assess the significance of surface water flood risk in conjunction with other flood risks together with guidance on possible approaches to surface water management in urban areas.

[76] Olsson, J., Berggren, K., Olofsson, M. *et al.* (2009). Applying climate model precipitation scenarios for urban hydrological assessment: A case study in Kalmar City, Sweden. *Atmospheric Research.* 92: 364-375

- Further information exchange on examples of "no-regret" or "win-win" measures in view of Climate Change between Member States and internationally.

Annex IV: Definitions of projections, forecasts and scenarios

"Climate Projection" means the calculation of the future climate by means of a climate model, where assumptions about the future development of the greenhouse-relevant emissions – the so called "emission scenarios" (emission of greenhouse gases) – are used at each time step as forcing.

When a projection could be branded "most likely" it would become a **"forecast or prediction"** (according to IPCC[77]). However, as current climate projections are based on hypotheses of future GHG emissions and also because the climate system's behaviour is not sufficiently well known, it is not possible to assign a high level of confidence to projections. Thus, contrary to weather forecast, the term "forecast" is not used for climate simulations.

As it is virtually impossible to foresee the exact development of climate and land use for a longer time, scenarios are often used to assess several possible future outcomes. A **"Climate Scenario"** is defined (also according to IPCC) as "a coherent, internally consistent and plausible description of a possible future state of the world. It is not a forecast; rather, each scenario is one alternative image of how the future can unfold. A projection may serve as the raw material for a scenario, but scenarios often require additional information. A set of scenarios is often adopted to reflect, as well as possible, the range of uncertainty in projections." Thus, the definition of a scenario includes the steps of (1) evaluation of uncertainty and (2) a deliberate decision about what "futures" are assumed in a study.

Scenarios may be derived from projections, but are often based on additional information from other sources." An important point is the clear distinction between scenarios and forecasts. Scenarios cannot predict the exact temperature or the water demand for a specific day in the future. They can, however, help to estimate how the mean behaviour of a system may change under certain circumstances.

Nowadays the so-called SRES Emission Scenarios (Special Report on Emissions Scenarios) presented by the IPCC are primarily used as a basis for the climate scenarios. They comprise a total of three scenario families (see box below) providing an assessment of the future emission development and of the resulting greenhouse gas concentrations. Here the difference is basically made between the economic and demographic development and the degree of globalisation. The impacts of political agreements to limit climate-relevant trace gas emissions (such as the Kyoto Protocol) are not considered in the scenario calculations.

[77] http://www.ipcc-data.org/ddc_definitions.html

A1: The *A1 scenario family* (divided into the scenarios A1FI, A1T and A1B on the basis of the ratio of fossil energies used) assumes a faster economic growth and a rather homogenous world with increasing cultural and social contacts between the different regions of the world. Differences in the per capita income reduce more and more, and the technological development progress is fast and efficient. The global population will peak in the middle of the current century.

A2: The *A2 scenarios* describe a very heterogeneous world oriented towards economy. Population growth continues at undiminished speed, and per capita incomes converge only in some regions and only at a very slow pace.

B1: Like the A1 family, the *B1 scenarios* anticipate fast globalisation, albeit under the assumption of economic structures transforming into a service and information technology oriented society. Here, an extensive introduction of clean and resource-efficient technologies is relevant for the evolution of greenhouse gas concentrations.

Annex VI: Role of the SEA Process in climate change adaptation

Table 5 SEA Process: How climate change should be considered in the process?

Stage A: Setting the context & objectives, establishing the baseline & deciding on the scope.

- Describe the current and likely future climate change baseline.
- Identify the likely significant problems and constraints caused by climate change
- Develop climate change objectives and indicators that take account of future climate change (see below).
- Consult with SEA Consultation Bodies such as the Environment Agency on Flood Risk.

Stage B: Developing and refining alternatives and assessing effects

- Suggest plan alternatives to deal with key climate change related problems
- Assess the effects of plan alternatives on the climate change objectives and indicators
- Refer to Strategic Flood Risk Assessment in the Environmental Report
- Integrate climate change adaptation into the final plan

Stage C: Preparing the Environmental Report

- Explain in the Environmental Report how climate change issues and uncertainty have been identified and managed

Stage D: Consulting on the draft plan or programme and the Environmental Report

- Consult authorities responsible for climate change management and others to provide advice on good practice (see Stage A)

Stage E: Monitoring the significant effects of implementing the plan or programme on environment

- Monitor if adaptation has been put in place/implemented • Be prepared to respond to any adverse

Table 6 Aspects of climate change - Example Possible Indicators Example Information sources

Climate/weather changes

- Sea level
- Precipitation
- Temperature
- River flows (both extremes)
- Flood levels in rivers
- Extreme events such as heatwaves
- Climate change scenarios, scoping studies, sectoral studies
- Climate monitoring and predictions
- • Land use change, flood risk

Local impacts of climate/ weather changes • Average annual flood incidence/ damage drought orders • No. cases of subsidence • River flows and water quality • • Environment Agency – flood risk maps, river flows, water quality
Adaptation Measures • % developments with Sustainable Urban Drainage Systems (SUDS) • No. or % homes/roads in floodplain • Household water use • • Environment Agency

ANNEX IX: List of contributors

This document is the result of different contributions from and discussions in the CIS Strategic Steering Group (SSG) on Climate Change & Water under the chairmanship of Germany and the European Commission.

Specific members of the SSG on Climate Change & Water coordinated the drafting of chapters 4, 5, 6 and 7. Chapter 4 and section 5.7 were coordinated by the EEA. Sections 5.1-5.6 were coordinated by the UK. The CIS Working Group on Floods coordinated the drafting of chapter 6 on floods and Spain coordinated the drafting of chapter 7 on water scarcity and droughts.

The members of the CIS SSG on Climate Change & Water, of which the members are listed below.

FOREWORD

The EU Member States, Norway and the European Commission in 2000 have jointly developed a common strategy for implementing Directive 2000/60/EC establishing a framework for Community action in the field of water policy (the Water Framework Directive). The main aim of this strategy is to allow a coherent and harmonious implementation of the Directive. Focus is on methodological questions related to a common understanding of the technical and scientific implications of the Water Framework Directive. In particular, one of the objectives of the strategy is the development of non-legally binding and practical Guidance Documents on various technical issues of the Directive. These Guidance Documents are targeted to those experts who are directly or indirectly implementing the Water Framework Directive in river basins. The structure, presentation and terminology are therefore adapted to the needs of these experts and formal, legalistic language is avoided wherever possible.

In the context of the above mentioned strategy, a drafting group was established in 2007 with the aim of preparation of technical guidance for the chemical monitoring of sediment and biota. This drafting group has been coordinated by Italy, France and the Joint Research Centre, and involved a range of experts from other Member States and from stakeholder organisations.

Monitoring of sediment and/or biota can be used together with the water matrix to provide a coherent and comprehensive picture of the status of the water bodies within each river basin district. The initial screening or certain chemicals in the monitoring programme will help to identify areas of concern and areas where additional effort is needed, such as increased intensity of sediment, biota, or water monitoring or direct measurements.

The Water Directors have examined and endorsed this Guidance during our informal meeting under the Spanish Presidency in Segovia (27-28 May 2010). We would like to thank the Drafting Group for preparing this high quality document. We strongly believe that this and other Guidance Documents developed under the Common Implementation Strategy will play a key role in the process of implementing the Water Framework Directive and its daughter Environmental Quality Standards Directive.

This Guidance Document is a living document that will need continuous input and improvements as application and experience build up in all countries of the European Union and beyond. We agree, however, that this document will be made publicly available in its current form in order to present it to a wider public as a basis for carrying forward ongoing implementation work.

We also commit ourselves to assess and decide upon the necessity for reviewing this document in the light of scientific and technical progress and experiences gained in implementing the Water Framework Directive and Environmental Quality Standards Directive.

TABLE OF CONTENTS

1. SCOPE OF THE GUIDANCE

1.1. Legal background - Sediment and biota chemical monitoring under the Water Framework Directive

Directive 2008/105/EC (Environmental Quality Standards Directive) defines the good chemical status to be achieved by all Member States in 2015 and gives, together with the Water Framework Directive 2000/60/EC (WFD), the legal basis for the monitoring of priority substances in sediment and biota.

For the majority of the substances of the list of priority substances (33) and 8 certain other pollutants included in the Directive, the establishment of Environmental Quality Standards (EQS) at Community level has been limited to concentrations in the water column. As regards hexachlorobenzene, hexachlorobutadiene and mercury, however it was considered impossible to ensure protection against indirect effects and secondary poisoning at Community level by EQS for surface water alone. It is therefore appropriate to establish EQS for biota at Community level for these three substances. In order to allow Member States flexibility in their monitoring strategy, they should be able either to monitor and apply EQS for biota, or to establish stricter EQS for surface water providing the same level of protection.

Furthermore, Member States should have the possibility to establish EQS (for the existing 33 priority substances + 8 certain other pollutants) for sediment and/or biota at national level and apply those EQS instead of the EQS for water set out in the Directive. Such EQS should be established through a transparent procedure, involving notifications to the Commission and other Member States, so as to ensure a level of protection equivalent to the EQS for water established at Community level. Moreover, sediment and biota remain important matrices for the monitoring of certain substances with significant potential for accumulation. In order to assess long-term impacts of anthropogenic activity and trends, Member States should take measures, subject to Article 3(3) of the EQS Directive, with the aim of ensuring that existing levels of contamination in biota and sediment will not significantly increase.

Article 3 of Directive 2008/105/EC states that:

“2. Member States may opt to apply EQS for sediment and/or biota instead of those laid down in Part A of Annex I in certain categories of surface water. Member States that apply this option shall:

a) apply, for mercury and its compounds, an EQS of 20 µg/kg, and/or for hexachlorobenzene, an EQS of 10 µg/kg, and/or for hexachlorobutadiene, an EQS of 55 µg/kg, these EQS being for prey tissue (wet weight), choosing the most appropriate indicator from among fish, molluscs, crustaceans and other biota;

b) establish and apply EQS other than those mentioned in point (a) for sediment and/or biota for specified substances. These EQS shall offer at least the same level of protection as the EQS for water set out in Part A of Annex I;

c) determine, for the substances mentioned in points (a) and (b), the frequency of monitoring in biota and/or sediment. However, monitoring shall take place at least once every year, unless technical knowledge and expert judgment justify another interval; and

d) notify the Commission and other Member States, through the Committee referred to in Article 21 of Directive 2000/60/EC, of the substances for which EQS have been established in accordance with point (b), the reasons and basis for using this approach, the alternative EQS established, including the data and the methodology by which alternative EQS were *derived, the categories of surface water to which they would apply, and the frequency of monitoring planned, together with the justification for that frequency"*

e) *and that:*

"3. Member States shall arrange for the long-term trend analysis of concentrations of those priority substances listed in Part A of Annex I that tend to accumulate in sediment and/or biota, giving particular consideration to substances numbers 2, 5, 6, 7, 12, 15, 16, 17, 18, 20, 21, 26, 28 and 30, on the basis of monitoring of water status carried out in accordance with Article 8 of Directive 2000/60/EC. They shall take measures aimed at ensuring, subject to Article 4 of Directive 2000/60/EC that such concentrations do not significantly increase in sediment and/or relevant biota.

Member States shall determine the frequency of monitoring in sediment and/or biota so as to provide sufficient data for a reliable long-term trend analysis. As a guideline, monitoring should take place every three years, unless technical knowledge and expert judgment justify another interval"

Furthermore monitoring of sediment and biota can also be used to describe the general contaminant status, and supply reference values for local and regional monitoring. Analyses of sediment and/or biota can be a cost-effective approach for initial screening of areas for contamination, to compare contaminant concentrations in different areas and to identify possible sources of contaminants. In using sediment and biota as a first level screening for certain chemicals in the monitoring programme, water measurements may be downscaled. The initial screening will help to identify areas of concern and areas where additional effort is needed, such as increased intensity of sediment, biota, or water monitoring or direct measurements.

1.2. Aim and structure of the guidance

This guidance document addresses the different requirements for compliance checking and temporal trend monitoring for biota and sediment, taking into account the obligations of the EQS Directive. The recommendations included in the guidance take into account current scientific knowledge and they should allow a harmonised implementation of sediment and biota monitoring across Europe.

The recommendations given in this guidance are addressed to surveillance, operational and investigative monitoring and should be applied to the current list of Priority Substances (33) + 8 other pollutants, and to specific river basin pollutants which tend to accumulate in sediment or biota.

Chapter 3 gives recommendations for the matrix selection for the monitoring of chemical pollutants in different water bodies

There are some general parts of the monitoring strategy that are similar to sediment and biota, for example the application of the QA/QC Directive (Commission Directive 2009/90/EC); these issues are addressed in Chapter 4 of the guidance.

For compliance checking against EQS values, harmonisation of the different tools of monitoring programmes is needed: e.g. site selection, sampling strategy, selection of species (for biota), choice of analytical methods. These aspects are described in Chapter 5 for sediment and in Chapter 6 for biota.

Chapters 4, 5 and 6 contain also general recommendations:

- to assess compliance with the no deterioration objective of the WFD;

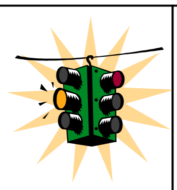
- to assess long-term changes in natural conditions and to assess the long-term changes resulting from widespread anthropogenic activities.

The assessment of the long-term impacts of anthropogenic activities includes the determination of the extent and rate of changes in concentrations of environmental contaminants.

Chapter 7 describes complementary methods for monitoring.

The guidance has been harmonised with the technical guidance document on EQS derivation (TDG-EQS) that is in course of publication [EC, 2010].

Since the WFD also covers the protection of transitional, coastal marine and territorial waters for chemical status, thus this guidance includes specific recommendations on these types of water categories



Look out!

The guidance for chemical sediment and biota monitoring will have to be adapted to regional and local circumstances.

1.3. Guidance documents for chemical monitoring

The Common Implementation Strategy of the Water Framework Directive entails the development of guidance documents in relation to the implementation of this directive. The guidance documents have been created to meet the request of Member States for further documentation of technical details important for harmonised implementation of environmental monitoring. The aim of these types of documents is to give further detail and thus facilitate the implementation of the WFD in the Member States, while also enhancing the degree of harmonisation, taking into account best available techniques, standard procedures and common practices.

Look in:
CIRCA public document library – guidance documents

http://circa.europa.eu/Public/irc/env/wfd/library?l=/framework_directive/guidance_documents&vm=detailed&sb=Title

Relevant for the purpose of the present guidance document is Guidance Document No. 19 [EC, 2009] prepared by the Chemical Monitoring Activity Expert Group. Guidance Document No.19 provides recommendations on the strategy for matrix selection and analytical aspects for analysis of water, sediments and biota under the WFD.

Thus both guidance documents are closely related and should be consulted together.

Another useful document will be the TGD-EQS in course of publication [EC, 2010] in which there is described the methodology for the derivation of EQS in water, sediment and biota.

Moreover, it is worth mentioning CIS Guidance Document No. 7 [EC, 2003], which contains general aspects of monitoring requirements under the WFD and CIS Guidance Document No. 15 [EC, 2007] which provides specific recommendations for groundwater monitoring.

Other useful guidelines relevant in the field of sediment and biota monitoring have been published in the context of OSPAR, HELCOM, MedPol Conventions and SedNet

2. TERMS AND DEFINITIONS

Selected terms and definitions of specific importance for chemical monitoring under the WFD are listed here. All other terms already agreed upon and defined elsewhere in the WFD and associated documents are used without amendment, but are not listed.

Analysis of covariance: (ANCOVA) is a general linear model with one continuous outcome variable (quantitative) and one or more factor variables (qualitative). ANCOVA is a merger of ANOVA and regression for continuous variables. ANCOVA tests whether certain factors have an effect on the outcome variable after removing the variance for which quantitative predictors (covariates) account. The inclusion of covariates can increase statistical power because it accounts for some of the variability.

Analysis of variance: (ANOVA) is a collection of statistical models, and their associated procedures, in which the observed variance is partitioned into components due to different explanatory variables. In its simplest form ANOVA gives a statistical test of whether the means of several groups are all equal, and therefore generalizes Student's two-sample t-test to more than two groups. ANOVAs are helpful because they possess a certain advantage over a two-sample t-test. Doing multiple two-sample t-tests would result in a largely increased chance of committing a Type I error. For this reason, ANOVAs are useful in comparing three or more means.

Bioaccumulation Factor: (BAF) See EQS guidance 2010.

Bioconcentration Factor: (BCF) See EQS guidance 2010.

Certified reference material: (CRM) reference material characterized by a metrologically valid procedure for one or more specified properties, accompanied by a certificate that provides the value of the specified property, its associated uncertainty, and a statement of metrological traceability.
[ISO Guide 35:2006]

Composite sample: two or more samples or subsamples mixed together in appropriate proportions, from which the average result of a designed characteristic may be derived from the same stratum or at the same sediment thickness. The sample components are taken and pre-treated with the same equipment and under the same conditions.

Two or more increments or sub-samples mixed together in appropriate proportions, either discretely or continuously (blended composite sample), from which the average value of a desired characteristic may be obtained.

[ISO 5667-12:1995 Water quality – Sampling - Part 12: Guidance on sampling of bottom sediments ISO 11074 2:1998].

Environmental specimen banking: ESB may be defined as the storage, under appropriate conditions, of material from which information about the state of the environment may be obtained afterwards.

Grab sample: samples taken of a homogeneous material, usually water, in a single vessel. Filling a clean bottle with river water is a very common example. Grab samples provide a good snap-shot view of the quality of the sampled environment at the point of sampling and at the time of sampling. Without additional monitoring, the results cannot be extrapolated to other times or to other parts of the river, lake or ground-water.

Lentic: refers to standing or still water. It is derived from the Latin *lentus*, which means sluggish. Lentic ecosystems can be compared with lotic ecosystems, which involve flowing terrestrial waters such as rivers and streams. Together, these two fields form the more general study area of freshwater or aquatic ecology.

Limit of detection: (LOD) means the output signal or concentration value above which it can be affirmed, with a stated level of confidence that a sample is different from a blank sample containing no determinand of interest.
[Commission Directive 2009/90/EC]

Limit of quantification: (LOQ) means a stated multiple of the limit of detection at a concentration of the determinand that can reasonably be determined with an acceptable level of accuracy and precision. The limit of quantification can be calculated using an appropriate standard or sample, and may be obtained from the lowest calibration point on the calibration curve, excluding the blank.
[Commission Directive 2009/90/EC]

Lotic: refers to flowing water, from the Latin *lotus*, past participle of *lavere*, to wash. Lotic ecosystems can be contrasted with lentic ecosystems, which involve relatively still terrestrial waters such as lakes and ponds. Together, these two fields form the more general study area of freshwater or aquatic ecology.

Octanol-water partition coefficient: (k_{ow}) indicates hydrophobicity of a chemical substance.

Quality: all the features and characteristics of a measurement result that bear on its ability to satisfy given requirements of quality.
[EN 14996:2006]

Quality assurance: all those planned and systematic actions necessary to provide adequate confidence that a product will satisfy given requirements of quality.
NOTE This include AQC, audit, training, documentation of methods, calibration schedule, etc.
[EN 14996:2006]

Quality control: operational techniques and activities that are used to fulfil requirements for quality.
[EN 14996:2006]

Random sampling: form of sampling whereby the chances of obtaining different concentration values of a determinand are precisely those defined by the probability distribution of the determinand in question.
[ISO 5667- 6:2005 Water quality-Sampling- Part 6 Guidance on sampling of rivers and streams]

Reference material: (RM) material, sufficiently homogeneous and stable with respect to one or more specified properties, which has been established to be fit for its intended use in a measurement process.
[ISO Guide 35:2006]

Sample: a limited quantity of something which is intended to be similar to and represent a larger amount of that thing(s).

Sampling frequency: Sampling frequency defines the number of samples per second (or per other unit) taken from a continuous signal to make a discrete signal.

Sampling point: precise position within a sampling site from which samples are taken.

[ISO 5667- 6:2005 Water quality-Sampling- Part 6 Guidance on sampling of rivers and streams. Modified definition]

Sampling station: a well delimited area, where sampling operations take place.
[IUPAC 2005 *Pure and Applied Chemistry* 77, 827–841]

Sampling strategy: The result of the selection of the sampling points within a sampling site.
[IUPAC 2005 *Pure and Applied Chemistry* 77, 827–841]

Soil adsorption coefficient: (koc) Soil adsorption coefficient normalised by soil organic carbon content. Usually measured for environmental chemicals according to OECD Test guideline 106.

Statistical sampling: sampling whereby the samples are taken at predetermined intervals (in space or time).
[ISO 5667- 6:2005 Water quality-Sampling- Part 6 Guidance on sampling of rivers and streams. Modified definition]

Test portion: The amount or volume of the test sample taken for analysis, usually of known weight or volume.

Uncertainty of measurement: a non-negative parameter characterizing the dispersion of the quantity values being attributed to a measurand, based on the information used.
[Directive 90/2009/EC]

Uncertainty arising from sampling: The part of the total measurement uncertainty attributable to sampling.
[EURACHEM/CITAC:2007 Measurement uncertainty arising from sampling: A guide to methods and approaches]

List of abbreviations

HELCOM	The Baltic Marine Protection Commission also called Helsinki Commission.
OSPAR	The Convention for the Protection of the Marine Environment of the North-East Atlantic or OSPAR Convention.
MEDPOL	The Med Pol Programme (the marine pollution assessment and control component of MAP) is responsible for the follow up work related to the implementation of the LBS Protocol, the Protocol for the Protection of the Mediterranean Sea against Pollution from Land-Based Sources and Activities (1980, as amended in 1996), and of the dumping and Hazardous Wastes Protocols.
SEDNET	European network aimed at incorporating sediment issues and knowledge into European strategies to support the achievement of a good environmental status and to develop new tools for sediment management.

3. COMPOUND AND MATRIX SELECTION FOR SEDIMENT AND BIOTA MONITORING

3.1. Introduction

The WFD classification of the chemical status of a water body is based on compliance with EQS. Directive 2008/105/CE sets the environmental quality standards for 41 substances in the water matrix, but also gives an option to the Member States to derive EQS for sediment and/or biota. The frequency of monitoring of priority substances in the water column (whole water or dissolved) differs from those in sediment and biota and it is clear that the choice of the matrix to be monitored will be strategic in terms of costs and resources for compliance checking. The minimum frequency required for water monitoring of priority substances is once per month (once every 3 months for river-basin-specific pollutants), but for sediment and biota the monitoring frequency can be once per year unless technical knowledge and expert judgement justify another interval.

The main aim of the WFD is the achievement of good chemical status for all water bodies, but, Member States can decide the matrix for certain substances.

For instance, sediment is a recommended matrix for the assessment of chemical status for some metals and hydrophobic compounds in marine and lentic water bodies. In dynamic lotic water bodies, however, sediments do not often provide an appropriate matrix for compliance checking because of high variability. Furthermore, in such water bodies, sediments can either be too perturbed to be representative or in some cases absent. In these cases this assessment could be made by measurement of the concentrations in suspended solid matter (SPM). In large lowland rivers, freshly deposited sediment collected by sedimentation traps can be used instead of SPM. In the latter case the equivalence between SPM and freshly deposited sediment must be verified.

For the purpose of trend monitoring, sediment, or alternatively SPM, and biota are the most suitable matrices for many substances because they integrate, in time and space, the pollution in a specific water body; the changes of pollution in these compartments are not as fast as in the water column and long-term comparisons can be made. Directive 2008/105/EC gives an indication of the substances that should be taken into consideration for trend monitoring as well as for the frequency of monitoring of those substances.

3.2. Physico-chemical properties of chemical pollutants

The choice of the matrix to be monitored depends firstly on the physico-chemical properties of the substances. The priority list of the WFD contains several (classes of) substances which have a low solubility in water, a corresponding high octanol/water partition coefficient (log K_{OW}; see Table 1) and a high potential for bioaccumulation and bioconcentration.

Look in:
Directive 2008/105/EC

Art 3, paragraph 3: Member States shall arrange for the long-term trend analysis of concentrations of those priority substances listed in Part A of Annex 1 that tend to accumulate in sediment and/or biota, giving particular consideration to substances numbers 2, 5, 6, 7, 12, 15, 16, 17, 18, 20, 21, 26, 28 and 30, on the basis of monitoring of water status carried out in accordance with Article 8 of Directive 2000/60/EC. They shall take measures aimed at ensuring, subject to Article 4 of Directive 2000/60/EC, that such concentrations do not significantly increase in sediment and/or relevant biota.

3.3. Selection of compounds to be monitored in sediment

The prime criterion for the selection of organic compounds to be monitored in sediments is their physico-chemical preference for the solid phase, i.e. a poorly soluble character in water. The more hydrophobic (water repulsing) a compound is, the less soluble it is in water, and therefore more likely to adsorb to sediment particles. A simple measure of the hydrophobicity of an organic compound is the octanol–water partition coefficient (K_{ow}), which is a good predictor of the partitioning potential of the contaminant in the organic fraction of the sediment (K_{oc}).

As a rule of thumb, compounds with a log K_{ow}>5 should *preferably* be measured in sediments, or in suspended particulate matter (SPM), while compounds with a log K_{ow}<3 should preferably be measured in water. For instance, HCB (hexachlorobenzene; log K_{OW}=5.7) should not be preferably monitored in water, but in sediment or in suspended particulate matter, because of its preference to adsorb to sediment particles (i.e. organic carbon).

Atrazine, on the other hand, with a log K_{OW}~2.5, should be monitored in water and not in sediment, due to its high water solubility.

For compounds with a log K_{ow} between 3 and 5, the sediment matrix or suspended particulate matter is *optional* and will depend on the degree of contamination. If the degree of contamination for a hydrophobic compound is unknown or expected to be low, sediment should be an additional monitoring matrix (due to accumulation).

3.4. Selection of compounds to be monitored in biota

The prime criterion for the selection of compounds to be monitored in biota is their physico-chemical preference for this matrix (e.g. various metals and lipophilic compounds); the metabolisation and depuration efficiency of the different species should also be taken into consideration for biota monitoring (see Chapter 6).

According to the monitoring programmes and plenty of scientific studies, the most common substances analysed in marine biota are organochlorinated compounds (especially PCBs, DDT and its metabolites and organochlorinated pesticides), PAHs (only in mussels because they are partially metabolised in fishes), TBT, and trace metals that tend to accumulate.

3.4.1. Organic compounds

For organic substances, monitoring in biota should be performed when the biomagnification factor (BMF) is >1 or when the bioconcentration factor (BCF) is >100; if no valid measured BMF or BCF (BAF) is available, a log K_{ow}>3 can be considered as an indicator for bioaccumulation potential.

The BMF is the ratio of the concentration of a substance in an organism compared to the concentration in food (prey) items. The BCF is the ratio of the concentration of a substance in an organism to the concentration in water.

It should also be ensured that there is no mitigating property such as rapid degradation (ready biodegradability or hydrolysis half-life <12h at pH 5-9, 20°C). If this is the case, then biota monitoring is not recommended. Information on molecular size can be an indicator of limited bioaccumulation potential of a substance, as very bulky molecules will pass less easily through cell membranes.

3.4.2. Metals

Biomagnification of metals in aquatic organisms is rarely observed and, if it does occur, it usually involves the organo-metallic forms of metals (e.g. methylmercury); a lack of biomagnification should not be interpreted as a lack of exposure or an absence of concern for trophic transfer. Even in the absence of biomagnification, aquatic organisms can bioaccumulate relatively large amounts of metals and this can become a significant source of dietary metal to their predators.

For metals, a BCF should not be used; this is because the model of hydrophobic partitioning, giving a more or less constant ratio C_{biota}/C_{water} with varying external concentration, (does not apply to metals). Further indications for metals are included in the TGD-EQS [EC, 2010].

3.5. Criteria for matrix selection

Based on the rule of thumb mentioned above, a distinction has been made between *preferred* (P), *optional (O)* and *not* recommended *(N)* matrices for the monitoring of priority substances in Table 1.

- Preferred (P): Monitoring should be performed in this matrix.
- Optional (O): Monitoring can be performed in this matrix, but also in other compartments/matrices; the choice will also be made on the basis of the degree of contamination of a particular matrix.
- Not recommended (N): Monitoring in this matrix is not recommended unless there is evidence of the possibility of accumulation of the compound in this matrix.

For metals, because of the high variability of these compounds, this distinction cannot be made except when they are in the form of organometals (e.g. methylmercury).

In some cases, sediment and biota are both preferred matrices and the choice should be made on the basis of local contamination and on the basis of the EQS derived.

These criteria are not mandatory and Member States can choose the appropriate matrix on the basis of their knowledge, provided they keep in mind the indications of Directive 2008/105/EC.

Table 1 Monitoring matrices for the priority substances and certain other pollutants listed by the EQS Directive

The substances in red are those suggested by Directive 2008/105/EC for sediment and biota trend monitoring. The values of the log K_{OW} are taken from the Chemical Monitoring Guidance n.19. The values of BCF are taken from the datasheets of the priority substances in the public section of the CIRCA forum (http://circa.europa.eu/Public/irc/env/wfd/library?l=/framework_directive/i-priority_substances/supporting_background/substance_sheets&vm=detailed&sb=Title).

P = preferred matrix, O = optional matrix., N = not recommended, n.a. = not applicable

Priority Substance	*BCF*	*Log K_{OW}*	*Water*	*Sediment/SPM*	*Biota*

[a] *Including Bis(pentabromophenyl)ether, octabromo derivate and pentabromo derivate*
[b] *HCH (all isomers) - BCF (lindane)*
[c] *methylmercury*
[d] *Nonyl- and Octylphenols do not follow the classical K_{ow} partition, because they can establish hydrogen bonds by the phenolic hydroxyl.*
[e] *Including Benzo(a)pyrene, Benzo(b)fluoranthene, Benzo(g,h,i)perylene, Benzo(k)fluoranthene, Indeno(1,2,3-cd)-pyrene. For these compounds the metabolisation in higher trophic levels should be taken into account.*

4. SAMPLING STRATEGY: GENERAL REQUIREMENTS AND COMMON ASPECTS OF SEDIMENT AND BIOTA MONITORING

The main purpose of any measurement is to enable decisions to be made. Fitness for purpose is therefore the most important requirement of any sampling strategy. The fitness for purpose of a sampling design, however, can only be judged from reliable estimates of its uncertainty and its impact on the monitoring objectives. Current practice in the estimation of uncertainty in environmental monitoring follows the general principles set out in the "*Guide to Expression of Uncertainty in Measurement*" [ISO 1993] whose underlying philosophy has been endorsed in all standardisation documents issued by International and National Standardisation bodies. The notion of "uncertainty" is closely related to other concepts of measurements such as "accuracy", "error", trueness, bias and precision [EURACHEM, 1995]. In this context the following important differences are to be recalled [EURACHEM, 2007]:

- Uncertainty is a range of values attributable on the basis of a measurement result and other known effects, whereas "error" is a single difference between a result and "true value".
- Uncertainty includes allowances for all effects that may influence results (i.e. both random and systematic errors); precision only includes the effects that vary during the observations (i.e. only some random errors).
- Uncertainty is valid for correct application of measurement and sampling procedures, but it is not intended to make allowances for gross operator errors.

It is therefore apparent that the act of taking a sample introduces uncertainty into a measurement result. In addition, sampling protocols are never perfect, as they cannot anticipate every possible eventuality at the moment of sampling.

In the context of this guidance, the main sources of uncertainty related to sediment and biota monitoring are the natural spatial and temporal variability within the sampling site (or population) as well as the measurement process including the act of sampling, sub-sequent steps of sample pre-treatment and storage until the actual measurement. Natural variability and the act of sampling itself are certainly the most important and least controllable contributors.

While sampling and measurement can be assessed to a certain degree using classical tools for quality control and measurements such as field blanks, reference materials, intercomparisons and so forth, the influence of the natural variability can only be dealt with if sufficient information on the system is available in the planning phase of a monitoring programme. The higher the complexity or heterogeneity of the studied water body, the higher the number of samples to be investigated and hence the more expensive the monitoring becomes.

In this context the proper definition of the scope and objectives of the monitoring programme are of pivotal importance, because they are crucial factors to define the sampling site, frequency, duration and methodology, including sample pre-treatment and subsequent measurements and tests. A leitmotif is that the monitoring should be designed in such a way that possible errors occurring during sampling and measurement can be statistically detected.

A preliminary or exploratory sampling programme can be useful to provide relevant information for designing the final sampling programme. In exploratory studies, data may be statistically analysed in several ways for several purposes. However there should still be a clear understanding of what must be measured from what population and how the samples are to be selected. The sampling strategy is an intrinsic component of the data, and may limit their use and interpretation.

Quantitative objectives for a selected primary purpose should therefore also be established for exploratory studies.

4.1. Statistical considerations

CIS WFD Guidance Documents No. 7 [EC, 2003] and No. 19 [EC, 2009] already give some general indications with regard to underlying statistical principles. It is not simple to decide frequency, number and time periods of sampling during the planning of the monitoring program without the aforementioned preliminary/exploratory campaign. But, it is clear that in the course of a monitoring programme further adaptation may be necessary.

Although sediment and biota are less influenced by fast changes in water quality, they are subject to random or systematic/seasonal variations. This needs to be considered, too. The derived statistical parameters such as the mean value, standard deviation, highest observed value or percentiles can only be estimates of the “true value”, which usually deviates from these data. In the case of randomly distributed values, which follow a normal or log-normal distribution, estimates become more reliable with an increased number of repetitions.

In case of systematic (e.g. cyclic) variations of the system under investigation, the choice of the sampling time is crucial in order to either capture the entire cycle or to cover maximum and minimum values.

4.1.1. Quantitative objectives

As mentioned above, a proper definition of the monitoring objectives is vital. For a correct estimate of frequency, length of time series, density of sampling grid, etc., a quantification of the objectives is necessary. In this context one may distinguish between two types of monitoring studies, which however frequently overlap in reality:

- temporal monitoring studies, aiming at the detection of temporal trends in the investigated matrix. Since sediment and biota are generally buffered in their reaction time to chemical stress (if compared to the water column), longer time series in general covering several years are needed to detect significant changes;

- spatial monitoring studies, aiming at the identification of spatial distribution pattern and anomalies. With sediment and biota monitoring being less subject to short-term variability, normal distribution may be assumed.

The ISO Standard 5667-1:2006 [ISO, 2006] gives appropriate indications on how to determine the necessary number of samples for the various purposes of monitoring. Some recommendations from this standard set are worth mentioning here:

- while random variations usually follow a normal or log-normal distribution, systematic variations are either following trends or cyclic patterns or a combination of both;

- the predominant type of variation (random vs. systematic) may vary for the same matrix for different compounds;

- if random variations are predominant (see preliminary investigations), the moment of sampling is less important;

- if cyclic variations are predominant, a systematic and regular sampling pattern is to be preferred;

- in case of doubt, random stratified sampling is the best compromise. In any case statistical considerations should be at the basis of decisions concerning the number of samples to be taken.

For normal distributions, the confidence interval *L* of the mean value of *n* results at probability of *K* can be calculated as:

$$L = \frac{2 \cdot K \cdot c}{\sqrt{n}}$$, with being the standard deviation of the distribution

Example: With a *confidence interval* of 10% around the mean value, a *confidence level* of 95% and a *standard deviation* of 10%, the *number of samples* to be taken is calculated as: $10 = \frac{2 \cdot 1.96 \cdot 20}{\sqrt{n}}$, hence *n* = 61 Samples. This is translated for instance into the sampling of 1 to 2 samples per week, if the monitoring period is one year.

The careful definition and description of the objectives of the monitoring study includes:

- the choice of the sampling matrices with a strict definition of the sampling units and a description of what they represent in time and space (this description is a prerequisite for an appropriate interpretation of the results);

- the definition of the required sensitivity of the programme, i.e. the smallest change to be detected for temporal studies or smallest difference between areas for geographical studies;

- the definition of the statistical power to detect such a difference at a specified significance level.

The definition of the sensitivity and statistical power of the programme is essential in order to properly estimate, for example, the number of samples per sampling occasion, length of the time-series, sampling frequency etc., required for the investigation. This power will decrease as sources of variance (analytical variance, natural environmental variance) increase.

As a consequence, in order to calculate, for example, the number of samples and the sampling frequency required to fulfil those objectives, an estimate of the sample variance is needed. Expected variance estimates could, perhaps, be extracted from similar ongoing monitoring programmes or, what is more reliable, be assessed from a pilot project using the same sampling strategy, sampling matrices etc., as the currently planned monitoring programme.

The necessary or possible power of a monitoring programme will vary with the purpose of the investigation and with the contaminant, matrix and area being investigated. It is thus not possible to give fixed values for all situations. It is the duty of the programme manager to specify the size of the changes the monitoring programme is expected to identify and at what power, or for those implementing the programme to estimate what it is possible to achieve. It is, however, essential that the quantitative objectives are determined before any monitoring programme is started.

A quantified objective for temporal studies could, for example, be stated as follows:

- *To detect a 50% decrease within a time period of 10 years with a statistical power of 80% at a significance level of 5%.* (A 50% decrease within a time period of 10 years corresponds to an annual decrease of about 7%).

And for spatial studies, for example as follows:

- *To detect* differences *of a factor 2 between sites with a power of 80% at a significance level of 5%.*

A significance level of 5% means that we are prepared to accept a risk of 5% to conclude from our data that there is a trend or difference when there actually is not. Similarly, a power of 80% means that we accept a risk of 20% to conclude that there is no trend or difference when there really is one. Statistical power and methods to estimate power are discussed in detail in Cohen [1988].

In the case of temporal monitoring studies, if no trend is found, it is essential to know whether this reflects a stable situation or indicates that the sampling strategy is too poor to detect even major changes in the contaminant load to the environment. One approach to solving this problem would be to estimate the power of the time series based on the 'random' between-year variation. Alternatively the lowest detectable trend could be estimated at a fixed power to represent the sensitiveness of the time series. It should be stressed that the power estimate must be interpreted with great caution. A matrix showing a very high power is not necessarily a good matrix for monitoring. If the matrix analysed does not respond to the environmental changes being monitored, the between-year variation would probably be low and consequently the power high. Another problem is that a single outlier could ruin an estimate of the between-year variation. Bearing these difficulties in mind, and as an example for the purpose of trend monitoring, the quantified objective could be stated as follows:

- to detect an annual change of 5% within a time period of 10 years with a power of 90% at a significance level ( ) of 5% with a one-sided test.

It has to be stressed though, that statistically significant trends do not guarantee that detected temporal trends are a result of a causal relation between concentration and time. If the samples are biased or not comparable over time, or if relevant confounding co-variants are not accounted for, "false-trends" may occur.

The statistical assessment of trends also always requires experts whose experience allows them to undertake a more accurate evaluation of the analysis results.

4.1.2. Representativity

4.1.2.1. The sample matrix

A first important aspect is the representativity of the sampling matrix in relation to the contaminant load and exposure at the studied monitoring site. It is therefore essential to describe very clearly what the suggested sampling matrices represent in terms of contaminant load or exposure. In addition to factors such as availability, sampling costs etc., it would be useful to provide additional information on, for example, concentration factors, bioaccumulation rates, metabolic capacity and, for biota, excretion rates.. Various tissues within the same species vary considerably with respect to the above-mentioned factors i.e. they may represent totally different ranges of time and space. They may also react to changes in the environment very differently.

Similar considerations apply when considering the use of sediment as a monitoring matrix. The concentrations of both organic and inorganic contaminants in sediment are very dependent upon the bulk properties (e.g. particle size distribution, and organic carbon content) of the sediment. Concentrations are much higher in fine grained sediment than in the sand or coarser fractions. A spatial survey of contaminant concentrations in sediment is often very strongly influenced by the spatial distribution of muddy sediment. Normalisation techniques have been developed to minimise the influence of differences in bulk composition between sediment samples and to reduce the potential for "false trends" in temporal data series arising from changes in bulk composition unrelated to contaminant inputs. The application of normalisation techniques needs to be planned as part of the preparation of samples prior to analysis, or to ensure that the appropriate determinands for normalisation are included in the suite of analytes.

4.1.2.2. Spatial representativity

A second aspect to be considered is the representativity of the sample in relation to the spatial variability of the sampling site. Questions such as: "*How many sampling sites do we need in order to appropriately represent a region?"* will inevitably be raised when monitoring contaminants. Any firm advice from a statistical point of view needs estimates on spatial heterogeneity. For spatial studies the objectives have to be clearly specified (e.g. spatial trends, differences between regions etc) and made quantitative.

A variogram may be used to describe the spatial correlation structure [Cressie, 1993; Davis, 1986]. Normalisation processes to reduce between-sample variance should be applied to field data before such a variogram is constructed, particularly for analyses of sediment.

In practice, such variograms are not available or may not be available for all monitoring areas, and some pragmatic approach, based on prior experience may be necessary. This emphasises the need obtain useful information from preliminary monitoring.

4.2. Data analysis

Data must be expressed as mean values and standard deviation, reporting also the number of analysed samples (*n*) and the range of measured values. This information should be complemented by additional information of possible relevance to the context of the monitoring (percentiles, trend analyses, etc.)

In any case data analysis should be performed in a transparent way with appropriate statistical methods to reveal and compare status and trends at local, regional, national and European scales.

Differences between periods and or sites can be tested by one- or two-way analysis of variance (ANOVA) or by multivariate methods such as cluster analyses (CA), principal component analyses (PCA) or positive matrix factorisation (PMF). Multiple Pearson correlations can reveal significant relationships between chemicals and co-linearity of regressions can be tested by covariance analyses (ANCOVA). Chemical concentrations trends can also be assessed by correlating their variations with time and Spearman's rank correlation used to assess their predictable co-variance; the Spearman's rank correlation statistical test has been widely applied to evaluate individual contaminants at site, regional and national scales.

4.2.1. Method used for trend analysis of time series

The main goal of trend analysis is to test objectively whether there is a meaningful systematic change in the time series, assessed against some measure of the random noise in the observations. The output from this component will usually be the probability that the test statistic of the method used could have arisen by chance when there is no trend. If this is less than some pre-specified value (e.g. 5 %), the result is considered to be significant, that is: the null hypothesis of no trend is rejected. What constitutes a meaningful change will depend on the objectives of the assessment, and is a major consideration in the choice of method as discussed in section 4.1.1.

For the trend assessment the following four separate but complementary components are identified:

1. graphical presentation of the time series with a summary line to indicate the general trend, presenting time series grouped by region, by substance, or by originating country, could provide a further opportunity to identify common trends, or common data anomalies, e.g., a consistent extreme value in a given year;

2. a formal test of trend, with trend defined in an appropriate way for the context of the assessment;

3. a quantification of the tendency to increase or decrease;

4. a power analysis which reflects the detectability of a possible trend.

The statistical method used to assess trends should be:

- robust, i.e., both routinely applicable to many data sets, and as insensitive as possible to statistical assumptions (e.g. Normal distribution) and problematic numerical features such as extreme data values, partial bulking of samples, and values less than LOD;

- intuitive, i.e., for the results of the analysis to be understandable without a detailed understanding of statistical theory;

- revealing i.e. to provide easy access to several layers of information about the major features of the data-both those of direct interest, such as evidence of simple trends, and the more negative features, such as missing years, years with all results below the limit of detection, extreme values, and so on.

In the context of trend assessment the method should be sensitive to the kinds of changes that are of concern in the assessment. Not all tests are equally effective at detecting all patterns of change. For a very focused test, this may be a disadvantage if all patterns of change are of interest, or an advantage if the focus is on patterns of interest. Three groupings of patterns of change may be considered to be of interest:

1. linear trend,

2. monotonic non linear trends,

3. non-monotonic trends.

Hence, if the purpose of the assessment is to detect monotonic trends and it has to be robust in the sense that it is unaffected by isolated extreme values, the Mann-Kendall test would be appropriate. If the purpose is to detect all trends, then the choice is between the compound Mann-Kendall test and the smoothers, with a final decision depending on the weight given to the other factors.

The statistical procedures currently used by OSPAR for trend detection in Northern seas are described in the “CEMP Assessment Manual for contaminants in sediment and biota”. [OSPAR, 2008]. The method used by OSPAR involves the use of a weighted smoother, and assessment for significant linear and non-linear trends. Fitting a weighted smoother is straightforward if the statistical weights are known beforehand. The statistical weights should be inversely related to the total environmental and analytical variance each year. Appropriate methods for estimating them will depend on the QA information available.

The weighting is a function of the performance of the laboratories in annual external Quality Assurance schemes (Laboratory Performance Studies). In the absence of external QA performance data the data points are all given equal weight.

For a mixture of theoretical and practical reasons, the OSPAR Commission found it appropriate to adopt three different *approaches to data analysis, based upon the length of the available time series:*

- 3-4 years compute the average of the median log-concentrations.
- 5-6 years fit a linear regression to the median log-concentrations and test the significance of the linear trend.
- >6 years fit a smoother to the median log-concentrations and test its significance, followed by tests of the significance of the components of linear and non-linear trend.

Although a linear regression model could have been fitted to data for 3 or 4 years, the power of this test would be low. Further*, where significant trends did occur, they would be more likely to reflect short-term trends than long-term changes. For these reasons, a simple summary of the average level was thought to be more useful. Similarly, it seems inappropriate to attempt to describe non-linear trends in time series with fewer than 6 years.*

Essentially, for each dataset with data for 6 or more years, the method is to summarise trends using a smoother; a non-parametric curve fitted to median log-concentrations. This summary is supported by a formal statistical test of the significance of the fitted smoother, and by tests of the linear and non-linear components of the trend.

Few statistical assumptions are required for the fitted smoother to be valid. Mainly, the annual contaminant indices should be independent with a constant level of variability. For the statistical tests to be valid, there is a further assumption that the residuals from the fitted model should be lognormally distributed. The theory and methodology are described in detail in Nicholson et al. [1998].

4.3. Quality Assurance/Quality Control

The quality and comparability of analytical results generated by laboratories appointed by competent authorities of the Member States to perform sediment and biota chemical monitoring pursuant to Article 8 of Directive 2000/60/EC should be ensured.

Commission Directive 2009/90/EC represents the legal basis for the performance of the analytical methods and gives technical specifications for chemical monitoring. Based on the requirements of this directive, the application of internal and external quality control measures, such as the use of blanks, standards, (certified) reference materials or regular participation in laboratory inter-comparison, is strongly recommended.

Look in:
Commission Directive 2009/90/EC

Article 1

Subject matter

This Directive lays down technical specifications for chemical analysis and monitoring of water status in accordance with Article 8(3) of Directive 2000/60/EC. It establishes minimum performance criteria for methods of analysis to be applied by Member States when monitoring water status, sediment and biota, as well as rules for demonstrating the quality of analytical results.

Article 3

Methods of analysis

Member States shall ensure that all methods of analysis, including laboratory, field and on-line methods, used for the purposes of chemical monitoring programmes carried out under Directive 2000/60/EC are validated and documented in accordance with EN ISO/IEC-17025 standard or other equivalent standards accepted at international level.

Article 4

Minimum performance criteria for methods of analysis

1. Member States shall ensure that the minimum performance criteria for all methods of analysis applied are based on an uncertainty of measurement of 50 % or below (k = 2) estimated at the level of relevant environmental quality standards and a limit of quantification equal or below a value of 30 % of the relevant environmental quality standards.

5. MONITORING OF CHEMICAL SUBSTANCES IN SEDIMENT

5.1. Sampling strategy for chemical monitoring in sediment

General criteria and good practices for sediment sampling strategy are already reported in CIS Guidance Document No. 19 [EC, 2009].

Sampling strategies for sediment monitoring may have two major approaches: a probabilistic design, where sampling points are randomly selected within the sampling site, and a targeted design, where sampling points are selected on the basis of an analysis of pressures and pre-existing knowledge of point sources.

Probabilistic design is more appropriate for diffuse source characterisation, whereas targeted design is better suited for the implementation of the WFD at surveillance, operational and investigative monitoring sites.

In targeted designs, sampling points are selected on the basis of prior knowledge of other factors such as water depth, bottom topography, nature of the sediment (clay, sand, pebbles, peaty), contaminant loading and accessibility.

In general, targeted sampling is appropriate for situations in which:

- the site boundaries are well defined;

- the objective of the investigation is to screen an area for the presence or absence of contamination. In CIS Guidance No. 19 [EC, 2009], section 4.3, it is further stated that "...*areas can be cost-efficiently scanned using sediments and biota to compare contaminant levels in different areas and to identify possible sources of contaminants to the area*". And "*In using sediments and biota as a first level screening for certain chemicals in the monitoring programme, water measurements may be downscaled. The initial screening will help to identify areas of concern and where to direct effort, such as follow up with water samples and direct measurements*.";

- information is desired for a particular condition (e.g., “worst case”) or site;

- schedule or budget limitations preclude the possibility of implementing a statistical design.

For trend analyses, the sampling strategies and the procedures of examination and analyses of sediments should ensure that continuity with pre-existing monitoring programmes is maintained. Any changes should only be made if comparability with long-term data is guaranteed. This also includes continuing to use suspended particulate matter (SPM) or freshly deposited sediments collected by sediment traps or sedimentation boxes as an alternative to sediments for monitoring contaminants in large lowland rivers.

5.1.1. Selection of sediment sampling stations

General criteria for the selection of monitoring sites in WFD monitoring programmes are discussed in CIS Guidance documents No. 7 [EC, 2003] and No. 19 [EC, 2009].

Whatever the water body, sediments should be sampled at sites that are representative of the water body or cluster of water bodies. This requires understanding of the hydrological and geo-morphological characteristics and the pollution sources. This information can be derived from earlier studies, current monitoring programmes or a dedicated preliminary survey.

Sediments are much less temporally variable, but inherently much more heterogeneous than waters. The homogeneity of a sampling area may be checked in a pilot phase by defining one or more transects (according to the area extent), where five sampling points for each transect are selected. In each sampling point, five or more independent surface sediment samples have to be collected. An aliquot for each sample should be analysed after homogenisation and sieving (see Section 5.2.6). The homogeneity can be checked for the between-sample (between sampling points in the transect) and the within-sample (within sampling points) variance, using an Anova/F-test. If the within-sample variance is of the same order as, or even exceeds, the between-sample variance, the whole transect should be considered as a single sampling site.

The areas where homogeneity has thus been checked will serve for the identification of the sampling sites and the number of replicates. Owing to the physical heterogeneity of the sediment, statistical analyses should be carried out on data normalised with respect to the fine fraction (see 5.1.5).

There is no need for even distribution of sampling sites in a water body. In a homogeneous water body, such as a pristine lake, the number of sampling sites may be relatively low. But if gradients are to be expected as a result of changing morphological and/or input conditions, or of areas that are of concern ('hot spots'), a higher number of sampling sites should be defined.

Known point sources, e.g. from present or past industries, need special attention, as they are not representative and may bias the overall evaluation of a given water body. Tributaries often have different water and thus also different suspended matter/sediment characteristics from the receiving river or lake. Receptor water bodies should be sampled downstream of the discharges or the tributary confluence, at a point where complete mixing has been established. According to Art. 4 of Directive 2008/105/EC, mixing zones should be designated by Member States. The Technical Guidance document for the identification of mixing zones under Article 4(4) of the EQS Directive is currently under development.

Net deposition areas with soft sediments characterised by a relatively high amount of fine fraction (the fraction <63 m, consisting of silt and clay) are preferred as sampling sites, whereas areas where sediments contain peat, pebbles or rocks, compacted sediments, or coarse sand should be discouraged. As a rule of thumb, sediments should contain at least 5% fine fraction (<63 µm), information which may have to be obtained from preliminary trial surveys.

Alternatively, especially in the cases of rivers without sediments or with perturbed sediments, SPM and freshly deposited sediment can be used to collect the desired fine fraction. Knowing that deposition of suspended particles from the water column is favoured in areas with relatively low energy in the water (waves, currents), the following general criteria can be provided for the selection of the sampling sites:

- in rivers and transitional waters (estuaries), the currents are highest in the central channel or river bed, in which means that a relatively low amount of fines deposited on the bottom. Higher concentrations of fine-grained deposits are found in areas where the water flow is lower, such as near the side of the river (in concave stretches of the river) and in accumulation areas within estuaries;

- in natural estuaries with complex suspended solids dynamics (i.e. estuaries with settling and erosion zones, tidal flats, etc.), representative sampling is possible only upstream of the tidal limit. In such cases, the sampling site should be located in the non-tidal zone of unidirectional flow (e.g. upstream of a weir);

- in lakes and reservoirs the highest energy dissipation occurs near the inlet of rivers, and on the shores (wave action). The highest concentration of fines may therefore be found away from these sites;

- in coastal waters, areas with high tidal currents must be avoided. Sedimentation areas, such as embayments or areas of relatively deep water, are preferred.

When the final objective is the assessment of a temporal trend in chemicals contamination, a representative number of sites should be selected, giving preference to sites used for surveillance monitoring. The same sampling sites should be used over the years. This requires continued accessibility, and also that the sampling site, and the related sampling points, are well defined by exact geographic coordinates, with the datum point of the reference system also being given. Finally, the site should be large enough to supply multiple samplings if sediment cores are taken.

5.1.2. Number of replicate samples per station

Multiple samples have to be collected at each sampling site in order to estimate factors contributing to the overall variance in the analytical data. It is recommended that three to five samples (independent replicates) are selected at each site.

QA/QC procedures should also cover the sampling phase, as it is part of the overall measurement process. The sampling procedures adopted in routine monitoring of sediments quality should be validated and sampling quality control performed. Validation allows the evaluation of the sampling quality under stated (routine) conditions and provides an estimation of the contribution of sampling to the measurement uncertainty (including the analysis). It can be performed by taking replicate (duplicate) samples (6–10 in the pilot phase) at the same point, differing as little as possible one from the other in terms of space and time. In general, only the random component of uncertainty (repeatability) arising from sampling may be assessed. Replicating the analyses on each duplicate also enables the contribution due to the analytical phase to be evaluated. Pooling of individual samples into one composite sample is not recommended in the pilot phase as this prevents the estimation of field variability, which is an essential parameter for power analysis and trend tests.

Since the potential range of substances to be analysed is wide, the sampling quality performances may be reasonably assessed only for a selected measurand (e.g. metals).

Whatever the sampling quality requirements, the sampling procedure performance may be kept under control during routine sampling activity by applying the same, previously validated, sampling procedure at the same sampling point. Quality control may be performed through the collection of replicate samples, as in the validation, and setting up a quality control chart. Frequency of sampling quality control depends on the extent of the sampling locations and of the planned sampling frequency.

5.1.3. Sediment sampling frequency

As a result of a usually limited sedimentation rate (usually in the range 1–10 mm/y, but larger values occur) and the physical and biological mixing of surface sediments, the composition of sediments generally is usually rather stable in comparison to the concentrations of contaminants in the water column, except for rivers characterised by turbulent flow. As a consequence, sampling of sediments generally requires i a lower frequency than sampling of e.g. surface waters.

Directive 2008/105/EC states that monitoring should be performed at a minimum frequency of once every year for compliance with EQS, and once every three years for temporal trend analysis, unless technical knowledge and expert judgement justify another interval.

Sediment samples should be collected at an appropriate frequency that matches the expected changes in the sediment, taking into account the hydrological regime and the sedimentation rate of the water body studied. Estuaries, rivers and reservoirs, and sometimes lakes, may show large differences in hydrodynamic characteristics over the year. The higher the expected/observed changes, the higher the frequency.

In highly dynamic water bodies such as estuaries, sampling several times per year may be required. However, the application of normalisation techniques (see Sections 5.1.5 and 5.4, below) can greatly reduce the variability arising from changes in the bulk properties of sediment (e.g. changes in particle size distribution arising from changes in water flow regimes).

It is recommended that sampling be undertaken during a period with low current velocities, and the preferred period corresponds to the time of lowest water discharge rate (flow). Moreover, bioturbation is lowest in the winter period. It is recommended to plan the sampling campaigns in the same time window every year, preferably under similar flow conditions.

Special attention should be given to sites significantly affected by changing sediment input, in which water flow and therefore accumulation rates may change seasonally, following, for example, flood events or ice cover. Sampling during or shortly after a flood should be avoided.

If high fluctuation in the concentration of contaminants during the year is measured or expected at selected hot spots, higher frequencies should be adopted.

It might be helpful to distinguish between variations in physics (e.g. high and low run-off periods) which lead to changes in bulk sediment composition (% sand, % mud etc.) and thereby lead to changes in the concentrations of contaminants when looking at the whole sediment, and processes such as seasonality in use of herbicides that lead to changes in pollutants load in sediment. The former should be addressed through normalisation methods, while the latter should be addressed by increasing sampling frequency.

Sediment sampling frequency could be reduced when parameters are demonstrated, by monitoring data and the analysis of pressures, to be significantly below the quality targets or when no significant trend can be observed or expected.

When monitoring for temporal trends, sound statistical analysis will require several data points in time. Notwithstanding that the WFD reporting cycle is six years, a recommended approach might be to sample annually for the first WFD cycle in order to allow a trend analysis with better statistical confidence for that cycle, and then reduce the frequency thereafter if considered appropriate. Trend analyses after 12 or 18 years would continue to make use of the assessed data from the first six years.

Sampling of suspended solids for trend analysis should be carried out at least 4 times a year, although monthly sampling should be the goal. The median of a year should be used to observe the trend, as it is less sensitive to the outliers (this eliminates, for example, findings made at times of high water, which are less representative for trend observation).

5.1.4. Sediment sampling depth

Sediment monitoring generally addresses the top layer of the sediment because this layer indicates the actual deposited material and the actual status of pollution. Furthermore, the top layers of the sediment form the habitat of benthic organisms, and the protection of ecosystems is the main aim of WFD. These top layers are the net result of deposition of particulate matter from the water column (sedimentation) and physical (e.g. by currents, waves) and biological mixing (bioturbation), which is restricted in most areas to the top 5–10 cm. Sediments and SPM are sources of food and are subject to dynamic interactions with the water column due to resuspension.

The main criterion for choosing the correct sediment sampling depth (the thickness of the sediment layer sampled) in a water body is knowledge of the deposition rate of the sampling site. In theory, the lower the deposition rate, the thinner the layer that one may want to sample. In situations with steady sedimentation and undisturbed sediments, such as some oligotrophic lakes, the very top layer of the sediment will contain the most recent information and thinner top layers may be sampled (from 0.5 to 1 cm depth).

In practice, apart from this kind of specialised environment where bioturbation and physical disturbance of sediment are negligible and undisturbed surface sediments can be sampled, it is recommended to sample the top layer of the sediment, from 1 to 5 cm depth, depending on the deposition rate. The sampling depth should be defined for each sampling site. In the case of highly perturbed sediment or in large fast flowing rivers, the sediment sampling depth could be more than 5 cm. For comparison reasons, sampling depths should be maintained over the years for the respective sites.

Different intervals may be appropriate for the sampling of sediment core profiles.

5.1.5. Sediment fraction to be analysed

Sediments consist of a large range of particles, ranging from the very fine clays (<2   m) to coarse pebbles and stones of several mm in size. Their surface is often coated by organic matter, which acts as a binding site for many pollutants and other compounds. The smaller the particle, the larger the relative surface area, that means that the greater part of many hazardous substances is contained in the finer sediment fractions, which are also the primary food source for biota.

Fine material (inorganic and organic) and associated contaminants are preferentially deposited in areas of low hydrodynamic energy, while in areas of higher energy, fine particulate matter is mixed with coarser sediment particles, which generally have a much smaller capacity to bind contaminants. This dilution effect arising from the presence of coarser material will cause lower and variable contaminant concentrations in the resulting whole sediment. Obviously, grain size is one of the most important factors controlling the distribution of natural and anthropogenic components in sediments, along with organic matter content. It is, therefore, essential to normalise for the effects of grain size in order to provide a basis for meaningful comparisons of the occurrence of substances in sediments of variable grain size distribution and texture within individual areas, between areas or over time.

When analysing whole sediment (i.e. <2 mm fraction) for spatial distribution surveys, the resulting maps may give a direct reflection of pollutant distribution only if the sediments have homogeneous bulk composition (e.g. are all mud, or are all sand) throughout the whole surveyed area. In areas with varying grain size distributions, however a map of contaminant concentrations will be closely related to the distribution of fine-grained sediments, and any effects of other sources of contaminants, for example anthropogenic sources, will be at least partly obscured by grain size effects. If samples used for a spatial survey consist predominantly of fine material (>80% fines), the influence of grain size distribution is of minor importance and may be ignored avoiding the need for sieving procedures.

In temporal trend monitoring, too, differences in grain size distribution can obscure trends.

Selection of the grain size fraction considered as the ‘fine fraction’ used for the analysis depends on the general aim of the sediment analysis; it should reflect the distribution of the particular analyte as a function of the sediment particle size.

Sieving to collect the <20 µm fraction is an effective way to reduce variability. In most areas, however, the portion of 20–63 µm is rather small compared to the fraction <20 µm fraction. For pragmatic reasons (labour-intensive sieving process to collect very fine fractions) analysis of the grain-size <63 µm fraction, representing the clay-silt fraction, is widespread in many current monitoring programmes. Consequently the recommended procedure for the correction for grain size effects in sediments is the collection of the <63 µm sediment fraction. This recommendation is made recognising the effort required to undertake the sieving process and the added risk of contamination.

In some water bodies, such as estuaries of large mainland rivers, the 20–63 µm fraction is not negligible. In these cases, even when sieving at <63 µm, co-factors (see Section 5.4) still need to be determined.

An alternative procedure, based on the normalisation to the <63 µm fraction, can be recommended in order to avoid the sieving process and the associated risk of contamination. As concentrations of contaminants in sandy sediments are usually negligible, chemical substances (both organic and inorganic compounds) may be analysed in the <2 mm fraction and subsequently normalised to a sample consisting of 100% of the <63 µm fraction. In order to get reliable normalised results, the amount of fines should be at least 10%. Moreover, with this alternative procedure it is mandatory to measure the actual granulometry of the analysed sediment sample.

SPM or freshly deposited sediment in rivers can be used as a source of <63 µm material, except in particular hydrological situations, such as floods, when large particles can be moved and redeposited.

5.2. Technical aspects of sediment sampling

Of the ISO 5667 series of standards providing guidance on sampling techniques; the followings should be taken into account for sediment sampling:

- Design of sampling programmes [ISO, 2006];
- Preservation and handling of samples [ISO, 2003];
- Sampling of rivers and streams [ISO, 2005];
- Sampling from lakes [ISO, 1987];
- Sampling of bottom sediments [ISO, 1995];
- Guidance on preservation and handling of sludge and sediment samples [ISO, 1999];
- Sampling of marine sediments [ISO, 2004].

Notwithstanding the importance of the general principle presented in the standards, which should be known by the staff carrying out the sampling, the exact procedure/equipment will always be dependent on the conditions at the actual sampling site. As sampling sites may be rather different, the staff should be sufficiently experienced to decide on the appropriate procedure/equipment. In general, the technical aspects of sampling do not depend on the water body concerned, but on the logistic requirements. Shallow waters may be present in any water body, deep waters are present in many lakes and coastal environments. The sampling operation is technically driven more by water depth than by the type of water body.

Even before sampling starts, it is important to check whether the sampling site is disturbed by unexpected events (tourism, boating, debris, etc). Samples should be collected from physically undisturbed sediments. For example, in manual sampling near the shoreline, the person taking the sample should avoid sampling in his footprints.

It is good practice to complete a sampling report, which may include a general description of collected samples including colour, homogeneity (presence or absence of stratification), presence or absence of animals (indication of bioturbation), surface structures, odour and any visible contamination (e.g., oil sheen).

Furthermore, contamination during sampling, sample pre-treatment (sieving, homogenising, freeze drying) and storage of samples has to be avoided. Other sources of contaminant degradation (oxidation, photodegradation) should be minimised.

Many further manuals, which describe technical procedures for sediment sampling, are available [see e.g. U.S. EPA, 2001; Kramer et al., 1994; Mudroch and Azcue, 1995; UNEP/MAP, 2007].

5.2.1. Sample volume

Sample volume is dependent on:

- The (expected) concentration of the hazardous substances (for organic micro-pollutants the sample volume should be larger than for trace elements);

- The percentage of the fine fractions which accumulate contaminants;

- The number of analyses that need to be carried out on the sample (nutrients, trace metals, organic micro-pollutants, radio-tracers, co-factors, etc.);

- The number of replicates for each analysis.

Obviously, for surface sediment samples, replicates may provide a larger sample volume, but for vertical profiles the volume of slices of sediment will remain limited. Samples obtained by corer are usually rather limited in volume (for a top 5 cm sample, an 8 cm Ø corer gives a sample of about 250 ml). In general it is recommended to obtain the following sample volumes (Table 2):

Table 2 Recommended sediment sample volumes

Type of analysis	Volume
Trace elements	50 ml
Organic micro-pollutants	200 ml

These are obviously only indicative values for operators because the sediment porosity should also be taken into account. If sandy sediments are sampled, the sample volume may need to be much larger in order to obtain sufficient amounts of fine material for subsequent analyses.

5.2.2. Sediment samplers

Either a grab sampler or a corer may be used to sample the top layer of the sediment, while in smaller and shallow rivers, scoops can also be employed. Grabs or corers are designed to penetrate the substrate as a result of their own mass or leverage. They come in a multitude of types and designs, often tuned to use in specific conditions. In general, their practical use depends on several factors such as water depth, sample volume, sediment type, construction material, ease of handling, and whether a surface sample or a vertical profile has to be collected. Table 3 provides a recommendation for the use of sampling equipment for surface sediment sampling according to water depth and sample volume. Small grabs and corers collect a sample of approximately 250 ml.

Table 3 Recommendation for use of sampler for the collection of the top layer of sediments (# = usable; - = not usable)

	Grab sampler	Hand corer	Gravity corer	Box corer
Water depth				
0–3 m	#	#	-	-
3–25 m	#	-	#	#
> 25 m	#	-	#	#
Sample volume				
<1–2 dm^3	#	#	#	#
>2 dm^3	#	-	-	#

It must be underlined that only the use of a large diameter or box corer enables reliable, undisturbed collection of the top surface layer for analyses. When using corers, about 20 cm sediment should be collected, and the top layer (from 1 to 5 cm depth, depending on the deposition rate) retained.

The choice of sampler type will be determined in part by the type of sediment. For the purpose of WFD monitoring, the following options are recommended [Slobodnik et al., 2004]:

- sand: both grab and corer systems can be used;
- clay: it may be necessary to use a corer because a grab system may not penetrate easily into the clay;
- consolidated bottom sediment: both grab and corer systems can be used;
- unconsolidated (very soft) bottom sediment: grab systems are not suitable, as they are prone to sink through the top layer. Corer systems perform better.

Analyses of depth profiles can be used to get additional information on the history of contamination and to reconstruct the past trend. This approach is best applied in sediments where the sediment accumulation rate is high and the rate of disturbance (physical or bioturbation) is sufficiently low so as to cause negligible disturbance to the contaminant profiles. Sediment profile samples are collected exclusively by corers.

5.2.3. Grab samplers

Grab samplers are normally mounted on a winch and attached to a rope or pole. The limited weight of small grab samplers allows operation by hand, which could prove convenient in the field. The sampler is locked in the open position and lowered to some distance above the bottom sediment. It is important to reduce the lowering speed when approaching the bottom as a bow wave may flush away the fine sediment before the sampler reaches the bottom. When the sampler touches the surface sediment, a latch is released allowing the 'jaws' to close when the cable/pole is pulled up, thus collecting a surface sediment sample. The grab sampler should be retrieved slowly to ensure that the jaws dig into the sediment and to avoid loss of the surface layer.

After retrieval, the sampler is lowered into a clear tray. Before opening the jaws, the water contained above the sediment is gently siphoned away, taking care not to wash away fine sediments at the same time. After discarding the water, the grab sampler is opened and emptied in the tray.

Problems in sampler operation include their sinking too deeply into very soft sediments, mixing of the target surface sediment layer, not collecting sufficient sediment in hard substrates, or stones between the jaws preventing their closure.

To minimise contamination, sediment that has been in contact with the sampler is to be avoided, and surface samples are collected from the central part of the sample. Stainless steel versions minimise contamination of the sample (beware of contamination of Ni and Cr). Other materials for grab samplers include coated steel samplers, but they may contaminate samples for trace element analysis (rust, paint). Alternatives are aluminium samplers.

5.2.4. Corers

Core samplers are used when information concerning the vertical profile of the sediment is of interest, or when grab samplers cannot be used because of, for example, the sediment type.

Corer tubes are usually made of PVC or Perspex, the latter offering an immediate view of the sample collected. A polyethylene inner sleeve may be used to protect the sample from contamination by the corer wall. For the determination of trace organic pollutants, other materials such as stainless steel could be chosen to minimise contamination.

Hand-operated corers can conveniently be used to collect surface sediments: they may be a short plastic tube of 8 cm Ø and are manually pushed into the undisturbed sediment for about 30 cm. If necessary, the air on top is replaced by ambient water, a rubber stopper is inserted and the sampler is retrieved. A cap is placed immediately at the bottom end. Then the water is siphoned off, and the top 5 cm of sediment is collected; a piston may help to push out the sediment. A hand operated corer with an extension tube or rod can be used to water depths up to about 3 m, depending on the currents. The core length obtained is limited by the diameter of the tube and the friction of the tube wall: maximum core length (tube diameter)^2. Hand corers have limited use for collecting profiles.

Gravity corers in principle act in a similar way to hand-operated corers, but in deeper water. The attached weight pushes the corer tube into the sediment. Often a valve is placed in the top section, preventing spillage of the sample during retrieval. Because of their weight, gravity corers are not easy to operate manually, and a winch is usually required. Core length is limited for the same reasons as for hand-operated corers, and they are of limited use for profile samples.

Box corers are very heavy, specialised equipment that collect large diameter undisturbed cores, from which replicate sub-samples may be collected (e.g. by hand-operated corer). As they are usually operated from research ships, they can be used in water depths >3 m. Usually the core length is maximum 1 m, and consequently they are of limited use for the collection of long profile samples. Operation requires specialised staff.

Usually one core is collected per sampling point. Within one core there is a chronology between different sediment layers. A replicate core, even collected nearby, may have a different sedimentation history and corresponding sediment depths may be different. Unless samples are collected by multi-corer, where the tubes are mounted in parallel and the distance between the cores is minimal, pooling of replicate samples is not recommended.

The distribution of sub-samples should be concentrated near the surface. The top of the sediment would be sliced to e.g. 3–6 slices (1–3 cm thick) and the lower part of the sample would be collected for reference.

5.2.5. Collecting of SPM and freshly deposited sediments

The following techniques are primarily used to collect suspended solid samples: centrifuge pumps and stationary or mobile settling basins or suitable traps/collection crates. In addition, samples of suspended solids can be collected through filtration. With filtration, however, the sample quantity is generally small and therefore barely sufficient for an analysis, especially of the organic substances.

Sampling with centrifuge pumps usually takes several hours and is more akin to taking individual samples while settling basins generally collect monthly composite samples. In fact, sedimentation traps or boxes may be exposed to the water for two to four weeks, to sample suspended sediments carrying the present contaminants. This sampling technique has the advantage that samples represent the very last deposited layers, especially in slow-flowing continental mainland rivers, which can be also used for trend analysis.

Settling basins do not allow for quantitative separation of the suspended solids from the water phase, and fine grains in particular are not collected in full. In contrast, centrifuge pumps almost completely separate suspended solids from the water, but they could influence the particle size distributions. These characteristics should be taken into account when the sampling methodology is chosen.

5.2.6. Transport and sieving

All samples must be sieved over 2 mm mesh as soon as possible after collection to remove large detritus and benthic organisms. Otherwise, during subsequent sample handling and processing, such as storage, freezing or ultrasonic treatment, biotic material will deteriorate and become part of the sediment sample. In order to minimise the potential for disturbance of the sediment/water equilibrium wet sieving is best performed at the sampling point with ambient water. The same water should be reused to prevent changing the equilibrium If field sieving is not possible, sieving should take place in the laboratory under controlled conditions.

Samples (sieved or not) are transferred preferably into wide-mouth, pre-cleaned bottles of amber glass (or aluminium, or other non-contaminating material) for organic analysis or into plastic bags or bottles for trace element analysis. Alternatively, amber glass jars can be used for all kinds of contaminants. Sampling containers should be filled to the top (minimal headspace) to reduce the likelihood of oxidation and loss of acid volatile sulphide (AVS) during transport. It is preferable to store samples under refrigeration (about 4°C) and transport them as soon as possible to the laboratory. Refrigeration is easily accomplished with cooling boxes and cooling inserts.

Transport of cores is critical as the integrity of the core has to be maintained. Samples near the sediment/water interface will be disturbed and will mix when transported in a horizontal position, thus losing their profile characteristics. In addition, even when transported in the vertical position, vibration will tend to compact the sediment. If possible, cores should be sub-sampled and sieved directly in the field.

Until the final sieving procedure that isolates the fines for subsequent analyses (see Section 5.1.5), which is normally carried out in the laboratory, the sample can be stored at 4°C for about a week and up to 3 months when frozen at -20°C, unless otherwise specified in the analytical methods for specific degradable compounds. Whenever possible, freezing should be avoided because it can change the grain size distribution of the sediment.

In the case of the AVS measurement, sediment should be preferably kept at 4°C, although freezing has negligible effects on AVS levels. If stored at 4°C, the period between sampling and AVS analysis should be no longer than two weeks.

If provided by the sampling strategy (see Section 5.1.5), the silt+clay fraction (<63 µm) could be separated by sieving over a 63 m mesh sieve. As clays tend to form lumps of considerably larger diameter, sediments should be sieved wet. A minimal amount of ambient water should be used. It is strongly recommended to avoid sediments becoming dry. If it happens, sediments should be pre-soaked in water for at least 2 hours to break up the lumps.

In the case of saline samples it is particularly important to sieve with water with approximately the same salinity as at the sampling location. If no local water is available, the correct salinity value can be obtained by diluting a stock of seawater collected from the open sea.

Sieving may be carried out by simple means, using a sieve mounted on a funnel filled with water and moving the sieve manually. For the processing of larger numbers of samples, sieves may be placed on vibrator tables. The water can be efficiently separated from the sieved material by centrifugation. Sieving procedures have been described and evaluated in the QUASH project [QUASH, 1999; Smedes et al., 2000].

Sieves are traditionally made of corrosion-resistant brass (rim and mesh). Today, stainless steel is preferred for organics analyses. These must not be used for the analysis of trace metals, however. For trace metals, polymer sieves are recommended (PVC or acrylic rim, with e.g. nylon or polyester mesh).

5.2.7. Preservation and Storage

Storage begins when the samples are taken. All storage methods will affect the sample to some extent, and the choice of preservation technique depends mainly on the objective of the sample collection. Because the first few hours after sampling are the most critical for changes to occur in the sample, preservation steps should be taken, where possible, immediately upon sample collection. No recommendations can be given for a universal preservation or storage technique. A technique for one group of analyses may interfere with other analyses. To overcome this problem, a sufficient sample volume should be collected to allow specific preservation or storage techniques for each specific group of analytes.

Temperature is the most important factor affecting the samples, from the time of sample collection through handling to the final analyses. Another source of contamination is the adsorption of contaminants from laboratory air. Degradation and volatilisation of pollutants could be a source of errors too.

In the laboratory, the sieved sediment samples should be deep-frozen at -20°C and, when frozen, freeze-dried in a freeze-dryer as soon as possible. Check contamination during freeze-drying by placing a glass jar with 2 g C18 bounded silica in the freeze dryer in parallel with the samples.

Air-drying is not appropriate due to high contamination risks. Besides, samples may be difficult to disaggregate and mineral structures may be affected. If a freeze-dryer is not available, in order to limit microbial breakdown, the samples could be air- or oven-dried at 25–30°C till more or less constant weight as soon as possible after sieving. Losses of some determinands (volatile or semi-volatile compounds, such as e.g. 2–3 rings PAHs) can occur during this process, even when the drying is done at cool temperatures (<30 C). Prior to analyses of inorganic constituents (e.g. metals), sediment samples may be dried at 105°C (except for mercury determination, which needs a drying step at <50°C).

Containers for storing lyophilised or dried sediment samples are preferably wide-mouth bottles with a screw cap. Samples taken for the analysis of organic contaminants must be stored in amber glass, polytetrafluoroethylene (PTFE), stainless steel or aluminium containers. Sediments collected for analysis of metals can be stored in closed plastic or glass containers. Since sediment particles have a small surface area which exchanges with the container surface, the contamination risk is limited and it is possible to use a glass jar for all determinations in order to simplify sediment characterisation.

For mercury, samples must be stored in acid-washed borosilicate glass or quartz containers, as mercury can move through the walls of plastic containers. For organotins, storage of samples is preferably done in amber glass bottles, but containers of other materials such as polycarbonate or aluminium are also suitable. Maximum suggested time of storage of freeze dried sediment before analysis is about 180 days (30 days for Hg) if stored in a cool, dark place.

Archiving sediment samples is a must in QA/QC procedures. All samples should be kept for the duration of the monitoring in order to be able to come back to any of them, or to all of them, in case of problems in the analysis or interpretation. In addition, it may be useful to archive part of the original sample in order to be able to re-analyse the material for (other) compounds at a later date. Freeze-dried sediments remaining after analyses are stored in the original sample bottle, closed with an airtight lid to protect against moisture. When stored in a cool, dark place, samples may be archived and stored for 10-15 years, i.e. for the duration of the monitoring programme. For less stable compounds this period may be shorter.

5.3. Analytical methods

Only a few standard methods exist for sediment analysis (for PBDE, Cd, Pb, Ni, pentachlorophenol, tributyl tin compounds) [Lepom and Duffek, 2005]. As regards soil analysis, standard methods are lacking for only 10 substances. However, existing ISO standard methods for soil analysis, summarised in CIS Guidance No. 19 “ANNEX I: List of ISO Standards for soil analysis” [EC, 2009], may be applied to sediments after validation on the appropriate matrix.

JAMP Guidelines for Monitoring Contaminants in Sediments [OSPAR, 2003] currently contain detailed advice on sampling, sample preparation and analytical methods for some contaminants in marine sediment. OSPAR Guidelines currently cover metals, chlorobiphenyls, PAHs, mono-, di- and tributyltin, PBDEs and HBCD; advice on PFOS, alkylated PAHs, co-planar CBs and dioxins in sediment is currently under development.

The analytical methods applied after extraction or digestion of the sediment, are generally the same for water and sediment samples. The principles of available analytical methods for priority substances are reviewed in CIS Guidance No. 19 “ANNEX II: Substance Guidance Sheets” [EC, 2009].

The use of standardised methods is recommended, because these methods have been finally validated in interlaboratory trials. Nevertheless, not all standardised methods meet the minimum performance criteria stated in Directive 2009/90/EC. The use of standardised methods should only be mandatory if the analysis or the quantification contains “method-defined” parts. This is the case for e.g. the selection of congeners of brominated diphenyl ethers, the quantification of alkylphenols, and both the selection and quantification of short chain chlorinated paraffins, if available.

The methods will, to some degree, dictate the amount of sediment sample required for each analysis. *Vice versa* the amount of sample used in an analysis affects the detection limits attainable by a particular method.

5.3.1. Organic compounds

Solvent extraction methods described in standards for soil can also be used for dried sediment. EPA has adopted various extraction procedures, from classical Soxhlet extraction to advanced techniques such as Microwave Assisted Solvent Extraction (MASE) and Pressurised Solvent Extraction (PSE).

Special care should be taken for volatile compounds for which extraction of wet samples, avoiding the freeze-drying step, could be preferable. Extraction of wet sediment samples requires the use of a first extractant that is miscible with water (such as acetone), followed by a less polar extractant such as pentane or hexane. This procedure works well for non-polar priority substances such as organochlorinated pesticides, PAHs, PBDEs and chlorinated benzenes.

Alternative extraction methods for volatile compounds use purge-and-trap or headspace techniques.

The analytical techniques for semi-volatile organic compounds generally involve solvent extraction from the sediment matrix. Extensive cleanup is required if there is a likelihood of (*a*) biological macromolecules, (*b*) sulphur from reduced sediments and (*c*) oil and/or grease in the sediment.

The recommended detection method for analysis of semi-volatile and volatile organic pollutants in sediment is based on the use of capillary-column gas chromatography (GC) with mass spectrometry (MS). For the determination of organohalogenated compounds, GC with Electron Capture Detector (ECD) can also be used. The most selective methods using GC/MS techniques are recommended for most organic compounds, because such analysis can often reduce problems caused by matrix interferences.

Non-volatile organic compounds require HPLC separation with selective detection such as fluorescent and electrochemical detection. Standard methods are under development based on mass spectrometric detection with atmospheric pressure ionisation hyphenated to liquid chromatography systems.

5.3.2. Metals

For the determination of metal concentrations in sediment, samples must be digested with concentrated inorganic acids in a traditional open system or, more commonly, in sealed vessels in a microwave oven and analysed by methods such as inductively coupled plasma-atomic emission spectrometry (ICP-AES) or ICP-MS, graphite furnace atomic absorption spectroscopy (GFAAS) or atomic fluorescence spectrometry.

OSPAR recommends the inclusion of HF in the digesting medium [OSPAR, 2003]. By this approach, the total metal content, including that part which is of geochemical origin, is measured and that procedure allows the application of normalisation co-factors based on Al or Li content (see 5.4). This approach requires knowledge of the distribution of background concentrations of trace metals of geochemical origin.

In surface waters, background concentrations are less assessed and are very variable in a water body. HF digestion could lead to an overestimation of the trace metals content. The use of less aggressive acid mixtures (such as for example concentrated nitric acid + hydrochloric acid, Aqua regia), which are moreover safer substitutes, is therefore recommended, depending also on the final detection technique.

SEM-AVS (Simultaneously Extracted Metals – Acid Volatile Sulphides) analysis should be carried according to the United States Environmental Protection Agency (US-EPA) method [U.S. EPA, 1991] integrated by the Dutch National Institute for Public Health and the Environment (RIVM). Extraction with 6M HCl solution should be carried out on a homogenised wet sample. The formed H_2S gas, collected in a NaOH-solution, is spectrophotometrically determined at 660 nm using dimethyl-p-phenylenediamine hydrochloride as colour reagent. Metals are determined on the filtered supernatans.

5.3.3. Quality Assurance / Quality Control procedures

Proper Quality Assurance/Quality Control procedures include the validation of methods by analytical laboratories, routine internal QC procedures and independent external QC procedures.

The validation of an analytical method, including the determination of measurement reliability, bias, etc., requires the use of certified reference materials. In CIS Guidance No. 19-"ANNEX III: Existing certified reference materials" [EC, 2009], a complete list of sediment certified reference materials (CRM) is reported. CRMs are currently available for the determination of metals, PAH and chlorinated pesticides in sediment. For other organic priority substances, no suitable CRMs have been developed yet.

Internal QC procedures should include the routine monitoring of the performance of analytical methods, for example by the inclusion of duplicate samples or (laboratory) reference materials in analytical batches. The results from these samples should be assessed using standard statistical methods such as Shewhart charts to ensure that the methods remain under statistical control.

It is recommended that laboratories participate in suitable external interlaboratory comparisons. A grouping of Proficiency Testing Laboratories has been established to meet the needs of WFD. This PT–WFD network (http://www.pt-wfd.eu/) is comprised of organisers of proficiency tests which support the implementation of the EU Water Framework Directive. It seeks to ensure that the demands of the EU WFD are met through the organisation of high-quality proficiency tests which are performed in a harmonised and comparable way.

5.4. Normalisation co-factors

Normalisation is defined here as a procedure to correct contaminant concentrations in sediment for the influence of the natural variability in bulk sediment composition (grain size, organic matter and mineralogy).

Isolation of the fine fraction by sieving can be regarded as a physical normalisation to reduce the differences in sediment granulometric composition (*see* Sections 5.1.5 and 5.2.6).

In data reporting, any geochemical-based differences in sediment composition that remains after sieving can be corrected for by the use of co-factors. It is also mandatory to report raw data, expressed as weight pollutant/weight sediment, together with normalising co-factors and/or normalised data.

For the analysis of trace elements in the sieved fine fraction, a common normalisation method involves the use of the aluminium (Al) concentration. Clay minerals are rich in (e.g.) Al or Li, the sands (quartz) are not. Generally, compared to aluminium, more accurate normalised data can be expected using lithium. Total sediments are analysed for the trace element, including the co-factor; the trace metal concentration is normalised with respect to the normaliser content that represents the fine fraction (normaliser content in sample minus the normaliser content in pure sand or in the >63 µm fraction). In this case Al or Li is used as a proxy to fine sediment particles. The aluminium content in the sandy fraction may, however, vary from area to area. Therefore, to use this method, a statistically meaningful relationship between Al and grain size must be established in the sediment of the area prior to the application of the method.

For the analysis of trace organic compounds in sediment, a widely used normalisation method involves normalisation using the total organic carbon (TOC) concentration. Clay and silt minerals are coated with organic matter, while the coarser fractions contain relatively very small amounts of TOC due to their small relative surface area. The ratio of [concentration of the organic compound]/[TOC] is the normalised value. However, care has to be taken, as organic matter in a sample is not always well defined and it can be composed of material with different properties. Furthermore, the nature of the organic matter may show spatial variation. Also, while normalisation using TOC is effective for lipophilic substances such as chlorinated compounds and PAHs, it may not be valid for other classes of compounds which bind to particles and clays with more polar bonds.

Detailed guidance on the use of normalising parameters for sediments is given in Annex 5 of the JAMP Guideline for Monitoring Contaminants in Sediments [OSPAR, 2003; see also OSPAR, 2001].

6. MONITORING OF CHEMICAL SUBSTANCES IN AQUATIC BIOTA

6.1. Introduction

The monitoring of chemical substances in aquatic biota should be performed according to the minimum requirements of Directive 2008/105/EC and according to the recommendations in CIS Guidance No. 19 [EC, 2009] and in the EQS Guidance document in course of publication [EC, 2010].

The objectives of biota monitoring under the WFD are:

- compliance checking against EQS values for the purpose of the classification of chemical (for the 33 priority substances and 8 certain other pollutants) and ecological status (in the case of river basin-specific pollutants) of the waterbodies;

- long-term trend analysis of concentrations of substances that tend to accumulate in biota in the context of surveillance monitoring programmes of WFD.

The substances to be monitored in aquatic biota should be selected on the basis of the recommendations given in Chapter 3.

The monitoring of mercury, hexachlorobenzene (HCB) and hexachlorobutadiene (HCBD), substances for which a European EQS has been derived, should be performed in accordance with the recommendations contained in this chapter.

Biota monitoring programmes under international conventions for inland, transitional, coastal and marine waters already exist: e.g. Helsinki Commission (HELCOM), OSPAR, International Commission for the Protection of the Rhine (ICPR), MEDPOL. In general, species that are already used in existing national or international monitoring programmes should be used for biota monitoring under Directive 2008/105/EC.

The methodology to determine the natural background concentrations of metals in biota is included in the EQS guidance in course of publication.

6.2. Sampling strategy for chemical monitoring in biota

The biota sampling strategy for a given water body should include the choice of the substances to be monitored (see Chapter 3), the selection of the species representative for that specific water body, the selection of the sampling sites, the monitoring frequency and the monitoring techniques.

The natural variability within biota samples should be reduced by an appropriate sampling design, keeping in mind that differences in age, size, sex and sexual maturity status can affect the measured concentrations of contaminants. Sampling strategies should be devised so as to minimise the impact of these factors. Biota sampling should only take place when fish and bivalves are in a stable physiological state, and outside the normal period of spawning. Fishes should be collected from areas characterised by relatively low natural variability.

Moreover, the following general recommendations are given:

- For the selection of species for biota monitoring, Member States should not use species that are endangered or that require special protection in compliance with “Habitat Directive” requirements or any other national or international action plan for nature conservation. Active biomonitoring, such as caging and transplantation procedures must avoid the introduction of allochthonous species to waterbodies. Non-native species should not be used in active biomonitoring.

- Sampling strategies for biota monitoring should seek continuity with pre-existing monitoring programmes when relevant. In some cases and for some species, harmonisation with the biota sampling performed for the purpose of the classification of the ecological status can be useful.

6.2.1. Selection of biota species and link with EQS derivation

In the selection of biota species, consideration should be given to the main purposes of the EQS Directive: trend monitoring and compliance with EQS. Where possible the same species sampled should be used for both purposes.

The species should be selected mainly on the basis of their ability to reflect the quality of the water body that has to be monitored and, in the case of compliance checking, on the basis of the trophic level for which an EQS has been derived.

The WFD requires biota EQSs to protect:

1. humans from adverse effects resulting from consumption of chemical-contaminated food (fish, molluscs, crustaceans, etc.);

2. top predators such as birds and mammals from risks of secondary poisoning brought about by consuming toxic chemicals in their prey;

3. benthic and pelagic predators (e.g. predatory fish) that may also be at risk from secondary poisoning.

The choice of species to be monitored should depend mainly on the identified protection goal (e.g. humans, top predators); where there are a variety of protection objectives, it is preferable to choose a species that can satisfy them all.

According to the EQS guidance in publication, if for a given contaminant it is not possible to monitor the same species (or a trophic level) for which the EQS has been derived, the biota quality standard should be adjusted to the appropriate trophic level of the species actually monitored .

6.2.1.1. Mercury and its compounds, hexachlorobenzene and hexachlorobutadiene

Biota EQS have been derived for mercury and its compounds, for hexachlorobenzene and for hexachlorobutadiene in Directive 2008/105/EC. For these substances specific recommendations for monitoring are therefore given, based on the criteria that have been used for the EQS derivation which are indicated in the datasheets of the priority substances available in the public section of the CIRCA forum:

(http://circa.europa.eu/Public/irc/env/wfd/library?l=/framework_directive/i-priority_substances/supporting_background/substance_sheets&vm=detailed&sb=Title).

For the substance class “Mercury and Compounds” the EQS of 20 µg/kg in prey tissue has been derived for methylmercury and the protection objective is the prevention of secondary poisoning of top predators; for this substance the species to be monitored should be a prey (diet) for top predators of the waterbodies to be classified. Prey can be fish or shellfish, depending on the local aquatic trophic chains.

For the substance “Hexachlorobenzene” the EQS of 10 µg/kg has been derived based on the risk for humans consuming seafood. It is therefore recommended that this substance should be monitored in edible parts of fish and shellfish that form part of the human diet.

For the substance “Hexachlorobutadiene” the EQS of 55 µg/kg is based on the protection of top predators from secondary poisoning. It is therefore recommended to monitor this substance in species that represent a prey (diet) for the aquatic top predators of the waterbodies to be classified. Prey can be fish or shellfish, depending on the local aquatic trophic chains.

6.2.2. Recommendations for the selection of biota species

In Europe, because of the varied geography and the wide variety of ecosystems, there is a huge number of aquatic biota species. As indicated earlier, the selection of biota species should be performed in compliance with the general requirements of the WFD and EQS Directive, but the choice of species will be necessarily limited by their availability. It is therefore important to have comprehensive knowledge of the geographical area to be represented by the collected sample.

The selection of the species should be based, if possible, on the following criteria:

- a relationship exists between contaminant concentrations in the species and average concentrations in the surrounding environment;
- the sampled organism is a potential food for predatory organisms or humans;
- the species accumulates the contaminants;
- the species is sedentary (migrating species should be avoided) and thus represents the sampling location, and does not originate e.g. from aquaculture plants;
- the species is widespread and abundant in the study region, to allow comparisons between different areas;
- the species lives long enough so that more than one year-class can be sampled, if desired;
- the species is large enough to yield sufficient tissue for analysis;
- the species is easy to collect and hardy enough to survive unfavourable conditions;
- the species is easy to identify.

When more than one species needs to be monitored in specific environments, organisms belonging to different trophic levels should be selected to evaluate the transfer of pollutants through diet. Top predators do not necessarily reflect site-specific bioavailability of chemicals but are useful for detecting the biomagnification risks.

In the following paragraphs, examples of species that meet the criteria for good monitoring practices are mentioned, but eventually the selection of actual monitoring species will also be governed by local conditions, such as latitude and altitude.

6.2.2.1. Suggested species for lakes

Perch (Perca fluviatilis L.)
Perch can be found in many parts of Europe, from Portugal in the south west, Spain and Italy in the south, Greece in the south east and northwards. It is also used as a matrix for contaminant monitoring in different European countries (e.g. Sweden, Finland, France, and Switzerland) and is

therefore a well characterised species. Perch is the most commonly used species within the national Swedish freshwater monitoring of organic contaminants and metals, but it is also used for coastal monitoring in the Baltic Sea. The fish species integrate the environmental contaminants in a given area and accordingly represent a good marker for environmental quality. Perch is fairly stationary up to a size of approximately 20 cm. The spawning season takes place between February and July and sampling should be avoided during this period.

Bream (Abramis brama)
Bream has a wide distribution within Europe with the exception of the extreme north and south. It is used for contaminant monitoring in e.g. Germany and France. It occurs in both fresh and brackish waters and is among the most frequently found fish species in central Europe. It is therefore available for long-term repeatable sampling.

Bream mainly feed on benthic organisms. Being bottom feeders, they are good indicators of pollution in the sediment, rather than just in the free column water. They are also resistant to a high load of pollutants.

The sampling should take place in August and September, after the spawning period; depending on the atmospheric conditions, it may be possible to conduct the sampling as early as the middle of July or as late as the middle of October.

Experience gained in very different types of waters reveals that eight- to twelve-year-old bream comply best with the criteria set for Environmental Specimen Banking (ESB-Germany), but specimens of other ages can also be chosen.

Arctic char (Salvenius alpinus)
Arctic char is used for contaminant monitoring in the alpine lakes of, for example, Sweden and Switzerland, where other fish species recommended for contaminant monitoring are not present. The sampling should take place outside the spawning season, which in the northern parts of Europe occurs between August and October.

In the parts of Europe where this species is rare, its use for monitoring purposes should be avoided.

European Eel (*Anguilla Anguilla*): Eels are benthic fishes, carnivorous in their feeding behaviour and preying on insect larvae, worms, crustaceans, snails, mussels, and fishes, in particular small bottom-dwelling species, resulting in high bioaccumulation of toxic pollutants. Eels have been demonstrated to be good indicators for a wide variety of chemical compounds (e.g. PCB, heavy metals, organochlorine pesticides). Because of the protected status eels should only be used for existing trend monitoring (to continue old monitoring programmes) and for this species the principle of conservation has to be respected.

6.2.2.2. Suggested species for rivers

Bream (Abramis brama) and chub (Leuciscus cephalus)
The bream and the chub are used as organisms for environmental monitoring because of their size, abundance and widespread presence. Sampling can be confined to bream aged eight to twelve years and takes place in the late summer after the spawning season (ESB-Germany). Specimens from outside this age bracket may also be used.

Brook trout (Salvelinus fontinalis) or Rainbow trout (Oncorhynchus mykiss)
These species are suggested in the mountainous regions (salmonide regions).

Zebra mussel (Dreissena polymorpha)
The zebra mussel is a sedentary inhabitant of slow-flowing and stagnant waters, where it filters vegetable and animal microorganisms. As a consequence, *Dreissena polymorpha* is exposed to hazardous substances, whether in solution or particulate suspension and is therefore useful in active biomonitoring and in toxicity and impact tests (ESB-Germany). The zebra mussel is an alien species and should be not used with caging in rivers where it is not yet known to be present.

Alternatively *Anodonta cygnea* should be used.

Other candidate species for biota monitoring include:

- European Eel (*Anguilla Anguilla*): See under 6.2.2.1.

- The aquatic bryophytes (*e.g.* genera *Fontinalis*) for heavy metals.

- The bivalves *Anodonta cygnea*, *Unio pictorum* and *Corbicula fluminea* which are additional suitable species for rivers, lakes and active monitoring (caging) strategies.

- The macroinvertebrates which can be used with caging : *Gammarus pulex, Chironomus spp*, in particular for metals bioaccumulation.

- Periphyton, which is also useful for a very broad range of contaminants, and is particularly recommended for heavy metals.

- The microinvertebrates *Hydropsychae sp.* and *Erpobdella sp.*

6.2.2.3. Suggested species for transitional, coastal and territorial waters

Molluscs
Bivalve molluscs are among the most widely used bioindicators, owing to the absence of regulatory mechanisms of internal concentrations of many chemicals, and their ability to accumulate trace metals, polycyclic aromatic hydrocarbons (PAHs), aliphatic hydrocarbons, halogenated organic compounds, phosphate organic pesticides, etc.. Because of their biological and ecological characteristics, mussels (*Mytilus spp*) have been commonly used in more than 50 nations during the last 40 years, providing a time-integrated picture of local contamination [Cantillo, 1998]. These species are also well characterised for the biological cycle and several sets of data are available on the influence of natural and environmental factors on bioaccumulation.

In this respect mussels (*Mytilus spp.*) should be considered the priority species to investigate, using natural populations or transplanted organisms. Alternative bivalve species which in specific circumstances could be considered (i.e. for their site-specific ecological importance) might include bivalves of the genus *Perna*, oysters (*Crassostrea spp., Ostrea spp.*), clams (i.e. *Donax spp., Chamaelea spp., Tapes spp., Macoma spp.),* and *scallops (Pecten spp., Chlamys spp,)*.

Another bivalve species recommended in the Baltic is *Macoma baltica*.

Species-related differences for concentrations of some trace metals should be considered for comparisons. For example oysters present much higher basal levels of copper and zinc than mussels, and similar species-specific features include elevated levels of copper in *Donax semistriatus*, and of cadmium in digestive tissues of scallops.

Fishes
A number of benthic or demersal fishes can be proposed for monitoring the presence of some chemical pollutants.

The most commonly used Mediterranean species include: the red mullet, *Mullus barbatus* or *M. surmuletus*, the seabass *Dicentrarchus labrax*, the gilthead seabream *Sparus aurata, and* various gobid species, i.e. *Gobius spp.* and *Zosterissessor ophiocephalus*. Suitable fish species for the Atlantic and the North Sea include the dab *Limanda limanda*, the plaice *Pleuronectes platessa*, the flounder *Platichthys flesus,* and the cod *Gadus morhua*. Other species could be considered of particular ecological/biological relevance in specific sites. Eel *Anguilla Anguilla* can be used only as referred in point 6.2.2.1.

Other species in the Baltic area include: eelpout (*Zoarces viviparus*) and herring (*Clupea harengus*).

Among fish species, those at the highest levels of food chains (top predators) are naturally exposed to larger amounts of contaminants accumulated through the diet, and higher basal levels are thus detected for specific chemicals such as mercury, and halogenated and persistent organic pollutants.

Seabird eggs could also represent a good matrix for the assessment of chemical pollution in the higher trophic levels (for example Guillemot, *Uria aalge,* in Sweden).

6.2.3. Selection of sites: general considerations

The geographical representativeness of a sample in lakes varies with, for example, species and size. Small fish (e.g. perch) represent a much smaller part of a lake than larger ones or other big predatory fish species. It is therefore important to register coordinates not only for the lake, but also for the sampling site within the same lake.

The fish should be collected from a sampling site representative of the area. The site should not differ from the general picture of the area of concern such as for example an isolated bay. Differences between a lotic and a lentic environment, high-flow and low-flow rivers, and feeding behaviour of the species should be highlighted.

In rivers the sampling sites have to be representative of the respective ecosystem, and/or of the respective sampling region. This means that they must not be close to local sources of emissions. The minimum distance from such pollution sources depends on the type of emissions and on numerous hydrologic and hydrogeographic factors, e.g. water depth, water width, surface and volume of the water body, degree of mixing, pH-value, oxygen content, water hardness, conductivity, trophic level, flow rate, wind direction, wind strength, character of the riparian zone, exposure, etc. The minimum distance from the nearest source of emission must therefore be ascertained separately for each sampling site.

For active monitoring with zebra mussels, a secure, undisturbed and sheltered position should be chosen.. Natural sources of irritation, e.g. too strong a current or a risk of siltation, need to be avoided, as do possible irritations by river boat traffic. Otherwise, the exposure spots need to be readily accessible, even in bad weather. In the selection and demarcation of sampling sites for the sampling of free-living populations (passive monitoring), the population must be of a sufficient size, density and stability in order to ensure good long-term sampling. Furthermore, long-term use of the sampling sites and access to the exposure spots must be secured by contract as a basic principle. The detailed arrangements will depend on the level of protection and the ownership structure.

In the case of shellfish in marine or estuarine areas, samples should preferably be collected from sub-tidal or inter-tidal regions, otherwise as near to the low water spring tide level as possible. If a specific pollution source is known, they should be collected as far as possible at the same depth and type of exposure (*i.e.* in terms of light and wave action) in order to reduce variability in contaminant uptake. The boundary of the sampling site must be specified. At locations where suitable natural populations are not available, caged mussels or other organisms may be used.

A minimum number of marine coastal stations should be selected in each country for national monitoring programmes. In order to select appropriate stations, knowledge of the ecological dynamics of specific areas and the support of dynamic information derived from remotely sensed satellite data can be useful. Satellite sensors could provide spatial and temporal patterns relevant to some sea surface parameters (such as temperature, chlorophyll-like pigments, suspended matter), or useful to visualise the geographical influence of river inputs, domestic/urban/industrial plant discharge, coastal runoff or general sea dynamics. Where possible, advantage should be taken of existing monitoring programmes, for example those operated by the regional conventions, e.g. OSPAR, HELCOM, MEDPOL etc.

6.2.4. Sampling period

For biota monitoring the sampling period should be selected carefully on the basis of the following criteria.

Concentrations of chemical pollutants in tissues of bioindicator organisms can be influenced by many environmental and biological factors, independent of the variations in anthropogenic inputs. In particular, seasonal fluctuations must be carefully considered for the correct interpretation of the results, and to discriminate natural variability from changes due to human impact.

Among the most relevant of the important environmental factors which modulate bioavailability and the tissue burden of chemicals are fluctuations of temperature, organic matter, presence of nutrients, water fluxes and circulation, up-welling phenomena, freshwater or river inputs, and land runoff. Seasonal changes of tissue concentrations have also been reported during phytoplanktonic blooms, which can modulate the bioavailability of several chemicals.

Other biological variables, including intrinsic species-specific features such as the phase of reproductive cycle, weight fluctuations, changes in relative tissue composition, the massive development of gonadic tissues during gametogenesis and the loss of weight during spawning, have all been demonstrated to be of particular relevance. Depending on the strategy and objectives of the monitoring plan, it can be recommended to select the sampling periods in advance or to consider the most important variables which might influence the results obtained.

When designing large-scale and/or long-term (years to decades) biomonitoring projects to assess temporal trends of contamination, the influence of seasonal variability can be reduced by defining in advance the sampling period(s) which will be kept constant for all subsequent years. Carrying out sampling of biota during a period in the year when contaminant concentrations are not being significantly affected by changes in physiological mechanisms is essential for consistency of sampling. Such periods of minimal change are generally related to periods outside the spawning cycle and when food supply is relatively constant.

In order to avoid such variations it is recommended that sampling take place in the off-spawning period. In order to obtain comparable data from the various sampling stations it is necessary to establish the off-spawning period at all these stations in order to ensure that samples are taken at the correct times.

“Early summer periods” can be suggested for several species, considering the generally favourable weather conditions and in order to avoid the impact due to the increase in tourist activities and the greater human consumption of fish and shellfish. For central Europe, the “Late summer period” can be suggested for cyprinides. Do not simply adopt a particular month used elsewhere without understanding the biological reasoning behind the proposed selections.

Sampling periods, however, often need to be adapted in a site-specific manner, to local characteristics, regional projects and requirements, specific objectives or accidental events. In such conditions, sampling periods cannot be decided in advance or on the basis of some standard formula. Nevertheless, the influence of more common biological and environmental factors can be easily evaluated with simple procedures, thus allowing proper comparisons between data obtained in different periods. The more important environmental factors at sampling time should be reported (i.e. date, seawater temperature, salinity, phytoplankton development): all this information is generally available online from regional or national environmental agencies and it does not represent an additional cost or effort for biomonitoring projects.

The influence of tissue weight, which can be subject to extended seasonal variations mostly related to gonadic development, trophic conditions and energy status, can be accounted for by measuring different types of condition indices (CI). For example, good results have been obtained with the condition index $K_f = 100^* M / L^3$ (M = weight in g, L = length in cm).

For bivalves, the index is calculated as the ratio between tissue weight and shell length (or weight or volume), while for fish the hepato-somatic or gonado-somatic indices reflect the ratio between liver (or gonad) weight and whole body weight. Although such measurements are only indirect estimates, their utility has been largely documented; in addition they are very easy to register (only a calliper and a balance are needed), and no additional costs or technical personnel have to be considered.

In marine areas, recommendations on sampling periods for different species and geographical areas are available from the regional conventions (OSPAR, MEDPOL, HELCOM etc).

6.2.5. Sampling frequency

Directive 2008/105/EC states that, for compliance with EQS, the frequency of biota monitoring should be at least once every year, unless technical knowledge and expert judgement justify another interval. ”*For the purpose of trend monitoring as a guideline a frequency of one every 3 years should be performed; unless technical knowledge and expert judgment justify another interval”.*

Sampling frequency should consider biological half life of contaminants, aim of monitoring, presence of anthropogenic inputs/pressure, and availability and quality of previous results or trends.

There is no ideal sampling frequency appropriate for all environmental conditions and monitoring purposes. More common sampling strategies for evaluating chemical accumulation in biota can be based on weekly frequencies (generally only for very short-term periods) or, more often, monthly, seasonal, six-monthly or at least annual. The choice of the most appropriate sampling frequency should consider and combine at least the following criteria:

- biological half life of investigated contaminants;

- the objective of the monitoring programme;

- the local presence of anthropogenic inputs and/or temporary pressures;

- the availability and quality of previous results or trends for the monitored area.

The biological half-life (or turnover) of contaminants reflects the rapidity with which, once accumulated by the organisms, these compounds can be metabolised and eventually excreted. Some metals (such as cadmium and lead) have a long turnover, in the range of 6 months, indicating that an episodic pollution event could be “registered” by the organisms for this duration.

On the other hand, metals such as copper, or polycyclic aromatic hydrocarbons, have a much faster turnover (in the range of 3–6 weeks), meaning that an episodic event could not be detected after a much longer period. Based on these considerations, a six-months frequency would not allow the detection of temporal fluctuations in bioavailability of PAHs (e.g. in a petrochemical or harbour area), while a monthly frequency would be not cost-effective to monitor lead accumulation in a coastal site.

In general terms, a surveillance programme could be based on a low-frequency (six-months/annual) sampling strategy, especially if the monitored area is not challenged by marked anthropogenic pressures. On the other hand, a higher frequency (monthly to seasonal) should be recommended in areas characterised by the presence of specific impacts and/or specific forms of pollutants (e.g. petrochemical sites, industries, river estuaries, harbours, etc.). This will allow patterns of variation to be understood and more cost-effective monitoring designs to be applied. A specific monitoring project, i.e. to evaluate the impact of a temporary activity (such as dredging) should include sampling periods before, during different phases of and after the end of operations. An "investigative" monitoring programme in an area where the source of pollution is unknown should begin with a high frequency (i.e. 1–2 months) which might be lowered depending on the results obtained and, again, the possible presence of anthropogenic impacts.

It is recommended for the purpose of trend monitoring to start at least with a cycle of one examination every 3 years. After several cycles it may be appropriate to downscale the frequency to one every 6 years.

6.2.6. Trend Analysis

The main characteristics of the data collected for the purpose of temporal trend analyses are the following:

- Collection of biota annually at the same time within each year.
- The time should be principally outside the spawning period.
- The same size range of the target species is sampled each year.
- Sampling guidelines are necessary to provide some control over both between-years biological variation (e.g. mean length, condition, stock composition) and within-year biological variation (e.g. individual fish length).

The presence of suitable biota depends on the respective water body types, and the selection of the biota must be tailored to the conditions found in the water body. The organisms chosen must be typical for the water body type and as far as possible resident species that occur frequently in the water body under investigation. This is to ensure that catching and studying the species can be guaranteed over a long period of time. In coastal waters flounder and blue mussels are suitable organisms while in inland water bodies bream, perch, chub and molluscs such as the zebra mussel can be used. It may be desirable to study two different fish species per monitoring point so that different feeding habits can be taken into account and to ensure that, if a fish species disappears, reference can at least be made to the trend in the other species.

6.3. Technical aspects of biota sampling

6.3.1. General

Either passive biomonitoring (collection of wild population) or active biomonitoring (translocation/caging of organisms) may be used. The advantages of the latter lie in the ability to choose the monitoring station, knowledge of the exposure duration, and the reduction of variability between individuals.

6.3.2. Sampling methods (passive)

6.3.2.1. Fish

Fish may be captured by trawling, netting, creels and other appropriate methods, depending on the species and location.

Electrofishing can be also used for small, shallow rivers (commonly chalk streams), drained canals or full navigational waterways with a maximum depth of 2.5 m.

The method of capture in lakes and rivers will depend on the type of water body. It is therefore not possible to use the same method of capture successfully in all types of water bodies. Anchored gillnets are used in deep, stagnant or slowly running waters; dragnets are particularly well suited for catching bream in shallow stagnant water bodies. In very large bodies of flowing water, bag nets with a fixed mouth can be used.

When fish can be sampled from either research vessels or commercial vessels, the former is the preferred option, since research vessels are likely have better facilities for processing and storing scientific samples. In both cases, the following precautions must be taken when selecting samples from the trawl catch to ensure that contamination is kept to a minimum:

- trained personnel must be present when a trawl comes on board to ensure that the sample can be isolated from possible sources of contamination during the release of fish from the net;
- the trawling time should not exceed one hour and the trawling speed should be as slow as possible to reduce damage and stress to the fish;
- fish which are visibly damaged or in bad condition must not be selected;
- clean containers should be available on deck to hold the samples temporarily before they are taken to the ship's laboratory. Containers used for holding fish collected from the ship's normal trawling operations must not be used;
- personnel must wear clean gloves when the samples are taken from the net. The samples should be transferred to the ship's laboratory as quickly as possible and rinsed with clean sea water to remove any material adhering to the surface;
- equivalent precautions should be taken on modern fisheries research vessels, when the catch is released from the net directly into facilities below deck; only material suitable for the subsequent analyses should be retained (see *Shellfish*).

For all methods of capture it is necessary to transfer the fish immediately after the catch into a net cage, which is floating in habitat water. This cage should be of sufficient size, fabricated without knots and must be freely floating in habitat water. Depending on the size of the fish, no more than 20 individuals at the same time should be kept in conditioning in one cage.

Alternatively, the fish can be kept in the transport containers, where they are provided with fresh air through a ventilation system. The advantage – compared to the net cage – is that the fish can be transported to the mobile laboratory if it has not been possible to set it up directly at the waterside.

The number of organisms sampled can be limited by the efficiency of the capture method. As a general rule, the optimal number of sampled specimens should allow 3–5 replicates for each class of investigated chemicals. Depending on the size of fish and approximate weight of tissues, individual samples or pooled samples can be considered. A single pool of tissue, or a series of pools of tissue, should be created from each sampling station. Each of the pools should be analysed for all contaminants of interest.

6.3.2.2. Shellfish

Bivalves can be sampled by hand, scuba diving, dredging or any other appropriate and convenient method. Individuals that are free of fouling and bored shells should be preferably sampled. When collecting mussels by ship, a commercial mussel dredge can be used. When collecting mussels by hand, personnel should wear gloves. Clean containers made of material suitable for the subsequent analyses should be used for transportation.

The number of sampled organisms should be sufficient for the whole set of chemical analyses and representative of the investigated area. Bivalves (especially mussels and clams) will be grouped in pools (see below) and approximately 5 replicates (each constituted by at least 3–5 specimens) should be considered for each class of chemicals. An appropriate number of specimens to be collected is normally about 100. As regards size, bivalves sampled from wild populations should be approximately 70–90% of the maximum size within the population. Such specimens will be of a similar age and therefore metabolically comparable. Sampling at a uniform size will also ensure comparability between populations.

6.3.3. Caging

The choice of an “active” monitoring strategy based on translocation procedures is a widely used approach where organisms are deployed in appropriate cages and maintained at the investigated sites for 4 weeks. The duration of exposure depends on site/species.

Caged organisms facilitate investigation in areas where native organisms are absent, and they reduce the influence of genetic/population differences, of seasonal variability or adaptive phenomena, all factors which can limit the capability to discriminate between different levels of environmental disturbance.

Analyses of caged organisms provide a time-integrated assessment of environmental quality over the 4-week translocation period, but do not reflect chronic exposures or long-term effects of chemical pollutants. They are therefore of particular importance when monitoring current bioaccumulation or monitoring exposure concentration-dose effects relationships.

Caging procedures are very well established and widely applied with mussels (*Mytilus spp*) and mosses. Generally caging is not suitable for fish because it cannot account for the natural urge to move and will lead to unnatural stress and illness. Furthermore, fewer standardised protocols are available for fish, which are often not tolerant to translocation procedures.

After collection of caged organisms (bivalves), transportation procedures are the same as described for wild specimens.

6.4. Choice of tissue for analyses and tissue preparation

6.4.1. Fish

The choice of appropriate tissues is more critical for fish and can be influenced by the monitoring aims, the classes of investigated chemicals, and the tissue availability. A number of replicates (3–5) should be prepared for analyses of each class of chemicals, pooling tissues of more specimens if necessary. For fish, the analysis of whole tissues is suggested if the objective of protection is the ecosystem. The tissue selected will also be dependent on the type of EQS used for compliance monitoring. If the EQS refers to edible (to humans) tissue, then analyses should be carried out on edible tissue (e.g. muscle tissue) rather than whole organisms.

Muscle tissues can generally provide sufficient amounts for analyses; they reflect the edible portion (by humans, but not by other organisms in higher trophic levels) and typically accumulate lipophilic pollutants such as halogenated compounds and methylmercury, and should be analysed for these pollutants. Accumulation of such compounds in muscle tissues can, however, be a long-term process, mediated by trophic transfer and greatly influenced by biomagnification, thus requiring a careful evaluation of trophic position when different species are compared; muscle concentrations do not reflect actual bioaccumulation and do not reveal recent temporal variations in chemical levels. In addition, these tissues are not a target for chemicals such as aliphatic or polycyclic aromatic hydrocarbons and the majority of trace metals.

The liver is one important target organ for some classes of chemicals, reflecting their current bioaccumulation but, depending on species and size, it may not provide sufficient tissue for analysis, unless pooled samples can be prepared.

Gills can be considered as an alternative to liver, since they are also an important target for some chemicals (not for hydrophobic organic contaminants, which accumulate in lipid-rich tissues) and do not generally represent a problem in terms of the amount of tissue available.

Dissection of fish tissues should be carried out onboard or as soon as possible after sampling in order to obtain reliable results. During dissection, biometric measurements need to be registered (length and weight of whole organisms, weight of whole liver and whole gonads). These parameters will be used to determine hepato- and gonado-somatic indices that reflect the ratio between liver (or gonad) weight and whole body weight that is useful for the choice of sampling period.

6.4.2. Shellfish

For mussels, the whole tissues can be dissected for chemical analyses. Mussels should be opened while still alive and avoiding tissue damage. Water contained within the shell is allowed to drain away. This is especially important for mussels collected in areas with high turbidity or on silt/clay bottoms; in such cases, whole tissues can be rinsed with clean seawater after being dissected.

If it is not possible onboard, organisms will be dissected in the laboratory. Before dissection, bivalve molluscs shall be allowed to depurate in clean seawater for 12–48 hrs before being processed. It should be reported whether or not the samples have been depurated. After collection, mussels will be packed in iced containers, wrapped in clean humid woven fabric (not in water) and transported to the analytical laboratory for dissection preferably within 24 hours of sampling: if longer periods are required to transport samples, organisms should be dissected and properly stored immediately.

For each sampling, 5 replicates, each constituted by the tissues of at least 3–5 specimens, should be prepared for every class of analysed chemicals. Biometric measurement (weight of tissues, weight and length of shell) should be registered for each individual before composite pools are prepared. The condition index is then calculated as the ratio between weight of tissues and weight (or length) of shells.

Samples can be stored at -20°C until processed for analyses. The same number of pools and specimens per pool should be used for comparing different sites and/or different periods.

6.4.3. Pooling of specimens of biota

It may be necessary to pool (bulk) biota tissues, particularly in the case of fish livers and mussel and other shellfish tissues, in order to provide sufficient quantities of material for chemical analysis or to save resources.

Pooling can distort the statistical analysis of log-transformed data by increasing the yearly mean concentration values and decreasing the power of tests to detect trends. It has, however, been shown that in general pooling does not influence trend identification (i.e. differences between years and associated regression coefficients will be unaffected, although trends may be less precisely estimated than from unbulked data), if pooling is consistent between years, i.e. if samples consist of the same number of pools which contain the same number of specimens.

If the sample variance is dominated by small-scale differences in time or space or by genetic and/or physiological differences between individual biological samples rather than of instrumental errors at the chemical analysis stage, it might be an option to use pooled samples. The statistical power of temporal or spatial studies is determined by the random/unexplained sample variation. The relation between the instrumental error and other sources of variation, and the relation between the cost of chemical analysis and collection and preparation of samples, will determine the number of individual samples in each pool and the number of pools that should be analysed to achieve good cost-efficiency.

Keeping the same number of individuals in the pool between years is the most important aspect, i.e. in the pool, for a given length class, the number should be the same each year. It is also important to maintain the same number of pools each year (preferably based on length-stratification of the sample if possible).

However, it has to be emphasised that there are a number of advantages in using individual samples, especially for temporal trend studies: information about sample variance is important in itself; changes in variance are often the first sign of a change in contaminant burden; freedom to choose an appropriate central measure (for right skewed distributions i.e. geometric mean values or medians) whereas pooled samples will represent arithmetic means. Furthermore, individual sampling enables adjustments for confounding factors (e.g. fat content, age, size) and detection of extreme values [Bignert et al., 1993].

6.5. Analytical methods

6.5.1. Organic compounds

Procedures for the analysis of organic contaminants in biota include extraction from wet or freeze-dried samples with organic solvents, removal or destruction of lipids, cleanup, fractionation, high pressure liquid chromatography (HPLC) or gas chromatographic separation and different kinds of detection, e.g. fluorimetric, electron capture or mass-spectrometric.

The total fat weight can be determined and used to normalise analytical results; this procedure should be considered as an alternative to weight normalisation.

The total fat weight should be determined using the method of Bligh and Dyer (1959) or an equivalent method. EU regulations discourage the use of chlorinated solvents and alternative methods, which use cyclohexane and isopropanol, have been developed [Smedes, 1999]. Critical reviews which compare the various available methods for tissue lipid determination can be found in literature [see e.g. Randall et al., 1991; Manirakiza et al., 2001].

The recommended methods for the analysis of semivolatile organic pollutants involve serial extraction of homogenised tissue samples with suitable solvents, followed by alumina and/or gel-permeation column cleanup procedures that remove co-extracted lipids. The extract is concentrated and analysed for semi-volatile organic pollutants using capillary GC.

Chlorinated hydrocarbons (e.g., PCBs and chlorinated pesticides) should be analysed by GC/ECD. The same tissue extract is analysed for other semi-volatile pollutants (e.g., PAHs, phthalate esters, nitrosamines, phenols, etc.) using GC/MS.

Unlike the situation for chlorobiphenyls (CBs), where GC techniques are used exclusively, two major approaches based on GC-MS and HPLC with variable wavelength fluorescence detection (HPLC-FLD) are followed to an equal extent in the analysis of PAHs. Decisions to perform analysis of non-chlorinated hydrocarbons and resulting data interpretation should consider that many of these analytes are readily metabolised by most fish and many invertebrates.

JAMP Guidelines for Monitoring Contaminants in Biota [OSPAR 1999] present the sampling and analysis of contaminants in fish, shellfish and seabird eggs. They are suitable for trace metals, chlorobiphenyls and some other chlorinated organic compounds, (*e.g.* DDT and metabolites, HCH, HCB and dieldrin). Technical details relating to sampling, analysis, QA and reporting are given in Technical Annex 1 (organic contaminants) and Technical Annex 2 (metals).

6.5.1. Metals

Analysis of trace metals in biota generally includes decomposition and dissolution of the sample, matrix separation and detection using element-specific spectrometric instrumental procedures (e.g. AAS, ICP-MS, ICP-OES).

Before the digestion procedure, samples should be oven-dried to constant weight or lyophilised to eliminate the water content; the oven temperature should be kept under 50°C to avoid loss of more volatile elements such as Hg. Wet weight and dry weight must be carefully measured. Analyses may also be performed on wet, homogenised samples, even though some digestion procedures are negatively affected by the presence of water; differences in water content could influence the comparison between different samples.

Digestion for trace metals normally involves a hot nitric acid or nitric acid/perchloric acid digestion and dissolution of the tissue sample. Microwave technology may be used for tissue digestion to reduce contamination and to improve recovery of metals.

A range of instrumental methods is available for the determination of metal concentrations in biota digests. It is important that possible matrix interferences on the quantification of elemental concentrations by element-specific spectrometric instrumental procedures (*e.g.* AAS, ICP-MS, ICP-OES, etc) are investigated. Procedures such as standard additions, or multiple dilutions, can be very useful. The matrix interferences encountered in analysis of metals may require case-specific digestion techniques for overcoming interference problems.

6.6. Preparation of data for analysis

Analytical data on contaminant concentrations in biota can be expressed in a variety of ways. For example, laboratories can express these data on dry weight (dw), wet weight (ww), or lipid weight (lw) bases.

Directive 2008/105/EC states that EQS for mercury, hexachlorobenzene and hexachlorobutadiene are expressed on a wet basis. In order to create comparability between data within and between sampling sites, and in order to allow comparison with assessment criteria such as EQSs, or other environmental assessment criteria, data on chemical concentration in biota should be expressed on a wet basis. In addition (but not as an alternative), other normalisation procedures can be presented, as well as appropriate and reliable conversion factors for dry weights and lipid weights.

A consequence of this approach is that the field data and data assessment criteria (EQSs) need to be expressed on the same basis, i.e. wet weight, dry weight or lipid weight. If an assessment criterion is initially expressed on a different base (unit) to the one used for the analysis of field samples, it is necessary to convert the results, for example from wet weight or lipid weight to dry weight.

Conversions are necessary to ensure that maximum use is made of the field data supplied by monitoring programmes. Conversion of field data should be only done, however, if the contaminant data for the sample are accompanied by the necessary specific conversion information (e.g. a measured value for % dry weight in the same sample).

6.7. Environmental Specimen Banking (ESB)

In the process of developing a monitoring strategy for biota it is crucial to consider the importance of environmental specimen banking. Environmental specimen banking can serve as a complement to environmental monitoring by:

- real-time monitoring, i.e., analyses of specimens for comparison with data from samples to be collected in the future for monitoring long-term trends in pollution at a particular site;

- retrospective monitoring, i.e., monitoring with reference to new and emerging polluting substances and natural substances the presence of which indicate environmental influence. Retrospective studies are also carried out when new, improved methods for analysis are introduced; these studies will also verify earlier results by way of renewed analyses;

- ecotoxicological research, i.e., research concentrating on biological effects in relation to concentrations of toxic substances in individuals and populations of animal species exposed to and influenced by environmental pollution.

7. COMPLEMENTARY METHODS

The application of complementary methods in designing monitoring programmes, in surveillance, and in operative and investigative monitoring under WFD has been briefly reviewed in CIS Guidance No. 19 [EC, 2009]. In that Guidance some complementary methods have been listed which can also be applied in sediment monitoring. This chapter offers some critical remarks on the application of passive sampling and techniques for toxicant identification to sediment and biota monitoring. Technical reports on the use of alternative effect-based (biomarker, bioassays) monitoring tools will be prepared as part of the next WG-E activity.

7.1. Passive sampling techniques

Passive samplers are the tried and tested technology for the determination of dissolved phase concentrations of bioaccumulative organics in the aquatic environment. This sampling technique is based on the deployment *in situ* or use in the laboratory of devices capable of accumulating contaminants dissolved in water or sediment pore water. Such accumulation occurs by diffusion, typically over periods of days to weeks. Contaminants accumulated in the sampler are eluted and their concentration levels measured, allowing the quantification of time-weighted average concentrations in water or equilibrium pore water concentrations in sediment. It enables time-integrated sampling or sampling of truly dissolved concentrations of contaminants in water or aquatic sediments. Even for those chemicals that are present at extremely low concentrations in the dissolved phase and are primarily accumulated in biota via dietary uptake, passive samplers generally extract sufficient amounts of residues for analysis. Passive sampling can also be employed in batch sediment extractions under laboratory conditions to provide estimates of contaminant concentrations in pore water or assessment of bioavailable concentrations of contaminants in sediment [Harmsen, 2007¸ ISO 2008]. A report for the ICES Marine Chemistry Working Group summarised the established or expected/potential performance of various passive samplers of compounds that are listed under WFD and other directives or conventions [Booij , 2009].

7.1.1. Application in sediment monitoring

Until recently sediment monitoring has relied on the determination of total or normalised contaminant concentrations. This approach, however, does not distinguish between freely dissolved and bound molecules and aims to assess the presence of chemicals rather than their chemical activity and availability [Smedes et al., 2007a, 2007b, 2007c]. Since many laboratory and field studies have demonstrated that biological effects in benthic organisms are not generally related to the total concentration of contaminants in sediments, alternative and more representative measures of the bioavailable fraction of contaminants in sediments are required. In addition, it has been shown that traditional empirical models tend to overestimate pore water concentrations.

The application of passive sampling to sediment monitoring can be undertaken *in situ* with buried passive samplers or in batch experiments in the laboratory following grab sampling or coring (and sectioning). Passive samplers can be used to:

- determine freely dissolved contaminant concentrations in pore water;
- estimate sediment-pore water partition coefficients for contaminants of interest;
- measure contaminant desorption rates;

- estimate the entire fraction of contaminants available for desorption within a relatively short time scale or fraction effectively contributing to the partitioning with pore water and/or biota;

- measure surface water/pore water activity ratios to estimate whether sediments act as a source or sink for contamination in the overlying water.

The most commonly used passive sampling approach is based on the principle that the passive sampler is exposed to a sediment sample until a thermodynamic equilibrium between the two phases is established. According to partition theory, which applies to most hydrophobic organic contaminants, the concentration of compound in the sampler is directly proportional (by the equilibrium partitioning coefficient between sampler and water) to the freely dissolved concentration of sampled compounds in pore water. Because this concentration is considered to be the driving force for the uptake of the contaminants by aquatic organisms, the bioavailability of a substance can be directly assessed using passive samplers. However, depending on sampler characteristics (e.g. surface and thickness of the sampler, diffusion coefficient in the sampler material), equilibrium may not be established for the most hydrophobic compounds during exposure and therefore performance reference compounds (such as used for surface water deployments) can be used to quantify sampler-pore water exchange kinetics and dissolved concentrations in such situations.

In all cases it is absolutely crucial to select appropriately the combination of sampler and sediment volumes in order to avoid significant depletion of the sediment and consequently of the pore water phase. The true freely dissolved concentration of contaminant in pore water can be determined when the sampler’s sorption capacity is kept well below that of the sediment sample to avoid depletion during the extraction. When the sorption capacity of sampler to sediment is kept high, samplers can be used to measure the amount of total contaminant in sediment that is available for release to the aqueous phase within a given time. This represents the fraction available to take part in partitioning with sediment organisms. The contaminants remaining in the sediment following such extraction can be considered effectively unavailable. This fraction can also be estimated by repeated/successive extractions of the sediment with an adsorbent phase such as Tenax. Such procedures also enable the quantification of contaminant desorption rates.

The concentration difference between the concentrations in pore water determined from the sediment versus those from the overlying water give direct information on the chemical activity difference between sediment and water, and on the direction of the contaminant diffusion at the sediment−water interface as well. This enables identification of sites where remediation of sediment may be appropriate treatment. Other parameters such as sedimentation rates and the resolution of sediment sampling close to the sediment–water interface are crucial for such measurements.

For metals, the technique of diffusive gradients in thin films (DGT) provides an important contribution to understanding the processes that metals undergo in sediments. DGT provide measurements in sediments that can be reported either as the mean flux of labile metal species to the device during the deployment time, or as the mean interfacial concentration in pore water. For a given device and deployment time, the interfacial concentration can be related directly to the effective concentration of labile metal [Davison et al., 2007]. This concentration represents the supply of metal to any sink, be it DGT or an organism that comes from both diffusion in solution and release from the solid phase. The primary use of DGT in sediments has been to investigate the distribution of solutes (metals) at high spatial resolution and to interpret the dynamics of the pollutant release from sediment. Pore water concentration profiles with a fine resolution can be obtained by deploying DGT probes vertically in sediment and across the sediment–water interface. Modelling of metal accumulation in DGT with increasing exposure time can allow the estimation of sediment–water partition coefficients for metals of interest.

7.1.2. *Application in biomonitoring*

Knowledge of dissolved phase chemical concentrations is a critical part of understanding how aqueous exposure levels relate to the pollutant concentrations measured in organisms at various trophic levels of aquatic ecosystems. The freely dissolved concentrations of pollutants represent the driving force for bioconcentration. Thus, passive samplers enable *in situ* determination of hydrophobic bioaccumulative organic compound exposure to organisms at the lowest trophic level (filter feeders, e.g. mussels) in nearly all food chains [Huckins et al., 2006; Smedes, 2007]. The estimation of bioaccumulation factors (BAFs) in certain species of concern (e.g. mussels) has been demonstrated. Moreover, since contribution of dietary uptake of organic compounds with log K_{ow}s <5.5 is generally very small, organism exposure assessment can be potentially extended to higher trophic levels for less hydrophobic compounds.

Studies have demonstrated that passive samplers are biomimetic when diffusional partitioning processes mediate concentrations in organisms of concern (i.e., when residue accumulation in organism tissues follows equilibrium partitioning theory). But the large number of variables, which potentially affect the accumulation of hydrophobic organic compounds in biota, suggests that it is unrealistic to expect any single passive sampler to be biomimetic of all biomonitoring organisms. Also, it is similarly unrealistic to expect that one or two species of biota mimic bioaccumulation in all organisms of concern.

Variables affecting pollutant accumulation in passive samplers are limited to physicochemical properties of the sampled chemical, exposure site conditions, and exposure scenario factors such as the constancy of chemical concentrations during the exposure period. The ability to generate chemical-specific calibration data and then adjust these values to site-specific conditions (e.g. using so-called performance reference compounds; PRCs) [Huckins et al., 2002] means that analyte concentrations obtained using passive samplers are directly comparable across sample sites.

There are some fundamental similarities in the characteristics and processes affecting the accumulation of hydrophobic organic compounds in biota and passive samplers:

- diffusion of non-polar compounds through non-porous organic polymers used in construction of passive samplers for these substances, such as low density polyethylene and silicone, has been shown to be similar to diffusion across biomembranes;

- the processes of pollutant diffusion across the water boundary layer and the lipid-like membranes of passive samplers and aquatic biota, and the partitioning between the polymers/lipids and the exposure water (according to equilibrium partitioning theory), are important factors in the accumulation of hydrophobic organic compound residues in both matrices;

- The uptake rate, defined in ng/time, is only dependent on the surface and if the volume/surface ratio (=thickness) is high, the time required to get equilibrium is high for both samplers and organisms.

On the other hand, there are some critical aspects that should be taken into account in comparing data obtained from passive samplers and biomonitoring organisms;

- When the accumulation of hydrophobic organic compounds in biota occurs solely by respiration or dermal absorption, there are significant correlations between the uptake rate constants measured in organisms used for biomonitoring and the passive sampler; in passive samplers, concentrations are often higher than those in biomonitoring organisms because there is a larger surface area in contact with the sampled medium;

- Although the relative magnitudes of uptake rate constants of passive samplers and organisms can be similar, the depuration rate constants are usually much greater in biomonitoring organisms than in passive samplers. The associated half-lives of residues in biomonitoring organisms are much shorter than in passive samplers;

- Active physiological processes such as metabolism may play a role in fast clearance from biomonitoring organism tissues. The lower depuration rate constant values in passive samplers compared with biota have a major effect on the retention of contaminants that are absorbed during episodic exposure events;

- Direct comparison of partition coefficients with BAFs can only be made when both passive samplers and biomonitoring organisms have attained equilibrium. Since many passive samplers are designed to remain in the linear uptake mode during typical exposure periods of several weeks, the attainment of equilibrium by passive samplers is an exception rather than a rule;

- If target compounds are environmentally persistent (i.e. not readily biotransformed) and dietary uptake is very limited, an improvement in the comparability between the two sampling matrices (i.e. biota and passive samplers) can be observed;

- When diet plays a major role in the uptake of hydrophobic compounds (e.g. in organisms at higher trophic levels), the patterns of hydrophobic organic compound residues in biomonitoring organism tissues and passive samplers will be different;

- Better correlations can be usually found with caged organisms (active biomonitoring). In an ideal case both methods provide a time-integrated assessment of environmental quality over the same exposure period. Such an approach does not, however, reflect chronic exposures or long-term effects of chemical pollutants (see section 6.3.3);

- In bivalves, BAFs inversely related to exposure concentration were observed in some cases because of the presence of chemical stressors which induced bivalve closure or reduced feeding;

- Unlike biomonitoring organisms, passive samplers accumulate sufficient residue mass for the quantitation of ultra-trace levels of extremely hydrophobic contaminants.

Nevertheless, monitoring by passive samplers has some practical advantages over the use of caged organisms:

- initial concentrations of contaminants in samplers are negligible, whereas it is often difficult to obtain non-contaminated test organisms;

- passive samplers do not metabolise pollutants;

- losses due to mortality are avoided;

- unlike biomonitoring organisms, samplers can be applied in environments with a very broad range of water quality parameters where biomonitoring organisms may not survive;

- the geographical range of available biomonitoring organisms limits their applicability, whereas passive samplers can be deployed in almost any environment;

- the uptake process in samplers is simple (diffusion and sorption) compared with that active in organisms;

- dissolved concentrations of pollutants accumulated by passive samplers are clearly bioavailable, whereas the contribution of non-incorporated residues in the gut complicates the estimation of contaminant bioavailability from chemical body burdens in whole organisms;

- passive samplers better retain contaminants that are absorbed during episodic exposure events (integrative sampling providing time-weighted average concentrations over a long period);

- certain behavioural, physiological and anatomical characteristics of biomonitoring organism species affect bioaccumulation;

- the analytical variability of the analysis of passive samplers is in most cases lower than that associated with matrices such as biota or sediment. This is because the samplers have a constant composition and sorption properties. Moreover, the level of matrix interferences is lower with extracts from passive samplers than with extracts from biota and sediment.

7.2. Sediment ecotoxicity test for the evaluation of ecological status and investigative monitoring

Chemical analysis of pre-selected sets of toxicants (e.g. priority pollutants) is often not able to explain ecotoxicological effects of complex environmental samples. Risk assessment based on concentrations, e.g. of priority pollutants in sediments or water, obviously does not reflect the risk of the actual mixture of contaminants, but only the risk of those pre-selected toxicants.

Bioassays, biomarkers and other ecotoxicological tests are useful tools for the evaluation of the real state of sediment in which both known and unknown contaminants are present at concentrations sufficient to cause toxicity to the test organisms. Effect-based monitoring is also useful for the development of investigative monitoring. Through a field inventory the long-term impact on benthonic fauna can be investigated. Combining the three assessment methods (chemical, bioassay, ecology) can give an answer (called the Triad approach) that cannot be given by any of the individual methods by themselves. The Triad approach has been described in detail by Chapman [1990].

There is a need for new monitoring tools that help to understand the link between chemical and ecological status. Combined biological and chemical–analytical approaches make important progress towards an identification of those toxicants that are relevant for site-specific risks and towards an estimation of the portion of an effect that can be explained by the analysed chemicals.

Toxicity identification evaluation (TIE) and effect-directed analysis (EDA), which both combine biological and chemical analysis with physicochemical manipulation and fractionation techniques, have been shown to allow for toxicant identification in many matrices and for many toxicological endpoints.

TIE on sediment is based on guidance published by the United States Environmental Protection Agency [US EPA, 2007]. The basic concept in TIE is to use physical/chemical manipulation of a sample to isolate or change the potency of different groups of toxicants potentially present in a sample. Rather than using a chemical detector to determine whether a change has occurred, a biological test, in this case a toxicity test, is used as the “indicator” to determine whether the manipulation has changed toxicity. The EPA Guidance document provides guidance for both interstitial water and whole-sediment TIEs and combines our current understanding of TIE methods for both marine and freshwater interstitial waters and whole sediments. This guidance does not include approaches for the implementation of sediment TIE in a regulatory context.

An upcoming alternative technique is Effect Directed Analysis or EDA, which is attracting interest mainly in Europe [Brack et al, 2007 and reference therein]. Based on a biological response, indicating a potential or actual undesirable effect, the responsible compounds may be identified by fractionation procedures and chemical analysis and counter-measures designed. Prerequisites for a successful application of the approach are (*a*) significant concentrations of specifically acting toxicants rather than an even distribution of potential toxicity over high numbers of compounds in very low concentrations, as may be observed in samples taken far from pollution sources and (*b*) the use of a toxicological endpoint that allows the detection of specific effects, rather than only baseline toxicity.

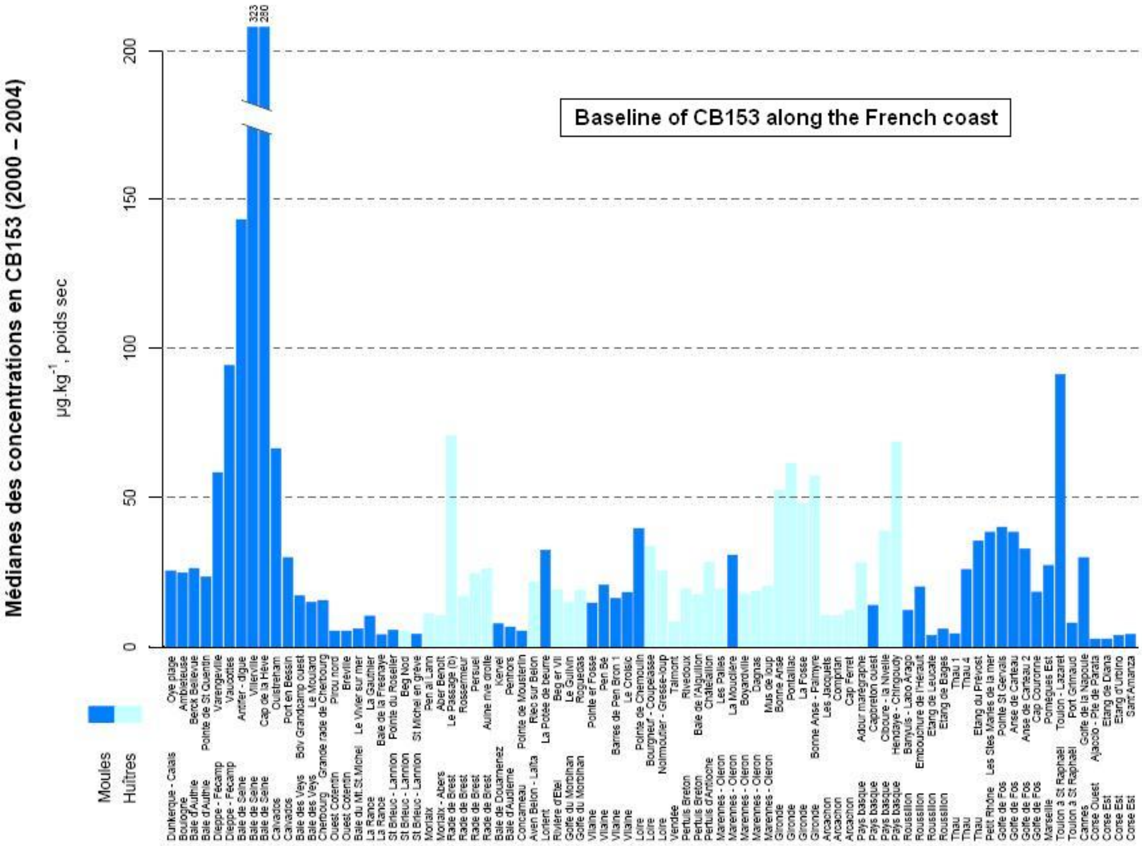
While TIE originates from effluent control in a regulatory context in the US, EDA is a more scientific approach developed by analytical chemists to identify unknown hazardous compounds in various environmental or technical matrices. TIE is based exclusively on *in vivo* testing, while EDA is applied to both *in vitro* and *in vivo* tests in order to detect active fractions and compounds. EDA is not restricted to identifying the cause(s) of acute toxicity; it also aims to identify potentially hazardous compounds in the environment, even if the concentrations present should not cause acute effects. Thus, extraction and pre-concentration procedures as well as the analysis of sensitive sub-lethal biochemical *in vitro* responses are important tools in EDA.

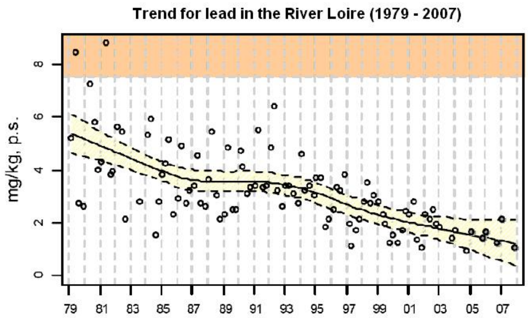
8. CASE STUDIES

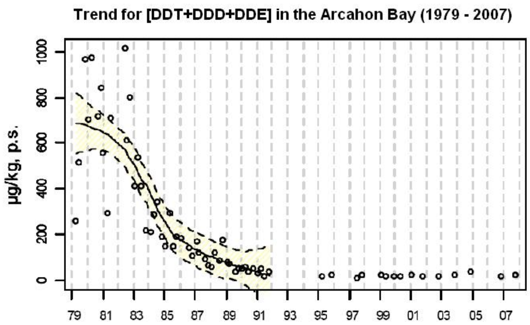
8.1. Case study 1

Background information
Title/Name of case study: RNO (Réseau National d'Observation de la qualité du milieu marin) French National monitoring network from 1974 to 2007. 1974 - 1988 : measurements in water samples (hydrology and some contaminants) **1979 - 2007 : Mussel Watch : contaminants in biota (this case study)** and sediment survey 2008 : Because of the WFD application, end of the Mussel Watch, back to the past (water).
Type of case study : **Spatial and temporal trends monitoring for contaminants in biota.** a 30 years mussel watch type monitoring network in France
Reporting Institution : **IFREMER (Institut Français de Recherche pour l'Exploitation durable de la Mer)** French Institute of research for the sustainable exploitation of the sea
Web-Link: http://www.ifremer.fr http://wwz.ifremer.fr/envlit
Main sources for further information; literature: Contact for the Mussel Watch (coordinator) : Didier.Claisse@ifremer.fr From 1983 to 2006 an annual bulletin presented results of parts of the network. They can be downloaded at http://wwz.ifremer.fr/envlit/documents/bulletins/rno
Objective of case study - Brief background information: The aim of the RNO was to evaluate the levels and trends of the coastal chemical contamination. It was created in 1974 by the Ministry in charge of the Environment and co-ordinated by IFREMER. The biota branch started in 1979 and contaminants in water were no longer measured in water after 1985 as they gave very poor results. This monitoring programme in biota was the main tool providing systematic knowledge of the contamination levels along the French coast. It was also the provider of French data for the international OSPAR convention. It was recently extended to the overseas departments, Martinique, Guadeloupe (Caribbean Sea) and the island of La Réunion (Indian Ocean). From its beginning in 1979, the RNO Mussel Watch collected about 10 000 biota samples, on which 150 000 measurements were made.
Contribution to
Specific contribution linked to WFD monitoring programmes In the frame of WFD, OSPAR and MEDPOL some sampling sites have been kept. Knowledge of contamination helped to design the monitoring programme of WFD.
Description About 80 sampling sites along the French coast were sampled (Mussels and oysters) first quarterly then twice a year (February and November). Samples were homogenized and freeze dried before analysis. Parameters were metals (9), DDT, DDD, DDE, a and g-HCH, PCBs (9 congeners) and PAH (37). All the samples have been archived in a sample bank since 1981.
Experiences gained - Conclusions - Recommendations **Experience gained** (see figures below) **:** National baseline for 9 metals, 14 organochlorines, 37 PAH. Reference sites and hot spots identified Temporal trends for 33 contaminants Knowledge of seasonal variations in biota as the sampling frequency was 4/year from 1979 to

2002.
Monitoring strategies, sampling, and analysis expertise. QA long experience
33 years time series and 30 years sample bank.







Conclusion:
Although it considers only bioaccumulative contaminants, this programme has greatly advanced the knowledge of marine contamination in France. It has also been a vehicle for improvement of analytical techniques in the marine environment.

Recommendations:
Quality has a price. Partners cannot be selected only on money criteria. The success of this program is largely due to the creation of a stable and durable community of partners. A sense of ownership of the project by the participants is essential. An exclusively commercial relationship with laboratories is inadequate.

Outlook - Next steps – Accessibility of results/information

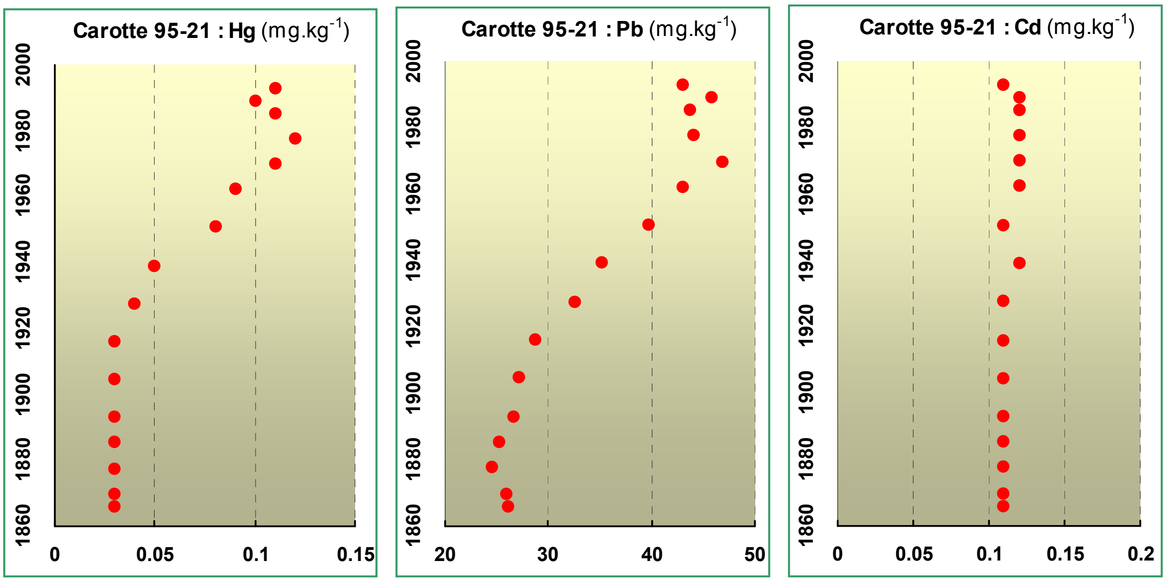
Data are archived with those from other monitoring networks (microbiology, phytoplankton, benthos…) in the database QUADRIGE[2]. Various tools and output software were developed to give public access to the raw data and trend analysis. http://wwz.ifremer.fr/envlit/resultats/surval__1 Then "resultats par paramètre"
Data can also be obtained by request to the coordinator.

8.2. Case study 2

Background information
Title/Name of case study: RNO (Réseau National d'Observation de la qualité du milieu marin) French National monitoring network from 1974 to 2007. 1974 - 1988 : measurements in water samples (hydrology and some contaminants) **1979 - 2007 :** Mussel Watch : contaminants in biota and **sediment survey (this case study)** since 2008 : Because of the WFD application, the program was modified.
Type of case study : **Spatial and temporal trends monitoring for contaminants in sediment.**
Reporting Institution : **IFREMER (Institut Français de Recherche pour l'Exploitation durable de la Mer)** French Institute of research for the sustainable exploitation of the sea
Web-Link: http://www.ifremer.fr http://wwz.ifremer.fr/envlit
Main sources for further information; literature: Contact (coordinator) : Didier.Claisse@ifremer.fr From 1983 to 2006 an annual bulletin presented results of parts of the network. They can be downloaded at http://wwz.ifremer.fr/envlit/documents/bulletins/rno
Objective of case study - Brief background information: The aim of the RNO was to evaluate the levels and trends of coastal chemical contamination. It was created in 1974 by the Ministry in charge of the Environment and co-ordinated by IFREMER. The sediment branch started in 1979 and contaminants in water were no longer measured in water after 1985 as they gave very poor results. This monitoring programme in sediment was conducted sporadically until 1992. From 1993 it has been formalized with a consolidated sampling design. It was intended to give knowledge of contamination levels along the French coast, further offshore than biota, and with an integration over several years rather than months (biota). It was also the provider of French data for the international OSPAR convention.
Contribution to
Specific contribution linked to WFD monitoring programmes In the frame of WFD, OSPAR and MEDPOL the sampling design has been modified (see below).
Description The first centimetre of the sediment can incorporate several years of inputs. Until 2007 the strategy was to cover the entire French coastline every ten years by means of annual sampling campaigns covering a different section of coastline each year. Measured contaminants are the same as in biota, accompanied by descriptive and normalizing parameters such as particle size, organic carbon, carbonates, aluminium, iron, lithium, manganese. On a few selected points, deep cores are taken and cut into many horizons. The analysis and dating of each of them can retrace the history of contamination over several decades (see below). WFD application has changed the frequency of sampling to 6 years instead of 10 and reduced the number of sampling sites for some regions. Cores are taken with a box corer in order not to mix the sediment layers. Samples are freeze dried before analysis. In addition to normalizing parameters, contaminants measured are metals (9), DDT, DDD, DDE, a and g-HCH, PCBs (9 congeners) and PAH (37). Most of the Samples are archived in a sample bank.
Experiences gained - Conclusions - Recommendations **Experience gained** (see figures below) **:** Experience in results normalisation. National baseline for 9 metals, 14 organochlorines, 37 PAH. Reference sites and hot spots identified Historical trends on some sites.

Monitoring strategies, sampling, and analysis expertise. QA long experience.
Sample bank.

Historical trends for Hg, Pb, Cd in a deep core taken in the *Golfe d'Aigues-Mortes* in 1995.



Conclusion:
Although it considers only hydrophobic contaminants, this program has greatly advanced the knowledge of marine contamination in France. It has also been a vehicle for improvement of sampling and analytical techniques in the marine environment.

Recommendations:
Quality has a price. Partners cannot be selected only on money criteria. The success of this program is largely due to the creation of a stable and durable community of partners. A sense of ownership of the project by the participants is essential. An exclusively commercial relationship with laboratories is inadequate.

Outlook - Next steps – Accessibility of results/information

Data are archived with those from other monitoring networks (microbiology, phytoplankton, benthos…) in the database QUADRIGE[2].

Data can be obtained by request to the coordinator.

8.3. Case study 3

Background information
Title/Name of case study: Monitoring of contaminants in sediments and suspended particulate matter.
Type of case study: Routine measurements at sampling sites in the freshwater reach of the river Elbe, and in North Sea estuaries started between 1980 and 1990 for surveying temporal and spatial development of concentrations of particle-bound contaminants.
Reporting Institution for the case study**:** Federal Institute of Hydrology, Koblenz.
Web-Link: Elbe: www.arge-elbe.de/wge/Download/DDaten.php; www.arge-elbe.de/wge/Download/DBerichte.php
Main sources for further information; literature: Heininger, P., J. Pelzer, E. Claus, u. S. Pfitzner: Results of long-term sediment quality studies on the river Elbe. Acta hydrochim. hydrobiol. 31, 2003 (4-5), 356-367; Heininger, P., Schild, R., de Beer, K., Planas, C., Roose, P., Sortkjaer, O: International pilot study fort he determination of riverine inputs of PAHs to the maritime area on the basis of a harmonised methodology. (2007): Trace metals as indicators for the dynamics of (suspended) particulate matter in the tidal reach of the River Elbe.- In: U. Förstner und B. Westrich (ed.): Sediment Dynamics and Pollutant Mobility in Rivers, Chapter 7.4: S. 296-304. Springer-Verlag Berlin Heidelberg, ISBN-Nr. 978-3-540-34782-8); Schubert, B., Pies, C., Heil, C.: Schadstoffmonitoring von Schwebstoffen und Sedimenten in Ästuaren (Monitoring of contaminants in suspended particulate matter and sediments in estuaries).- In: Aspekte des Schadstoffmonitoring an Schwebstoffen und Sedimenten in der aquatischen Umwelt, 18. Chemisches Kolloquium, 16.-17.06.2009, Koblenz; Guidance document 19: Case study „ Conversion of pollutant concentrations measured in suspended particulate matter (SPM) into total concentrations in the whole water sample; Claus, E.: Empfehlung für Schwebstoffuntersuchungen an Überblicksmessstellen im Elbeeinzugsgebiet; ordered by: Ad-hoc-Arbeitsgruppe der Arbeitsgruppe Oberflächenwasser der Flussgebietsgemeinschaft Elbe, 2010 (Draft).
Objective of case study - background information: In surface waters, some of the priority substances are predominantly adsorbed to solids, i.e. to sediments and SPM. For trend assessment, these contaminants are monitored in sediments and SPM. For trend detection of particle-associated contaminants in solids, samples should represent a defined sedimentation period. For sediments, sampling depth should therefore reflect the period under consideration, i.e. sedimentation rates should be known. However, often these are not known or too small for representing the surface sediment of a defined period of e.g. one year reliably. Sampling periods of SPM, however, are well defined, and SPM can be used as an alternative for sediments for trend monitoring. The objective of the case study is to support the use of SPM for trend monitoring and compliance checking, where appropriate.
Contribution to support trend monitoring of contaminants in sediments and compliance checking with EQS
Specific contribution linked to WFD monitoring programmes Specific monitoring of contaminants adsorbed to suspended particulate matter and sediments. Monitoring results can support trend monitoring of contaminants in sediments and compliance checking with EQS, where these are available for sediments on an EU or national level.

Description At several stations along the freshwater reach of the river Elbe and in the North Sea estuaries, particle bound contaminants are monitored in sediments and SPM. In areas of low hydrodynamic energy with fine-grained sediments and high sedimentation rates, sediments are mainly sampled with grab samplers or a corer. Particularly, if areas of low energy are lacking, SPM is sampled by sedimentation traps over a period of usually 4 weeks or by flow-through centrifuges over periods of several hours. Frequency of sediment sampling varies from 1 – 2 samples/a to 12 samples/a. SPM is generally sampled 12 times/a. Sampling frequency depends on the hydromorphological regime and sedimentation rates. As contaminants strongly tend to accumulate in fine-grained particles and organic matter, a correction for differences in grain size distribution is carried out (normalisation), unless samples show similar composition. Assessment of contaminant concentrations takes into consideration river discharge. Especially in estuaries, concentrations are strongly influenced by the freshwater discharge.
Experiences gained - Conclusions – Recommendations **Experience gained:** Monitoring programmes have been operated by the Working Committee for the Protection of the River Elbe (ARGE Elbe) and the Federal Institute of Hydrology for more than 10 – 20 years. A reliable trend assessment requires long term measurements. Comparative measurements revealed, that contaminant concentrations resulting from monitoring in sediments and in SPM at the same or a nearby stations are approximately equivalent, provided potential differences in sample composition are corrected for and sediment samples reflect a similar sedimentation period as SPM. **Conclusion**: Sampling of surface sediments requires less time, effort and cost than sampling of SPM and easily yields sufficient sample mass for analyses . Usually, grain-size correction is required for sediments, unless samples are predominantly fine-grained. Also contaminant concentrations in SPM sampled with sedimentation traps have to be normalised, as fines may not be separated completely. If a centrifuge is used for sampling SPM, no further grain-size correction is required. Usually, sediments do not reflect a defined period, unless high sedimentation rates prevail. In contrast, SPM can be sampled over a defined period. SPM sampling can be applied, if SPM concentrations are >10 mg/l. **Recommendations**: - Sediment samples and SPM sampled with sedimentation traps should be normalised, e.g. by analysing a fine fraction. - The frequency of sampling has to take into account hydrodaynamics and sedimentation rates prevailing at sampling sites. - Especially, when using SPM, the assessment has to take into consideration river discharge. Also in estuaries, freshwater discharge should be considered in the assessment. - For a reliable trend assessment, time series should be longer than 10 years.
Outlook - Next steps – Accessibility of results/information

8.4. Case study 4

Background information

Title/Name of case study:

Sediment cores for retrospective monitoring of contaminants in lakes.

Type of case study:

Sediment stratigraphy (core) studies to reveal recent history of contaminants to be strongly restricted or phased out (e.g. Priority Hazardous Substances).

Reporting Institution:

Finnish Environment Institute.

Web-Link: http://www.ymparisto.fi

Main sources for further information; literature:

Objective of case study - background information:
To monitor the progressive reduction in the contamination of priority substances (PS) and phasing out of Priority Hazardous Substances (PHS).
To assess compliance with the no deterioration objective (concentrations of substances are below detection limits, declining or stable and there is no obvious risk of increase) of the WFD.
To assess long-term changes in natural conditions and to assess the long term changes resulting from widespread anthropogenic activity.

Contribution to:

Specific contribution linked to WFD monitoring programmes
Cost-effective method to check the recent history of substances with high affinity to particle phase. The concept is based on short sediment core sampling (ca. 10 to 30 cm), checking the recent history of priority hazardous substances such as HCHs, HCB, HCBD, Hg, PAHs and TBT. This is useful information for the assessment purposes in the first phase of WFD (before 2015). The method is readily applicable to many candidate substances such as PCB, PCDD/F and PFOS.

Description
Short core sediment monitoring/survey to look at the recent history (<30-40 yrs) of contaminants. The top of the sediment is sliced to e.g. 3-6 slices (a´ 0.5-3 cm) and one reference slice from deeper sediment layers (> 20cm) depending on the sedimentation rate.

There is good knowledge of the typical sedimentation rate in Nordic lakes from tens-hundreds of lakes, sampled e.g. for Hg surveys. The sedimentation rate in these lakes can be from 0.5-2.0 mm/yr to more than 10 mm/yr. Sedimentation is not, however, several centimetres per year. Note that these lakes represent a very significant portion of the whole lake population in Europe.

In comparison to a grab or single sample of sediment surface, slicing the sediment reveals the relative timescale of the subsequent samples. Analysing only one top layer does not reveal any timeframe, only the present status of the sediment, at least on the first sampling occasion.

After analysing this "trend" of ca. 5 slices (with 2-3 replicates and perhaps pooling), one can shift to biota (fish) monitoring to follow the future changes (yearly) of the same contaminants. In Finland, this strategy/method will be applied to surveillance, impact and investigative monitoring in all River Basin Management Areas. Sediment cores have been analyzed for 5-10 locations (depending on the substances) and will be studied consequently ca. 5-10 locations per year.
Experiences gained - Conclusions - Recommendations **Experience gained and conclusion:** In the past, many of the polluted lakes were dated using radiochronology. Sediment dating is very much site (and core) specific, but the general picture is possible to reveal for substances with little degradation/diagenesis in the sediment and long history in use/emissions and later in regulation (PAHs, most OCPs, metals, TBT, PBDE). This has been demonstrated widely for e.g. Pb, Hg, PCB and PCDD/F in similar studies in Boreal and Alpine European lakes as well as in North America and Arctic regions (see literature above). The accumulation conditions in (well selected) lakes are not as difficult to interpret as in marine systems. **Recommendations**: The concept works only for certain types of environments such as lake sites with relatively well known sedimentation rates and little influence of water currents. The technique is also applicable to sheltered coastal conditions, at least in the Baltic Sea.
Outlook - Next steps – Accessibility of results/information Short core sediments can provide some information, which it is not possible to gain with other WFD matrices. Retrospective analysis of cores is invaluable information on the effectiveness of the past control policies for Priority Hazardous Substances and other strongly controlled PBT/vPvB substances. Regionally coherent sediment data can be compiled for larger geographical assessments and status reports. Results will be made available in data bank of SYKE, utilised in WFD status reporting and in scientific reports and publications.

8.5. Case study 5

Background information
Title/Name of case study: PCDDs, PCDFs, DL-PCBs, NDL-PCBs, and PBDEs in fishes collected from the urban tract of the River Tiber
Type of case study: A preliminary monitoring activity was undertaken to individuate the priorities in terms of POPs contamination for the development of a research project in the area of urban ecology in the City of Rome and for the evaluation of fish species as indicators of water quality contamination.
Reporting Institution: Italian National Institute of Health
Web-Link: http://www.iss.it/
Main sources for further information; literature: Miniero R, Guandalini E, Brambilla GF, Dellatte E, Iacovella N, Abate V, De Luca S, Iamiceli A, di Domenico A (2010). PCDDs, PCDFs, DL-PCBs, NDL-PCBs, and PBDEs in fish collected from the urban tract of the river Tiber. *Monitoring and Assessment*, Submitted for publication
Objective of case study - background information: The main objectives of this preliminary monitoring programme were: the individuation of relative performance of the chub (*Leuciscus cephalus*) in the assessment of chemical contamination, individuation of priorities of specific tracts of River Tiber within the urban environment, prioritization of chemical contaminants among the ones taken into consideration.
Contribution to :
Specific contribution linked to WFD monitoring programmes Assessment of the chemical contamination of a freshwater system in an urban context
Description Substances monitored: Dioxins (PCDDs), furans (PCDFs), dioxin-like action polychlorobiphenils (DL-PCBs), non dioxin-like action polychlorobphenils (NDL-PCBs), and polybromodiphenylethers (PBDEs) *Sampling area:* The sampling sites are located at three sites along the river Tiber in Rome, all of them lying in the urban area. Collected specimens: the European chub was chosen as a representative of species living in the water column for the purposes of the study. Number of samples and frequency: At each site 1 pool of 10 individuals was analysed. From each specimen, the skin was removed and only the fillets were taken into consideration for the POPs determination.
Experience gained: The eel is going to be abandoned as a popular bioaccumulation indicator, because is in decline and a suitable substitute needs to be found On this issue, the chub shows some interesting characteristics, but its role in term of bioaccumulation indicator needs to be further clarified. This species is common in freshwater basins and relatively easy to collect. **Conclusion**: Among the three sectors of the river Tiber investigated, some contamination differences were found in the fish sampled. On the whole, these differences appear to be of minor importance, indeed, in analysis of the chemical-specific contamination profiles, the chub samples show an

inter-site consistency. This appears particularly evident for PCDD and PCDF. **Recommendations**: The chub's capability as an indicator of chemical pollution needs to be further explored. In particular in terms of site-specific detection of contamination profile. To this end, it is also recommended that parameters about its biology need to be taken into account to define its role as a bioaccumulation indicator.
Outlook - Next steps – Accessibility of results/information This preliminary study constitutes a basis for developing a research project in the field of urban ecology related to a river basin. The Department of Environment and Primary Prevention (*Ambiente e Connessa Prevenzione Primaria*) of the Italian National Institute of Health is an important Italian institution involved in developing projects at national and international level on POPs human and environmental risk assessment. Info about this issue can be found via the following website (in Italian and in English): http://www.iss.it/

8.6. Case study 6

Background information
Title/Name of case study: National Swedish Contaminant Monitoring Programme in Marine Biota
Type of case study : **Spatial and temporal trends monitoring for contaminants in biota.** Monitoring activities within the Swedish national contaminant programme in marine biota
Reporting Institution : Environmental Protection Agency (Sweden)
Web-Link: www.naturvardsverket.se
Main sources for further information; literature: *Bignert, A., Nyberg E., Asplund L., Eriksson U., Wilander A., Haglund P. 2007. Comments Concerning the National Swedish Contaminant Monitoring Programme in Marine Biota. Report to the Swedish Environmental Protection Agency, 2007-03-31. 128 pp.* Bignert A., Göthberg A., Jensen S., Litzén K., Odsjö T., Olsson M. and Reutergårdh L. 1993. The need for adequate biological sampling in ecotoxicological investigations: a retrospective study of twenty years pollution monitoring. The Science of the Total Environment, 128 (1993) 121-139. Green N.W. and Rönningen. 1994. Contaminants in shellfish and fish 1981-92. Joint Monitoring Programme (JMP) Norwegian biota data. NIVA 1995, report no. 585/94
Objective of case study - Brief background information: The main objectives of the monitoring programme in marine biota could be summarised as follows: to estimate the levels and the normal variation of various contaminants in marine biota from several representative sites, uninfluenced by local sources, along the Swedish coasts. The goal is to describe the general contaminant status and to serve as reference values for regional and local monitoring programmes to monitor long term time trends and to estimate the rate of found changes – to assess compliance with the no deterioration objective. to estimate the response in marine biota of measures taken to reduce the discharges of various contaminants to detect incidents of regional influence or widespread incidents of 'Chernobyl'- character and to act as watchdog monitoring to detect renewed usage of banned contaminants. to indicate large scale spatial differences to explore the development and regional differences of the composition and pattern of e.g. PCB's, HCH's, DDT's and PCDD/PCDF as well as the ratios between various contaminants.
Contribution to:
Specific contribution linked to WFD monitoring programmes Surveillance monitoring design and operational monitoring design for biota
Description Substances monitored: Metals, for example Hg, Cd, Pb and Cu and organic substances, for example PCB, DDT, Lindane, brominated flameretardants, dioxins, PFCs and PAHs. *Sampling area:* The sampling sites are located in areas regarded as locally uncontaminated and, as much as possible, uninfluenced by major river outlets or ferry routes and not too close to heavily

populated areas.

Collected specimens: For many species adult specimens are less stationary than sub-adults. To increase comparability between years, young specimens are generally collected. Only healthy looking specimens with undamaged skin are selected.

Number of samples and frequency: At the new Baltic and west coast sites in general 2 pools of 12 individuals are analysed from each site/species (herring and perch). 10-12 individual specimens from the old Baltic sites (reported to HELCOM) and Swedish west coast sites (reported to OSPARCOM) are analysed annually from each site/species. For guillemot eggs and perch (old sites), 10 individual specimens are analysed. Organochlorines in blue mussels are analysed in pooled samples containing 10-20 individual specimens in each pool.

Experiences gained - Conclusions - Recommendations
Continuous development of design for both a spatial and temporal monitoring programme and also increased knowledge of choice of matrix. The importance of quantifying objectives.

Conclusion:
Herring is the most commonly used indicator species for monitoring contaminants in biota within the monitoring programme (COMBINE) in the HELCOM convention area and is sampled by Finland, Estonia, Poland and Sweden. Herring muscle tissue is fat and thus very appropriate for analysis of fatsoluble contaminants i.e. hydrocarbons.

Cod is among the ‘first choice species’ recommended within the OSPAR Joint Assessment and Monitoring Programme (JAMP) and HELCOM COMBINE. The cod liver is fat and organic contaminants are often found in relatively high concentrations. For that reason, it is also a very appropriate matrix for screening for ‘new’ contaminants.

Mussels are one of the most common used organisms for monitoring contaminants in biota. Adult mussels are sessile and hence it is easier to define the area the samples represent, compared to fish. Blue mussel is among the ‘first choice species’ recommended within the OSPAR JAMP.

Recommendations:
It is very important that the objectives of the monitoring are quantified before designing a monitoring programme. When the objectives are defined the choice of sampling location, matrix, sampling method and analytical procedure could cause problems if the proper guidelines are not followed.

Outlook - Next steps – Accessibility of results/information

The programme on marine biota is a long term programme with continuous development and possible addition of new substances in the future.

IVL Swedish Environmental Research Institute is national data host for the programme. Results and data can be found via the following website (in Swedish only):

FOREWORD

The Water Directors of the European Union (EU), Acceding Countries, Candidate Countries and EFTA Countries have jointly developed a common strategy for supporting the implementation of the Directive 2000/60/EC, "establishing a framework for Community action in the field of water policy" (the Water Framework Directive). The main aim of this strategy is to allow a coherent and harmonious implementation of the Directive. Focus is on methodological questions related to a common understanding of the technical and scientific implications of the Water Framework Directive.

In particular, one of the objectives of the strategy is the development of non-legally binding and practical Guidance Documents on various technical issues of the Directive. These Guidance Documents are targeted to those experts who are directly or indirectly implementing the Water Framework Directive in river basins. The structure, presentation and terminology are therefore adapted to the needs of these experts and formal, legalistic language is avoided wherever possible.

In the context of the above-mentioned strategy, several guidance documents directly relevant to groundwater have been developed and endorsed by the Water Directors. They provide Member States with guidance on e.g. the identification of water bodies (CIS Guidance No. 2), the analysis of pressures and impacts (CIS Guidance No. 3), monitoring (CIS Guidance No. 7) etc. in the broad context of the development of integrated river basin management plans as required by the WFD.

As a follow-up, and in the context of the new Groundwater Directive (2006/118/EC) developed under Article 17 of the Water Framework Directive, Member States have expressed the need to clarify a range of issues, which resulted in the development of new guidance documents complementing the existing series, focusing on aspects covered by both the WFD and the Groundwater Directive, namely Groundwater Monitoring (CIS Guidance No. 15), Groundwater in Drinking Water Protected Areas (CIS Guidance no. 16), Prevention of Direct and Indirect Inputs of Pollutants (CIS Guidance no. 17) and Groundwater Status and Trend Assessment (CIS Guidance No. 18).

To complement these guidance documents and in order to support the ongoing implementation process of the WFD, it was decided to set up recommendations about the generic elements of risk assessment, the use of conceptual models and their specific implementation for groundwater under the WFD building upon the experience and knowledge gained within the RISKBASE project funded under the 6th Framework Programme. For this purpose, an informal drafting group has been established under the umbrella of the CIS Working Group on Groundwater (WG C). This drafting group has been coordinated by Austria (RISKBASE), DECHEMA, and Arcadis (NICOLE), and involved a range of experts from other Member States and from stakeholder organisations.

The present Guidance Document is the outcome of this drafting group. It contains the synthesis of the output of discussions that have taken place since 2007. It builds on the input and feedback from a wide range of experts and stakeholders that have been involved throughout the procedure of Guidance development through meetings, workshops, conferences and electronic media, without binding them in any way to this content.

GWD – Groundwater Directive (2006/118/EC)
RBMP – River Basin Management Plan
TV – Threshold Value
WFD – Water Framework Directive (2000/60/EC)

1. INTRODUCTION

Under Article 5 of the Water Framework Directive (WFD), in 2005 Member States developed and reported on the first risk assessment for groundwater bodies and the likelihood of meeting or failing the WFD's environmental objectives, including good status (see WFD Art. 4b) by 2015. As a further preparation for the first cycle of River Basin Management Plans (RBMP), which were due to be published in December 2009, monitoring programs and threshold values have been established. Within this first management plan period (2009–2015) a review of risk assessments is due to be performed by December 2013 and thereby prepare for the second river basin management plan starting in December 2015, as noted in Figure 1. The relationship between the Article 5 risk assessment and the status assessment is noted in Chapter 2.4 and Figure 4.

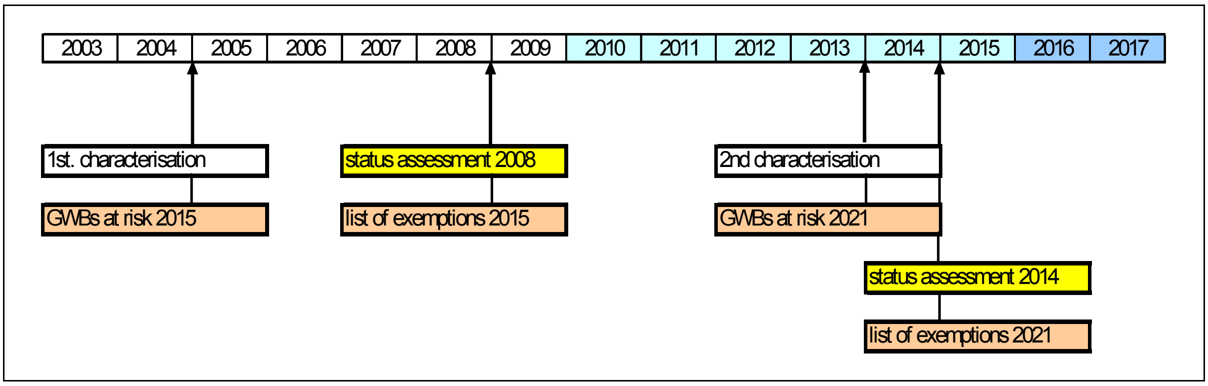

Figure 1: Implementation of the WFD – Timetable 1st and 2nd cycles.

This guidance document describes the generic elements of risk assessment, the use of conceptual models and their specific implementation for groundwater under the WFD. Emphasis is given to the broader notion that characterisation and risk assessment concern five objectives defined within Article 4 (see Chapter 3). Accordingly the document on hand provides insight in risk assessment and the use of conceptual modelling in a holistic manner. Aiming to reframe the context it does not describe a restricted procedure or a step-by-step recipe.

Risk assessment tries to draw a causal chain linking the origin of a hazard or pressure (e.g. an identified or estimated loading of a polluting substance) along an environmental pathway to consequences for human health or the environment (using concepts such as vulnerability, exposure and impact assessment). It should also provide some assessment of the probability of, and confidence in, such a forecast. Scientifically this is generally known as the 'source-pathway-receptor' paradigm (SPR). Risk assessment procedures in practice have to address a variety of topics and scales. Therefore the applied procedures vary and need to be suitable for purpose.

The procedures recommended in this guidance are based on experience and lessons learnt since the first WFD Article 5 reports (e.g. as discussed at the WG C Workshop in January 2004). Such procedures need also to take into account and refer to the first results of the monitoring programs implemented under the WFD.

The main focus of this document is to describe a coherent approach on how to assess risks caused by different pressures (such as diffuse and point source pollution with respect to groundwater quality and abstraction with respect to groundwater quantity) at different scales ranging from site scale (local) up the scale of a groundwater body. Therefore the document is complementary to Guidance Documents Nos. 15 (Monitoring), 16 (Groundwater in Drinking Water Protected Areas), 17 (Direct and Indirect Inputs) and 18 (Groundwater Status and Trend Assessment).

During the process of assessing SPR relationships a conceptual understanding and/or a series of hypotheses will be built up based on the available evidence. This conceptual model may be tested and progressively refined as new data are obtained. The use of conceptual models as an essential tool in groundwater risk and status assessment is recognized by the new Groundwater Directive (GWD, 2006/118/EC) and is discussed in Chapter 3 of this guidance.

It is important to recognize the role of risk assessment in groundwater management, including the preparation of information and data to enable the planning of monitoring systems and the development of remedial measures. A prerequisite to groundwater risk assessment is a sound understanding of groundwater systems, which is supported by Conceptual Models and needs to be developed and adapted to the cycles of groundwater management.

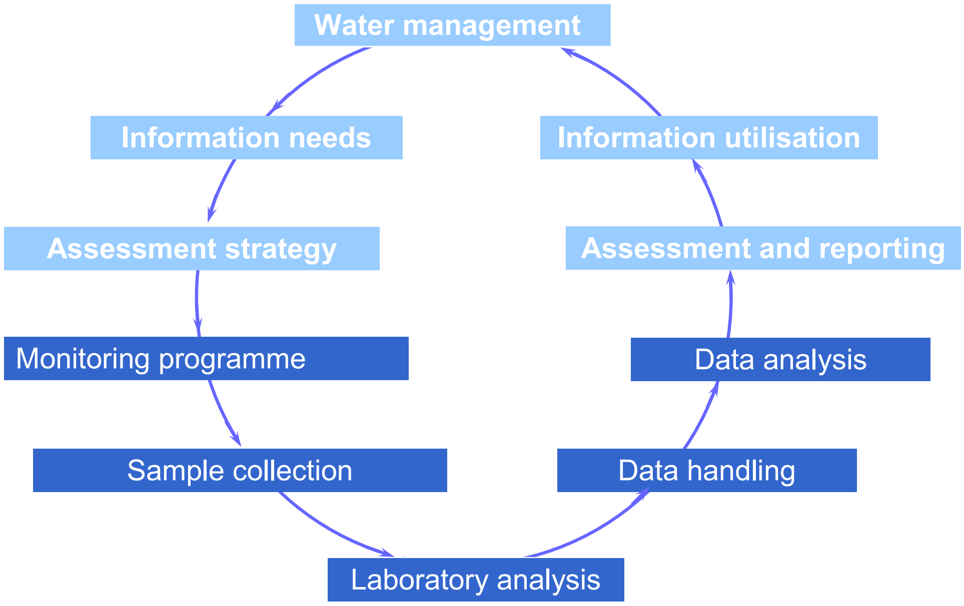

Figure 2: The water management cycle (Ref 9)

2. RISK ASSESSMENT OVERVIEW

2.1 Scope

This guidance document is concerned with the use of 'risk' and 'risk assessment' in the WFD and GWD as noted in Annex I. Thus, in the context of this guidance document, risk needs to be understood specifically as risks not to achieve the environmental objectives of the WFD (see 2.3 and 3) and not in its classic perspective of possible risks for human health and the environment. The first cycle of river basin planning under the WFD started in December 2003 when the WFD had to be implemented into national law. The first River Basin Management Plan for the period of 2009–2015 (RBMPs) had to be published in December 2009. The preparation of the next RBMP cycle starts very soon as at least three years before the beginning of the period to which the plan refers (by 2012), Member States have to publish a timetable and work programme for the production of the plan. The review of the risk assessment according to Article 5 WFD is due in 2013. Further risk characterisation for groundwater during the next planning cycles will also consider monitoring data and the status assessment procedures (including the use of threshold values set by Member States).

2.2 Towards risk-based management - integrating assessments and management

Drawing on an analysis of established approaches to risk management, the International Risk Governance Council (IRGC) has developed a Risk Governance Framework whose purpose is to help policy makers, regulators and risk managers both understand the concept of risk governance and apply it to their handling of risks. A detailed description of the framework was published in IRGC's White Paper "Risk Governance – Towards an Integrative Framework" in 2005[1]. An introduction to the framework is available on the IRGC website[2].

In its 2005 White Paper on Risk Governance, the IRGC has put forward a model of inclusive Risk Governance (see Figure 3), which offers a structure for an integrative process regarding assessing and managing risks. The framework comprises four phases: Pre-Assessment, Risk Appraisal, Characterisation and Evaluation, and finally Management (informed decisions and implementation). A fifth, Risk Communication, runs parallel to these phases.

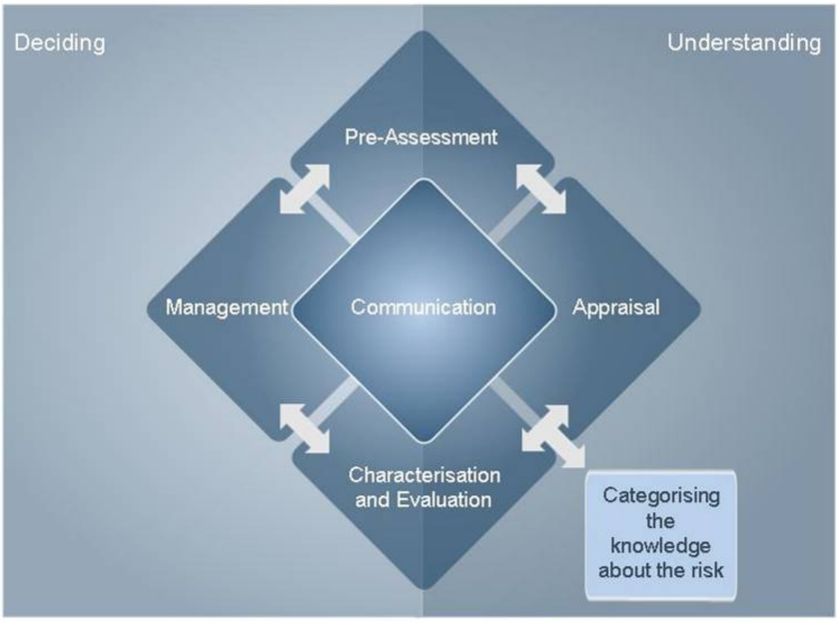

Figure 3: Basic Model of Risk Governance (IRGC 2007a)

---

1 IRGC White Paper No1 "Risk Governance – Towards an Integrative Approach", IRGC, Geneva, 2005. The full text of this document can be downloaded from www.irgc.org

2 http://www.irgc.org/IMG/pdf/An_introduction_to_the_IRGC_Risk_Governance_Framework.pdf

In terms of the IRGC framework groundwater risk assessment within the implementation of the WFD can be understood as representing the pre-assessment phase, which is a prerequisite to establish an integrated and coherent information and data collection process for ending up with a sound understanding at the characterisation and evaluation phase (phase 3). This phase can be understood as being equal to the status assessment. Importantly it is to recognize that the evaluation according to the IRGC framework puts emphasis on having an acceptability and tolerability judgement.

RISKBASE[3], a Coordination Action on Risk Based Management of River Basins, understands the WFD as being risk-based, ecologically centred and recognizing the need to balance improvements to water and ecosystems quality with economic benefits (Brils J. and Harris B, Eds. 2009). Asking for well-designed, coordinated and monitored 'learning catchments' to transform the general framing and develop best practice the risk governance framework described by the International Risk Governance Council is recommended as a source of inspiration to integrate assessments and management.

2.3 Objectives defined by the WFD

Underlying the many references to risk within the WFD (see Annex 1) is the concept that we are assessing the impact of human activity on the environment and specifically those impacts that threaten our ability to meet the objectives of the WFD (as set out in Article 4[4]).

Article 4 contains five objectives for groundwater:

1. Prevent or limit the input of pollutants;
2. Prevent the deterioration of status of groundwater bodies;
3. Achieve good groundwater status (both chemical and quantitative);
4. Implement measures to reverse any significant and sustained upward trend;
5. Meet the requirements of protected areas.

WFD objectives apply at different scales and so the Source-Pathway-Receptor (SPR) model for each of these objectives will also be scale dependent. This will have a direct effect on the scope and scale of the conceptual models that are an essential part of describing and assessing risks.

For groundwater quantity, risk assessment is focused on objectives 2, 3 and 5 and in particular quantitative status as defined in Annex V, 2.1.2 of the WFD. Taking account of all the elements of this definition requires assessment of risks at scales varying from local (impacts on individual dependent surface waters or terrestrial ecosystems) to groundwater body scale (available resource balanced against the recharge and abstraction).

Taking in account the description of good qualitative status in WFD Annex V all the objectives of Article 4 apply for groundwater quality. The relationships between these objectives are more complex and interdependent, as described below and in CIS Guidance Documents nos. 17 and 18 (Refs 1, 2). Risks need to be assessed for a wide range of SPR relationships at scales from the very local (for example, consideration of whether engineering design and operational controls applied to storage of hazardous substances in a tank are sufficient to prevent their release from the storage system and entry into groundwater) through to medium scale (for example, impacts on individual abstraction boreholes or terrestrial ecosystems) and finally to whole groundwater bodies (whether a body achieves good status).

2.4 Temporal scale of groundwater risk assessment

We also need to consider the time horizons over which risks need to be assessed. In order to manage risks on a day to day basis the primary focus for the prevent or limit objective is the immediate impact

3 Integrated risk-based Management of the water-sediment-soil system at river basin scale; funded under the EC 6th RTD Framework Programme (FP6), reference GOCE 036938

4 In the case of Groundwater Chemical status this includes meeting the requirements of Article 7 (Drinking Water Protected Area objective; CIS Guidance Document no. 16).

of an activity on groundwater with a view to maintaining existing good controls, improving management where necessary, restricting or prohibiting that activity as most appropriate. In contrast, the ability to achieve good groundwater status has to be evaluated taking into account the typically long time-scales associated with hydrogeological processes at the groundwater body scale. Risk management measures may take many years (or even decades) to have a significant impact on status.

Status assessment (the classification of water bodies) is formally undertaken and reported once every six years and is based on monitoring data collected over the previous river basin planning cycle. The current status of the water body reflects any effects resulting from measures that have been undertaken in previous plan periods. In contrast, the risk assessments for all the Article 4 objectives (considering both chemical and quantitative status), as described in Article 5 of the WFD (obligation to submit a report according to Article 15 of the WFD) and noted in Figure 4, looks forward a couple of years and attempts to predict what the condition of the groundwater body will be at the end of the next river basin management plan period. Based on this assessment and the procedures noted in Articles 4 and 11 of the WFD, measures may be put in place. These measures, which should reflect the risks identified in the Article 5 report, may comprise strategic planning, remediation schemes, abstraction controls and “prevent or limit” measures mentioned above.

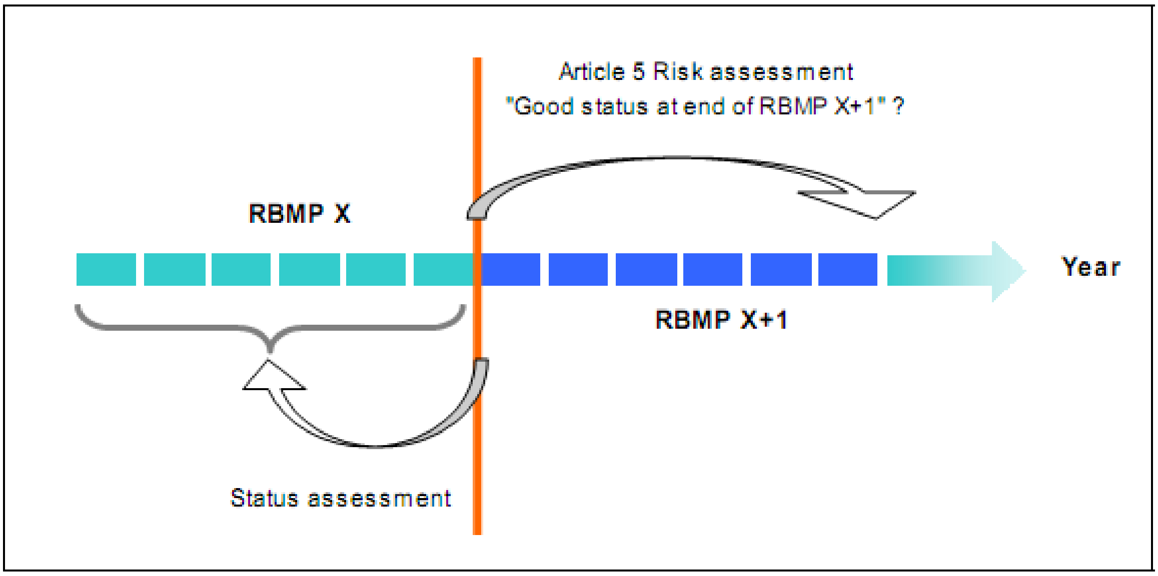

Figure 4: Risk assessment regarding the status objective looks into the future whereas status assessment looks back on the performance (from CIS Guidance document No.18)

2.5 Considering uncertainty

Uncertainty affects all stages of the risk assessment and management processes. Analysing the sources and magnitudes of uncertainties can help to identify knowledge gaps and inform decision makers on the most appropriate risk management measures, including whether or not precautionary action is necessary. When making decisions on risk management options it is important to understand how different sources of uncertainty (in data, from sampling, environmental variability, lack of knowledge and in models) contribute to the variation in the final risk estimates. Sensitivity analysis (varying parameter values in the risk model to examine the variation in outcomes) is very useful in this respect.

Compared with most environmental media, the groundwater environment is rather inaccessible, highly heterogeneous and difficult to observe/monitor. The movement of pollutants in three spatial dimensions and over the long timescales that are typical of many groundwater environments make predictions difficult. As a consequence a large degree of uncertainty is inherent in many hydrogeological assessments, particularly with respect to pathways. For example, movement through and attenuation in the unsaturated zone is a key factor in determining the risk to groundwater quality from an activity on the land surface. Yet this pathway by its nature is one of the most difficult to monitor.

Risk assessment and uncertainty analysis are of wide application in groundwater protection. They can act as a counterbalance to the costs and practical difficulties in directly observing pollutant linkages. For many subsurface processes a statistical or deterministic approach to risk assessment may not be necessary or feasible and a “weight of evidence”[5] approach may either be sufficient or the best we can achieve. In both circumstances conceptual models (see chapter 3 and Annex II) are an essential supporting tool to risk assessments in these circumstances.

2.6 Tiered risk assessment

Rarely in groundwater assessments do we have sufficient data to make reliable predictions in outcomes. Tiered risk assessment combined with a simple assessment of confidence can assist in focusing resources on those areas of highest uncertainty and of utmost relevance to risk management decisions.

A typical example of tiered assessment is given in Figure 5. Here the risk assessment aims to divide a group of groundwater bodies into those that are “at risk” or “not at risk” failing to meet good status. Risk screening is used to pragmatically divide the groundwater bodies in an efficient course of action into those where there is high confidence that the body is “not at risk” or is “at risk” failing to meet the status objective (based on monitoring and hazard data and clear environmental standards). What remains in the centre of the figure is a group of bodies where there is relatively low confidence (substantial uncertainty) in the assessment. Qualitative assessments as well as semi-quantitative assessments are pressure and parameter-specific (e.g. evidence for parameter A, uncertainty and further investigation necessary for parameter B) and prepare the final classification.

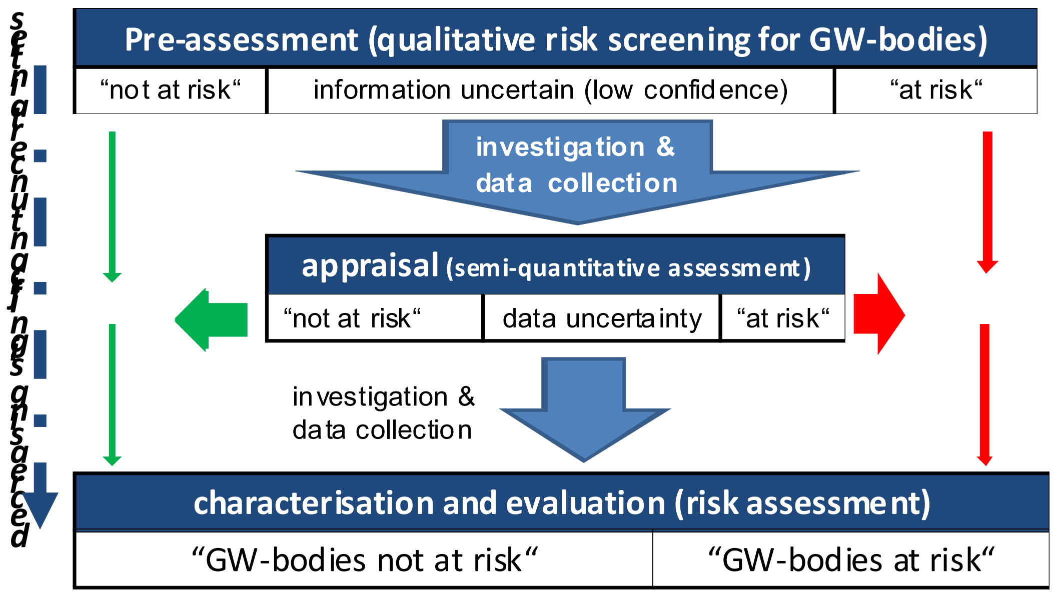

Figure 5: Tiered approach for risk assessment (from Technical Report on Groundwater Risk Assessment – adapted)

At the next level of assessment (appraisal often termed as semi-quantitative assessment) further data collection and analysis are focused on the remaining bodies. These are then further divided into “not at risk”/”at risk” bodies where there is now sufficient confidence in the assessment, leaving a further tranche of bodies where there is still significant uncertainty. The process is then repeated until all bodies can be assessed with an acceptable degree of uncertainty. It follows that additional investigation and monitoring should be focused on those areas where there is most uncertainty rather

5 The use of whatever data are available to make an assessment of the most likely outcome or the ‘direction of travel’ in the assessment.

than those areas where there is confidence that groundwater is in a good or poor condition in relation to the “at risk” assessment. If significant data uncertainties remain the characterization and evaluation needs to follow a transparent ‘weight of evidence’-approach to classify a groundwater body as being “at risk” or not.

Tiered assessment is implicit in the overall WFD river basin planning process. The initial characterization is often based on little data but is conservative. Where risks are identified further characterisation is required to identify the likely pressures and impacts and areas of uncertainty. From the second cycle onwards uncertainty should diminish because monitoring data, from the WFD monitoring programme will be available. These data in turn can be used to improve the risk assessment. Figure 2 shows that the monitoring strategy, measures and status assessment (including the setting of threshold values) take place after risk assessment. So for the planning cycle (n+1), the knowledge gathered during the previous planning cycle (n), should be used to review monitoring strategy, measures and threshold values.

2.7 Risk Assessment and the precautionary principle

The approach taken by the European Commission in applying the precautionary principle is elaborated in a communication document from 2000[6]. In the Rio Declaration[7] the precautionary principle was interpreted as follows:

“Where there are threats of serious or irreversible damage, lack of full scientific certainty shall not be used as a reason for postponing cost-effective measures to prevent environmental degradation.”

Following this principle it is not acceptable to delay taking action because of uncertainty where there is a risk of serious harm. The use of risk assessment can sometimes seem to be in conflict with this principle. In reality risk assessment can be employed to clarify issues and identify impacts that are serious enough to warrant precautionary action.

The use of the precautionary principle presupposes a scientific evaluation of the risks which, because of the insufficiency of the data, their inconclusive or imprecise nature, makes it impossible to determine with sufficient certainty the risk in question[8].

Conversely risk assessment can also identify where impacts are unlikely to occur and/or be serious. If further investigation would significantly improve our knowledge and confidence and provide better focus for risk management measures, action may be delayed, providing no serious or irreversible harm would result.

The principle should be considered within a structured approach to analysis of risk which comprises three elements: risk assessment, risk management and risk communication. Where action is deemed necessary, measures based in the precautionary principle should be, inter alia:

- subject to review, in the light of new scientific data, and
- capable of assigning responsibility for producing the scientific evidence

necessary for a more comprehensive risk assessment.

The prevention of the input of hazardous substances to groundwater is an example of where a precautionary approach has been adopted. Substances are classified as hazardous based on their inherent toxicity, persistence and bioaccumulative properties. Despite this fact, there are circumstances where evidence of hazardous substances in groundwater does not contradict the precautionary principle. Given a risk assessment (supported by monitoring data) can demonstrate that such inputs are environmentally negligible and all necessary and reasonable measures to prevent have been taken, they are tolerable under the GWD and in accordance with the precautionary principle.

2.8 Improved risk assessment through the river basin planning cycles

The first Article 5 reports submitted by Member States (in accordance with Article 15) had to make predictions based on relatively sparse data and often with only a broad knowledge of the operational requirements of the WFD Article 4 objectives. For example, at the time the first Article 5 reports were compiled the detailed requirements for groundwater quality (and in particular groundwater chemical status) were unknown as these were subject of the GWD and CIS guidance (Ref 2). The first risk assessments will therefore be associated with substantial uncertainties.

Member States now have the benefit of both clarity on objectives and operational requirements, with several years of monitoring data and the first status assessments (classifications). Conceptual models can now be used to assimilate and focus new risk assessments on areas of greatest uncertainty. By this process we can build on the work of the previous river basin planning cycle and improve our future risk assessments.

Through time, the scope and scale of risk assessments (and associated uncertainties) should decrease, reflecting better data and the impact of measures, unless new threats to the environment appear. A minimum level of risk assessment will always be necessary as the WFD will continue to require forward predictions of complex environmental conditions and processes.

3. CONCEPTUAL MODEL OVERVIEW

3.1 What are conceptual models and what are they used for?

A conceptual model is the basis for reliable decisions in groundwater risk assessment and management. The aim is to have an instrument for:

- Experts discussing, developing and complementing their understanding of the groundwater system
- Communication with the public and decision makers: making non-experts understand how an aquifer system is working;
- Understanding and visualization of both simple and complex groundwater bodies, depending on the purpose;
- Assessing risks related to groundwater;
- Visualisation of how, where and when risks may impact groundwater;
- Planning of monitoring systems and measures to protect or remediate groundwater;
- Prediction of the effects of measures;
- Providing a reliable basis for simulating and predicting processes in groundwater with mathematical or numerical (computer) models;
- To help an assessor identify whether a groundwater body achieves its Article 4 objectives;
- To identify the reasons why a groundwater body fails any status objectives;
- To allow short-listing of the potential measures that are most likely to remedy the situation in an effective and sustainable manner;
- Justifying exemptions/alternative objectives where there is a risk of failing to achieve good groundwater status.

In the new Groundwater Directive as well as in several of the CIS Guidance Documents the use of ‘conceptual models’ is mandatory or recommended (see chapter 3.3). The term ‘conceptual model’ is not defined in the Groundwater Directive, nor is there a common definition by the Guidance Documents that recommend its use (different definitions see Table 2). The circumstances under which conceptual models can be applied may vary widely, from detailed assessments by hydrogeologists to a simplified picture of interacting processes for communication purposes with stakeholders. The fact that the use of conceptual models is recommended in several Guidance Documents, emphasises that conceptual models are *important* tools in groundwater management.

First experiences with the characterisation reports and status assessments indicate that Member States use very different approaches. *Working Group C has initiated this Guidance with the aim of creating a common understanding of conceptual models and risk assessment and the use of conceptual models within groundwater management*. The term conceptual models have been introduced in several Guidance documents before, to support different purposes. This Guidance intends to complement these earlier documents and gives an overview of available knowledge on this subject, relating it to the different steps of groundwater management.

It is also not the intention to choose a ‘correct’ definition of the term ‘conceptual model’ but rather to discuss how models, including conceptual ones, can assist in groundwater management. The philosophy behind the WFD is to start thinking about (ground)water management with all available knowledge (no matter how little), then focus on what are or may be environmental or human risks and then collect information where needed to improve understanding. In this process, one may start with a schematic description, then point out possible risks, start monitoring and use the monitoring results to improve the understanding of the system and the effectiveness of measures. If necessary for a better understanding, or for a selection of the most appropriate measures, the conceptual models may evolve into (complex) numerical models. The starting schematic model can definitely be called a *conceptual* model. A complex numerical model is definitely *not* a *conceptual* model anymore. For the purpose of groundwater management it doesn't really matter to what extent models are still called *conceptual models*. What counts is that simple models are sufficient for the initial phase of groundwater management, and that more complex models need to be used only if and when appropriate within the management process.

Definition of conceptual model

In the context of this guidance, a conceptual model is a means of describing and optionally quantifying systems, processes and their interactions. A hydrogeological conceptual model describes and quantifies the relevant geological characteristics, flow conditions, hydrogeochemical and hydrobiological processes, anthropogenic activities and their interactions. The degree of detail is based on the given problems and questions. It is one of the basic steps for the management of groundwater bodies.

Conceptual models are needed to describe groundwater quantity (linked to quantitative status) as well as chemical composition (chemical status) of groundwater, as referred to in the WFD.

Conceptual models can be developed to different degrees of complexity, from simple qualitative descriptions of the geology to complex combinations of qualitative and quantitative descriptions of the hydrogeological processes and the impacts. To cover the different needs for management of groundwater bodies, spatial investigation scales vary from small (10-100's m^2) to large (km^2) and time resolution from hours/days to month/years. It depends on specific tasks and problems (e.g. groundwater quantity, chemical composition, point source pollution, diffuse pollution, interaction with surface waters, land use). For transboundary groundwater bodies it is highly recommended that jointly agreed conceptual models are developed.

Annex II describes a way of setting up a conceptual model. Depending on the special requirements of the different WFD activities described above, a basic three step procedure is suggested, with differing data requirements, scales and complexity.

3.2 Role of conceptual models within groundwater management

The management of groundwater systems consists of steps in a continuous cycle as described in the Introduction (see Figure 2). Within the cycle of groundwater management conceptual models can be used in different phases with a different purpose, such as risk assessment, monitoring strategy and status assessment (see Figure 6).

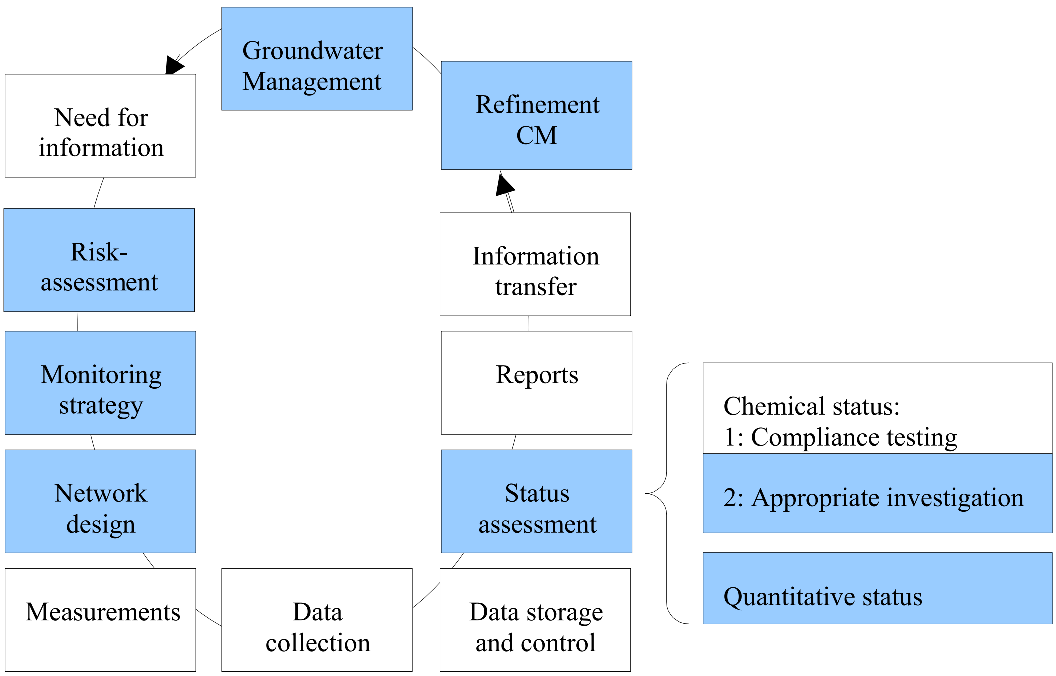

Figure 6: Role of conceptual models in groundwater management in blue the steps where conceptual models can be useful or may be even essential)

In the *first phase* of the implementation of the WFD, groundwater bodies had to be delineated and characterised (Groundwater Body System). The main emphasis was on the general description of the hydrogeological system, including the chemical and quantitative conditions in the groundwater body. This system could mostly be understood and made transparent to the public with the help of basic (simple) conceptual hydrogeological models:

- These models should roughly describe groundwater flow directions in relation to the main watercourses and the position of important terrestrial and aquatic ecosystems within the groundwater body, as well as the distribution of relevant land uses.
- It is a good starting point for planning a monitoring strategy and developing a representative monitoring network - by comparing the number and distribution of existing monitoring stations with hydrogeological and hydrochemical data, the distribution of (potential) inputs and the receptors that could be affected.
- Existing conceptual models may be refined and the need for more detailed (hydro)geological data at a more local scale can be assessed. New hydrogeological data and the results of monitoring may lead to more complex conceptual hydrogeological models at more detailed scales if necessary.

In the *second phase*, during the first status assessment in 2009 additional data (hydrochemical monitoring data, groundwater level data, recharge and abstraction rates) were collected:

- Additional data can now be integrated into the existing conceptual models.
- Based on the results of the first status assessment and a refined conceptual model, the future development of groundwater status (quantitative and chemical) can be assessed.

In the *third phase*, the assessment of the future development of groundwater status leads to a prediction of whether the good quantitative and chemical status of groundwater can be achieved by the end of the (next) plan period. If not, (additional) measures have to be undertaken by a Member State:

- In predicting the effectiveness of measures in time and space, sometimes more specific data are needed. In particular, the behaviour of seepage water in the unsaturated zone and groundwater flow times can be added to a conceptual model and may lead to incorporation of a more sophisticated mathematical model.

3.3 Use of conceptual models and references in CIS guidance documents

3.3.1 Use of conceptual models within the WFD

The WFD does not contain the term 'conceptual model', but implicitly requires the set-up of conceptual models, by requesting Member States to characterise all water bodies. For each water body it has to be determined whether there is a risk of failing to meet the objectives at the end of the plan period. A conceptual model is indispensable for this purpose. The most important parameters to be taken into account in characterisation are listed in WFD Annex II, paragraphs 2.1 and 2.2 (see Look-Out-Box below) and discussed in Chapter 5 of this guidance.

LOOK OUT!

Annex II of the Water Framework Directive

2. GROUNDWATERS

2.1. Initial characterisation

Member States shall carry out an initial characterisation of all groundwater bodies to assess their uses and the degree to which they are at risk of failing to meet the objectives for each groundwater body under Article 4. Member States may group groundwater bodies together for the purposes of this initial characterisation. This analysis may employ existing hydrological, geological, pedological, land use, discharge, abstraction and other data but shall identify:

- the location and boundaries of the groundwater body or bodies,
- the pressures to which the groundwater body or bodies are liable to be subject including:
  - diffuse sources of pollution
  - point sources of pollution
  - abstraction
  - artificial recharge,
- the general character of the overlying strata in the catchment area from which the groundwater body receives its recharge,
- those groundwater bodies for which there are directly dependent surface water ecosystems or terrestrial ecosystems.

2.2. Further characterisation

Following this initial characterisation, Member States shall carry out further characterisation of those groundwater bodies or groups of bodies which have been identified as being at risk in order to establish a more precise assessment of the significance of such risk and identification of any measures to be required under Article 11. Accordingly, this characterisation shall include relevant information on the impact of human activity and, where relevant, information on:

- geological characteristics of the groundwater body including the extent and type of geological units,
- hydrogeological characteristics of the groundwater body including hydraulic conductivity, porosity and confinement,
- characteristics of the superficial deposits and soils in the catchment from which the groundwater body receives its recharge, including the thickness, porosity, hydraulic conductivity, and absorptive properties of the deposits and soils,
- stratification characteristics of the groundwater within the groundwater body,
- an inventory of associated surface systems, including terrestrial ecosystems and bodies of surface water, with which the groundwater body is dynamically linked,
- estimates of the directions and rates of exchange of water between the groundwater body and associated surface systems,
- sufficient data to calculate the long term annual average rate of overall recharge,
- characterisation of the chemical composition of the groundwater, including specification of the contributions from human activity. Member States may use typologies for groundwater characterisation when establishing natural background levels for these bodies of groundwater.

The initial characterisation had to be carried out for all water bodies. Therefore the data listed according to WFD, Annex II, paragraph 2.1, should be available for all groundwater bodies. Many of the data required for developing conceptual models can be derived from the initial characterisation. Often this will be sufficient for at least basic conceptual models. Further characterisation (see Look-Out-Box and WFD Annex II, paragraph 2.2) only needs to be conducted for groundwater bodies that are considered to be ‘at risk’ of failing the WFD’s environmental objectives following the initial characterisation. (Note that, as explained in chapter 2, in case of doubt a groundwater body should be declared ‘at risk’.)

One aim of using conceptual models is to *describe the relation* between groundwater quality/resources, the local (geogenic) conditions and anthropogenic inputs/impacts *in an understandable way*. In the case of no or only little groundwater (monitoring) data the conceptual model contains basic information, e.g. on land use distribution within the area of the groundwater body, a rough estimation on depth to groundwater, characteristics and thickness of the overlaying soil and groundwater flow direction. Nevertheless with this more generic information it is already possible to give a first rough estimation on what kind of impacts (pollution, damage caused by abstraction) could be expected in which region of the groundwater body. At this stage the role of the conceptual model is to provide the basis for a reasonable set-up and extension of a monitoring network.

Subsequently, monitoring data is used to check the assumptions made for the first conceptual model. This improvement of the conceptual model is an important element in the groundwater management process in order to increase system understanding and to develop effective planning and control measures. This check and (re)balance may have various outcomes:

- In the case of a good correlation between the conceptual model assumptions and the measured data (especially when no risk of deterioration of good status can be observed[9]), usually there is no further need to refine the conceptual model or collect additional data.
- Where there is significant divergence, this has to be explained. This requires the collection of more data (e.g. extension of monitoring network, increased monitoring frequency) or additional data (e.g. input of substances, degradation/retention capacities, flow/spreading velocities in groundwater/leachate). This process may need to continue until the improved conceptual model can describe the measured data in a consistent way, with sufficient certainty.
- To find impartial criteria with sufficient certainty is difficult (see also section 3.6). Resolving the uncertainty sufficiently may be difficult, but it is better to invest in a good conceptualisation than to base measures on a weak conceptual model, with the risk that those measures may be ineffective in meeting WFD objectives or are simply unnecessary.

3.3.2 'Conceptual models' in guidance documents

Conceptual models are mentioned in several previously published guidance documents as listed in Table 1. In some of these documents, a definition is given (see table 2). Several of the documents stress the iterative process of developing conceptual models and refining them where necessary. They note that conceptual models are useful in:

- understanding the significance of pressures;
- design of a monitoring network;
- interpreting monitoring data;
- evaluating the monitoring network;
- establishing threshold values;
- status assessment;
- trend assessment.

[9] Note that, according to Article 5.2 of the Water Framework Directive, the characterisation "shall be reviewed, and if necessary updated". That implies that a complete re-characterisation is not always needed.

Table 1: Overview of EU guidance documents relevant for groundwater. Indicated is whether the document holds definitions and/or recommendations for conceptual models. Taken from Spijker et al., 2009.

CIS Guidance document	Definition	Recommendation
No 3, Pressures and Impacts	-	+
No 7, Monitoring	+	+
No 12, The role of Wetlands	-	-
No 15, Groundwater Monitoring	+	+
No 16, Drinking Water Protected Areas	-	-
No 17, Guidance on Preventing or Limiting Direct and Indirect Inputs	+	+
No 18, Guidance on Groundwater Status and Trend Assessment	+	+

Table 2: Definitions of conceptual models given in four guidance documents.

Guidance document on Monitoring:
'A conceptual model is a simplified representation, or working description, of how the real hydrogeological system is believed to behave. It describes how hydrogeologists believe a groundwater system behaves'

Guidance document on Groundwater Monitoring:
'Conceptual models are simplified representations, or working descriptions, of the hydrogeological system being investigated'

Guidance document on Preventing or Limiting Direct and Indirect Inputs:
'A conceptual hydrogeological model is the schematization of the key hydraulic, hydro-chemical and biological processes active in a groundwater body'

Guidance document on Groundwater Status and Trend Assessment:

'Conceptual models are (...) a working understanding of the geological and hydrogeological system being studied'

This guidance document deals with risk assessment, one of the areas for which conceptual models can be applied. Therefore the remaining part of this chapter as well as Annex II, focus on the use of conceptual models in risk assessment.

3.4 Properties of conceptual models

3.4.1 Spatial and temporal scale

Before developing a conceptual model, it is important to determine its areal extent and its boundaries. A conceptual model for a groundwater body looks different than a model for a catchment area of one abstraction site. In both cases however, it is important to realise that an effect which is observed at one point, can be caused by a pressure at some distance. Therefore the spatial boundaries of the model should be chosen carefully and in 3 dimensions. In case of doubt, it is better to choose the boundaries well beyond the area of interest albeit they may subsequently be reduced as hydrogeological/physical information allows the zone of potential influence to be delineated (e.g. as groundwater flow direction or the geological boundaries of an aquifer system are established); the iterative process described before will lead to a better understanding of the relevant area. Similarly, it is important to consider the temporal scale relevant for the model.

Annex II describes this in more detail.

3.4.2 Main points during set-up of a conceptual model

Four aspects are important during set-up of a conceptual model.

1. Main characteristics:
    a. Scope and questions to be answered - to determine the degree of detail and complexity of the conceptual model.
    b. Determination of the relevant area.
    c. Definition of vertical and horizontal structuring units (hydrogeological units).
    d. Land use distribution
2. Parameterisation/quantification:
    a. Description and quantification of important hydraulic, geochemical and hydrochemical parameters introduced *where possible and necessary*.
    b. Consideration of processes with slow kinetics (e.g. solution processes, unsaturated zone flow, changes in surface conditions, climate variations).
    c. Description of the most important climatic and unsaturated zone parameters.
    d. Identification of emerging issues that could pose a potential risk.
3. Dealing with uncertainties: we need to assess potential uncertainties, variability, and whether data are representative.
4. Evaluation of a conceptual model: it is advisable to start with a simple model, then analyse its performance and, by stepwise improvements, make a more complex model if the simpler model is not sufficient. It might be necessary to return to a previous step if it turns out that the conceptual model is not consistent with actual data.

Corresponding to these systematic issues it is important to recognise that establishing and refining a conceptual model is an iterative process and all relevant parties should be involved this process.

3.5 Look out for visualisation

It is important to document all steps of the conceptual model. The complexity of the visualisation is dependent on the scoping questions and the potential audience. It can extend from simple 2D maps to more elaborated cross sections and 3D pictures. Annex II gives a more detailed description of the procedure, with proposals for an appropriate level of visualisation.

An example of visualisation is taken from www.wfdvisual.com (see Figure 7) and completed with labels describing the most relevant information. A three-dimensional basic picture like this without exact scale can be used for information of politicians, stakeholders and the interested public to help visualise the hydrogeological situation and the data needed. This picture shows the spatial distribution of an aquifer and the overlying unsaturated zone, the flow and direction of groundwater and surface water and hydrogeological features of the aquifer, such as aquifer type (fissured), lithology (sandstone), permeability etc. By combining the hydrological components - precipitation, groundwater recharge, surface water and groundwater - in one picture, the (conceptual) relationships can be shown. Also shown are the pressures (both for chemical quality and quantitative status) as well as the relevant receptors.

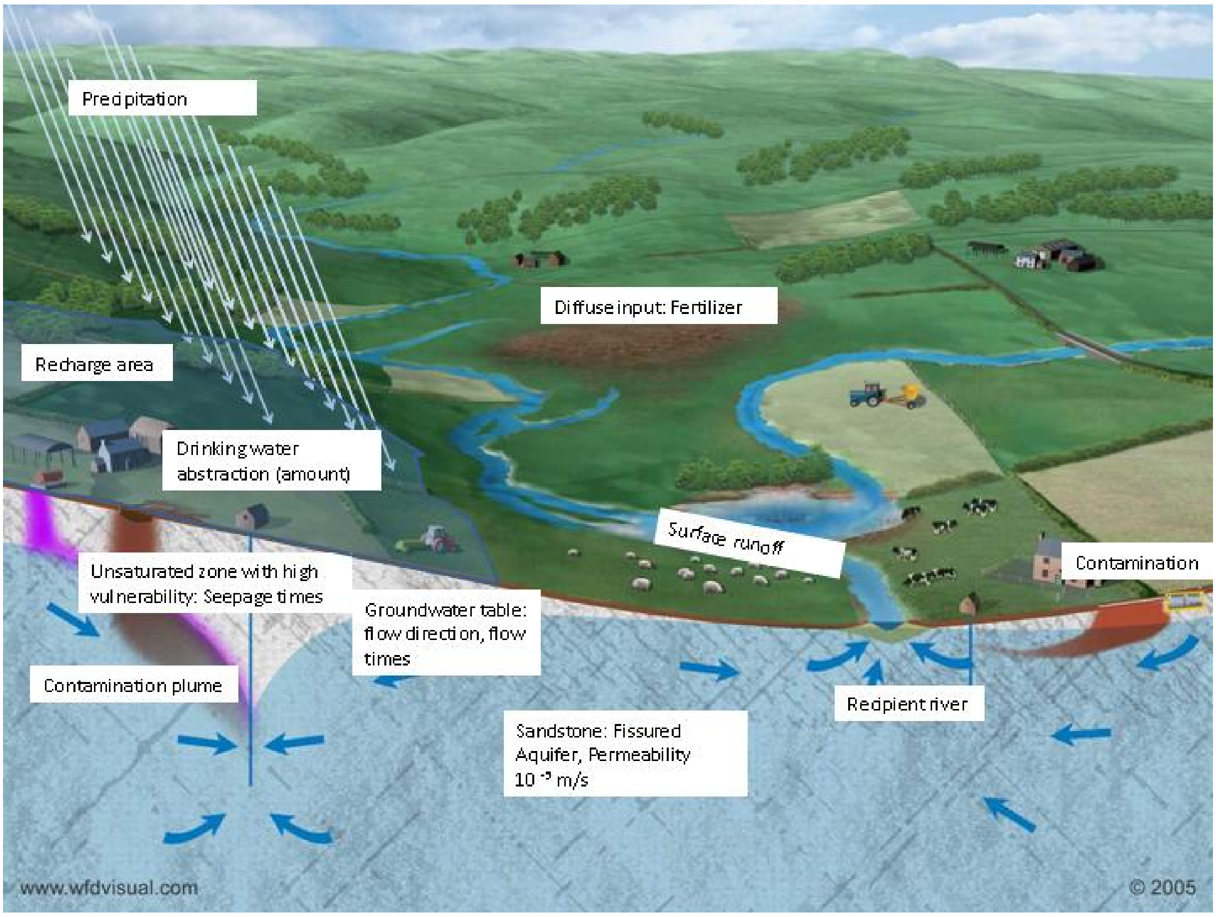

Figure 7: Visualisation example for a conceptual model. Reproduced with permission from WFDVisual.com (www.wfdvisual.com).

3.6 Validation and quality assurance of conceptual models

A conceptual model is dynamic, evolving with time as new data are obtained and as the model is tested. Its development and refinement should adopt an iterative approach. Before re-characterisation takes place, the conceptual model should be evaluated, refined and validated. All data concerning the nature of the groundwater body collected during the characterisation process should be tested against the conceptual model, both to refine the model and to check for data errors. In doing so, the distance to target should be kept in mind: the closer a groundwater body gets towards poor status the more accurate the conceptual model should be in order to carry out a correct compliance test.

Wherever possible, validation of a conceptual model should be based on sufficient monitoring data. Where this is not possible, an analysis of the characteristics of the pressures and receptors combined with monitoring data can be a suitable validation method. Following the approach applied to the selection of relevant substances (CIS Guidance Document No. 3), one can analyse the pressures on a groundwater body (top-down), analyse the observed effects on receptors (bottom-up), and compare these, taking into account travel times within the environment. This comparison offers insight in the validity of the conceptual model. Overall, the weight of evidence should support the conceptual model.

In general it is important to plan and log the validation steps that will be carried out, taking into consideration aspects such as availability of data and the distance to the final objective.

4. WFD OBJECTIVES AND RISK ASSESSMENT

This chapter discusses the use of risk assessment with respect to the five objectives of Article 4 (see Chapter 2.3). For the objectives prevent or limit (1), good groundwater status (3) and protected areas (5), a lot of information is already available. Especially relevant are the following:

- CIS Guidance Document No.3 'Analysis of Pressures and impacts' (2003):
  - (page 25–50) chapter 3 describes a 'general approach for the analysis of pressures and impacts'
  - (page 63–65) section 4.5.3 deals with tools to assist the analysis of pressures and impacts, especially for groundwater
  - (page 70–76) sections 5.2 and 5.3 deal with 'information needs and data sources' when analysing pressures and impacts.
- Technical Report on Groundwater body characterisation (2004):
  - (page 6 and 7) extracts about initial and further characterisation are especially useful for *how* risk assessment can be performed. These deal with chemical and quantitative status as well as with inputs.
- Technical Report on Groundwater Risk assessment (2004):
  - (page 13 and 14) extracts about initial and further characterisation (sections 2.4.1 and 2.4.2)
  - (page 14–18) chapter 3, 'specific guidance', sections 3.1, 3.2 and 3.3. Deals with:
    - identifying driving forces and pressures;
    - identifying significant pressures;
    - assessing the impacts of pressures
  - (page 19) evaluating the risk of failing the objectives
- CIS Guidance Document No.16 'Guidance on Groundwater in Drinking Water Protected Areas' (2007)
- CIS Guidance Document No.17 'Guidance on preventing or limiting direct and indirect inputs' (2007)

The above documents are not legally binding, but they are a result of discussions between many practitioners involved in implementing the groundwater aspects of the WFD and therefore represent a common understanding.

4.1 Prevent or limit the input of pollutants

This objective can apply at all scales from local (for point sources) to groundwater body (mostly for diffuse sources) and is described in detail in Guidance Document 17 (Ref 1). "Prevent or limit" measures are the first line of defence and are the most effective mechanism for protecting groundwater quality. If we correctly assess risks to meeting the 'prevent or limit' (P/L) objective and then implement appropriate risk management measures, in time all the other WFD groundwater quality objectives will be met.

The risk assessments for inputs of hazardous substances (which we must prevent) and non-hazardous substances (which we must limit to avoid pollution) are distinct.

For hazardous substances the risk assessment is curtailed in the sense that it has previously been determined (by the WFD and GWD) that, subject to the exemptions in Article 6 of the GWD, any entry into groundwater is undesirable and should be prevented[10]. In effect all sources (hazardous substances) are assumed to have similar characteristics and the target or receptor in all cases is the water table. SPR characterisation therefore is confined to the source (volume and physico-chemical properties) and the pathway linkages, in particular the ability of unsaturated zone (where this is present) to attenuate the inputs.

For non-hazardous substances a full SPR characterisation is needed as the sources may vary in terms of inherent hazard and the target may be groundwater in the vicinity of the input (in the case of a sensitive and valuable groundwater resource) or a receptor some distance down-gradient of the input, such as an abstraction or dependent aquatic or terrestrial ecosystem. What constitutes harm at the

[10] Guidance Note No.17 describes what prevent means in the context of this objective.

targets (receptors) will vary according to the nature of the pollutant as well as to uses and the sensitivity of the receptor. The procedure for making this assessment is outlined in CIS guidance (Ref 1).

In terms of conceptual modelling only a relatively simple, site specific model may be sufficient to understand a local groundwater system and to assist the assessment of the risk of point source inputs to the P/L objective. The wider scale of diffuse inputs may require a more complex model to support the risk assessment.

Due to the very wide range of potential hazards and the multiple points of compliance, it is difficult to map the risks to the P/L objective for the purposes of the WFD Article 5 reports. Maps of potential sources of contamination can only give an initial hazard assessment at a large scale. Effective systems of permits or other controls may be in place. In this way risks are being managed to meet the P/L objective and it would be misleading to indicate that there is a risk of not meeting that objective. It is suggested that Article 5 P/L "at risk" maps should focus primarily on releases (point sources or delineated diffuse sources) that may not be under sufficient control to meet WFD objectives. There would then be a more direct relationship between the risk maps and the need to implement additional measures during river basin management planning.

4.2 Prevent the deterioration of chemical status of groundwater bodies

The risks of not meeting this objective comprise two elements:

- Those risks associated with a failure to have sufficient P/L measures (for both diffuse and point sources) in place – in other words, are all existing activities (potential hazards) under control?
- Risks arising from sources of contamination in the ground, where the original activity has ceased or is now under control but there is residual contamination that could impact in time on the status of water bodies.

The latter risk is particularly common in hydrogeological situations where flow is slow in the unsaturated zone or in the groundwater body, in deep aquifers and where recharge is low. It is particularly important in these cases to have a conceptual model that looks at historic as well as current activities and examines different time lines/temporal scales.

Because of the time lags (delays) between inputs at the land surface and impacts on the groundwater environment it is possible that some groundwater bodies may deteriorate from good to poor chemical status even when all necessary and reasonable measures to prevent or limit further inputs have been taken. Modelling may be necessary to make a full appraisal of the risks in such cases and these models will need to be supported by a validated conceptual model.

4.3 Achieving good groundwater status

CIS Guidance Document 18 describes the requirements for meeting good status. A number of tests or elements apply to both chemical and quantitative status as noted in Figure 1 of that document.

In order to undertake the "at risk" assessment for the next planning cycle, an assessment of the risks of not meeting good status for each test will be necessary. Initially the baseline conditions from which this assessment can take place must be defined. This will consist of an assessment (based on monitoring data) of both the current condition within the groundwater body and any significant trends in quality and/or level/flow conditions. This will then need to be combined with data on current and predicted land and water uses and inputs to groundwater (source characterisation).

A significant risk to any one of the elements of status will cause the groundwater body to be at risk of failing either groundwater quantitative or chemical status. This system is simple but a resulting map of risk for all the tests combined may not present a clear view of actual risks. It is recommended that risk maps for each element or test for good status are presented so that these can be directly compared to the status (classification) maps. The greater the number of pressures the more detailed the supporting conceptual model will need to be.

For some tests an assessment of deterioration is part of the test for good status (Drinking Water Protected Area and Saline intrusion tests), so there can be overlaps with the risk assessments for deterioration in status and the trend assessment.

Where there is a risk of failing to achieve good groundwater status, the conceptual model and risk assessments will play an integral part in justifying exemptions/alternative objectives.

4.4 Implement measures to reverse any significant and sustained upward trend

The risk assessment for this objective will be closely linked to the assessment of deterioration noted above – in many cases the monitoring data that will assess compliance will come from the same monitoring network. The main difference will be that in order to assess risks of not meeting this objective, we need to not only assess deterioration in quality but also when this deterioration will cease and when the trend will be reversed. Predictions will be over long time scales (probably several river basin management plan periods) and will be inherently uncertain.

A key part of the risk assessment will be consideration of not only the impact of past and current land use activities but what are also the likely future land uses that may have an impact on the predicted trends. Planned measures will need to be factored in to the assessment. Climate change could be a significant factor that may influence such long term trends. For example, changes in recharge or farming practices could reverse (or assist) the measures already taken to reverse upward trends. A series of future land use scenarios may need to be considered using the conceptual model of the groundwater body to assess in principle the potential impacts. This may extend to quantitative modelling to assess the effectiveness of any remedial measures under these different scenarios.

4.5 Meeting the requirements of protected areas

For both chemical and quantitative status, protected areas in practice come within the status objective via the requirement to assess the risks to dependent ecosystems. In addition, compliance with Article 7.3 (Drinking Water Protected Area objective) is one of the elements of meeting good groundwater chemical status.

In order to carry out a risk assessment for drinking water abstraction sites all information within the catchment area on inputs, groundwater characteristics (geohydrology and -chemistry) should be analysed in connection with each other. An initiative such as a Drinking Water Protection File can be a suitable platform for this (Wuijts et al., 2007; see Annex III). This approach can be applied to the analysis of dependent ecosystems as well.

5. ELEMENTS TO CONSIDER DURING THE 2ND PLANNING CYCLE

5.1 How to consider information and data of the previous planning cycle

5.1.1 Key issues

As noted in the introduction to this guidance, planning for the second cycle of WFD RBMPs starts soon after the delivery of the first RBMPs. The preparation period is significantly reduced from the 9 years of the first cycle (2000–2009) to 6 years (2010–2015), with the first key deliverable, the next Article 5 characterisation report, due in December 2013. Whilst Member States can (and must) build on the work undertaken during the first cycle it will be a significant challenge to undertake second cycle planning whilst simultaneously implementing first cycle measures.

The key elements of second cycle characterisation and risk assessment will be:

- Refinement of water body delineation, where necessary;
- Review of pressures and risks to identify changes and new pressures;
- Factoring in climate change;
- Refinement of characterisation procedures to ensure consistency of approach with classification (status assessment).

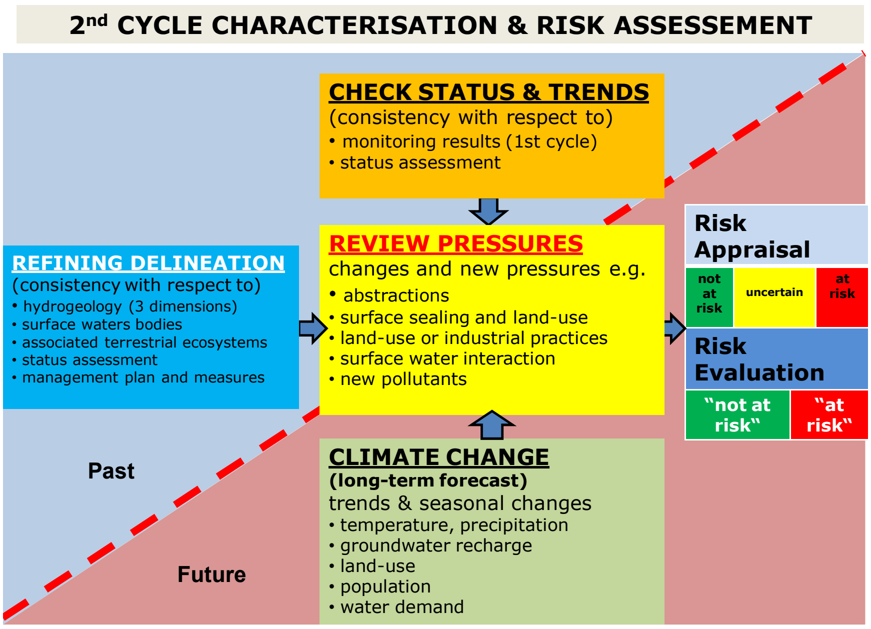

Figure 8: Key elements to consider during the 2nd planning cycle

5.1.2 Water body delineation

The delineation of water bodies, although subject to CIS guidance is not prescribed in detail in the WFD and therefore many different approaches have been adopted by Member States. Water bodies are management units and therefore their delineation should reflect management issues at the river basin district level.

With the benefit of experience from the first planning cycle, Member States may wish to change water body boundaries. However, in doing so, they should consider the consequent changes in status assessment/classification that may then follow. Radical changes in boundaries may affect the ability to provide a stable baseline against which the effectiveness of measures and progress in meeting WFD status objectives can be assessed – it will be difficult to assess compliance between RBMP cycles.

All groundwater bodies need to be associated with dependent surface water bodies - groundwater status is in part determined by the condition of these dependent water bodies. Therefore, changes in the delineation of both groundwater and surface water bodies must be taken into consideration. Potentially changes in status (both deterioration and improvement) could occur simply by changes in boundaries, whereas in practice there may be no environmental changes.

As a general guide it is advisable not to make whole scale changes in groundwater body boundaries from one river basin management plan to another unless this is essential to manage these water bodies and meet WFD objectives.

The WFD only requires the reporting of groundwater body boundaries in two dimensions and in some cases Member States may not have defined the third (depth) dimension for their groundwater bodies. However, it is advisable that the full spatial extent of groundwater bodies is defined and incorporated in conceptual models for the second river basin planning cycle, even if this is not formally reported.

The maximum depth of the groundwater body may be governed by purely hydrogeological factors or a consideration of whether there are any resource issues within a deep aquifer. As they are management units, it is not necessary to define groundwater bodies in deep aquifers that are not exploited by man and have limited connection to dependent ecosystems. Status assessments may serve no purpose in such circumstances but there is still a requirement to protect groundwater quality under the ‘prevent or limit’ objective.

5.1.3 Characterisation of groundwater bodies

The characterisation within the second planning cycle has to take into account all the information gathered during the initial and further characterisation exercises in the first planning cycle. In addition all the data and information obtained from monitoring and other investigatory activities should be integrated in the new assessment.

First of all it has to be checked whether the delineation of groundwater bodies and dependent surface water bodies has changed. Then initial characterization (see Look-Out-Box chapter 3.3), should be conducted for any newly defined groundwater bodies or simply updated for existing groundwater bodies. These data are then used to assess whether a groundwater body is “at risk” of failing WFD objectives (including good status) at the end of the second management plan period (see chapter 4).

For groundwater bodies previously assessed as not being “at risk” checks must be made as to whether there are existing or planned changes in land use, abstraction or other factors causing a risk for the groundwater body itself, or for risks to directly dependent surface water ecosystems or terrestrial ecosystems or the risk of impairment of human and other legitimate uses that could prevent the achievement of WFD objectives.

Further characterisation must be carried out for all “at risk” groundwater bodies (see Look-Out-Box, chapter 3.3).

5.1.4 Monitoring data

In the first planning cycle some Member States may have had little or no monitoring data on some of the significant pressures and impacts. With the implementation of WFD monitoring requirements all Member States should now have improved data which can be used to assess the accuracy of the first cycle risk assessments and to update the conceptual model of the groundwater body and/or the risk assessment. Based on any additional data gained to support the second cycle of characterisation, monitoring strategies and networks should be reviewed and if necessary revised. However, in refining monitoring networks checks must be made to ensure that monitoring to assess the effectiveness of measures and long term compliance with WFD objectives is not disrupted and the necessary consistency and comparability of data with previous cycles is maintained.

5.2 How to consider changes

5.2.1 Changes in land use

The first cycle of initial and further characterisation should have set a baseline against which the measured and predicted future effects of new developments on groundwater quality and quantity can be assessed. If this baseline is incomplete, it should be further developed during the second cycle characterisation and risk assessment.

A key focus should be changes in agriculture and its water demand, due to e.g. future increasing production of biofuel or increasing monocultures for the production of fast growing firewood. Also important is the prediction of changes in population and future land use (e.g. growing towns, decreasing population in the countryside, changes in transport infrastructure, industrial activities, connectivity and interaction to surface water).

Groundwater quantity is often influenced by changes in land use. The sealing of the soil by building new traffic infrastructure and new settlement areas can have significant consequences for groundwater recharge. In addition to this, there can be an increase of water abstractions in the vicinity of settlements due to higher drinking water demand for population and industry. Changes in agriculture can cause a higher groundwater abstraction due to higher needs of irrigation.

Changes in land use also affect groundwater quality: ploughing up grassland mobilises the store of nitrogen. Higher needs in irrigation could be responsible for an increased leaching of nutrients from the soil. Growing new sorts of crop can cause a higher demand on fertilizers and pesticides. In this case it is very important to estimate the protection properties of the soil and the unsaturated zone and to avoid the cultivation of crops with high fertilizer or pesticide demand on high vulnerability soils and aquifers.

5.2.2 Climate change

Groundwater resources and their long-term replenishment are controlled by long-term climate conditions. Climate change will therefore have a great impact on groundwater resources during the next decades. Although time scales of climate change and river basin planning cycles are different it is of importance to describe expected changes systematically already now.

Climate change can cause very different impacts on groundwater systems, from droughts and water scarcity in the Mediterranean region to increases in recharge in the mid-European countries. In humid regions, more frequent and intense precipitation incidents and longer dry periods may occur.

Groundwater will be less directly and more slowly impacted by climate change as compared to e.g. rivers. This is because rivers get replenished on a shorter time scale, and drought and floods are quickly reflected in river water levels. Groundwater, on the other hand, will be affected more slowly and sometimes by different patterns of precipitation. Only after prolonged droughts (particularly with reduced winter rainfall) groundwater levels will show declining trends.

Seasonal changes in precipitation are one important effect of climate change. Predictive models (e.g. Germany) forecast an increase of precipitation in the winter months and a decrease in the summer months. For agriculture, this has an effect on the irrigation demand in the summer months. Even if there is a higher groundwater recharge for the whole year, the increasing of groundwater abstraction in summer due to irrigation and a higher demand of public water supply may locally cause a long term trend of declining groundwater levels with all its consequences e.g. risks for terrestrial ecosystems and influences on the chemical quality of groundwater. Also irrigation itself can have impacts on groundwater quality, as more nutrients can be washed out of the soil.

Increased variability in rainfall may also decrease groundwater recharge in humid areas because more frequent heavy rain will result in the infiltration capacity of the soil being exceeded, thereby increasing surface runoff. In semi-arid and arid areas, however, increased rainfall variability may also increase groundwater recharge, because only high-intensity rainfalls are able to infiltrate fast enough before evaporating, and alluvial aquifers are recharged mainly by inundations during floods. (Groundwater and Climate Change: Challenges and Possibilities, BGR and GEUS, 2008).

For the second cycle of WFD Article 5 risk assessment, a consideration of the predicted changes in precipitation and groundwater recharge and the influence of its consequences (higher drinking water consumption in summer, rise in irrigation measures, surface runoff) is considered essential. The data of the dynamic regional climate modelling CLM / REMO could be used to estimate the effects of climate change in Europe. Climatic water balances using forecasted precipitation and temperature data can provide regional groundwater recharge data for the future. In connection with predictions of the development of population, water demand and changes in land use, the impact on quantity and quality of the GWB should be evaluated for the coming periods of the RBMP.

5.3 Risk assessment, Status and the use of threshold values.

5.3.1 Alignment of characterisation and status assessment methods

The characterisation exercise for the first planning cycle was carried out before the requirements of the new Groundwater Directive (2006/118/EC) and therefore the detailed requirements for groundwater chemical status assessment were known. The use of threshold values in status assessment is a further key development, as noted below.

We also now have supporting guidance (e.g. CIS Guidance Document No 18). As a result there may be wide divergence between the first cycle characterisation and classification assessment methods - the Article 5 reporting of pressures and impacts may not necessarily align with the elements or tests of good status. It is recommended that the future risk assessments undertaken as part of characterisation should take into consideration the status elements defined in the new Groundwater Directive and its associated guidance.

5.3.2 The Groundwater Directive

The Groundwater Directive in its preamble point 7 states that '(..) threshold values should be established, (..) , in order to provide criteria for the assessment of the chemical status of bodies of groundwater.' The chemical status is defined in the Water Framework Directive, Annex V, Table 2.3.2. Good groundwater status, according to that definition, refers to a situation where:

- no saline or other intrusions take place;
- quality standards are not exceeded (the Groundwater Directive set standards for nitrate and pesticides);
- the quality of groundwater does not lead to failure to achieve the environmental objectives for associated surface waters nor any significant diminution of the ecological or chemical quality of such bodies;
- the quality of groundwater does not lead to significant damage to terrestrial ecosystems which depend directly on the groundwater body;
- changes in conductivity do not point to intrusions.

According to Article 3.7 of the GWD, the European Commission has to prepare a report on the establishment of these threshold values within Europe. This report was published in March 2010 (Ref 8) which is a first important step of the implementation of the Directive.

The Groundwater Directive also specifies how threshold values should be used in determining the groundwater chemical status (Article 4.2). Basically, if groundwater quality standards or threshold values are not exceeded anywhere in the groundwater body by (time-averaged at each sampling site) the measurements, the body is in good status. In all other cases, the groundwater body does not immediately get assigned as "poor status", but Member States shall carry out an 'appropriate investigation'. In that investigation, Member States shall determine whether:

- the exceedance represents a 'significant environmental risk';
- the conditions for good chemical status of table 2.3.2 of the WFD are met;
- (for groundwater bodies from which water is abstracted for human consumption) the requirements of Article 7.3 of the WFD are met (avoiding deterioration in order to reduce the level of treatment required);

- the ability of the groundwater body to support human uses has not been significantly impaired by pollution.

In addition to the definition of the good chemical status from the WFD, the GWD explicitly mentions 'significant environmental risk', the requirements of Article 7.3 and the human use of groundwater in the context of good chemical status.

5.3.3 Guidance document on groundwater status and trend assessment

Referring to the Groundwater Directives, CIS Guidance Document 18 (Groundwater status and trend assessment) further elaborates the assessment of status, including the 'appropriate investigation'. The guidance document also deals with confidence in the status assessment and suggests the introduction of a surface criterion of 20% to quantify the 'significance of an environmental risk'. This would mean that, provided the other tests have been met, an exceedance of less than 20% of the area does not lead to a poor status of the groundwater body. Nevertheless it needs to be recognized that besides this generic recommendation, specific considerations on pressures (e.g. land-use), the characteristics of groundwater bodies and possible receptors (e.g. surface water) are the necessary assumptions to derive a surface criterion more specifically.

5.3.4 Implications for risk assessment

Although there is a framework for the use of threshold values in CIS Guidance Document No.18, the selection and precise use of threshold values (TVs) is determined by Member States and must be reported in their RBMPs. Threshold values should be derived for those pollutants responsible for the 'at risk' declaration of a groundwater body and must be set at a level whereby if no threshold value is exceeded, this means that there is no significant impact on the receptors noted in the definition of good chemical status. This in effect sets a potential upper limit to a threshold value. In contrast, there is little constraint on the lower limit to which a threshold value is set within the Directive itself. This is down to a variety of practical considerations and the level of precaution that the responsible body within the Member State wishes to adopt. In effect this means that, in terms of risk assessment, threshold values may be set at any level from a risk screening level (no risk to the receptor) through to a risk management level (higher values would result in damage to the receptor).

For the above reasons great care has to be exercised in applying threshold values to the risk assessments undertaken during characterisation – their application must take into account the status assessment method within which they have been used by the Member State. A further consideration is that whilst Member States may have reported (minimum) overall TVs for a groundwater body, they may have used different values in the assessment of each of the component elements of status. Environmental standards will vary between receptors and any risk assessment undertaken during characterisation needs to take account of such variations.

It is also important to note that initial characterisation is conducted to determine whether the groundwater body is "at risk" of failing any of the WFD's environmental objectives, of which status is only a part. In the context of the WFD this is a precautionary risk screening exercise, which is quite distinct from the need to assess whether there is actual damage to a groundwater body from human activity (i.e. poor status) and therefore whether remedial action (measures) should be taken.

What does this all mean for the use of TVs in risk assessment? If TVs have been set at the risk screening level, then they can be used as such during characterisation to identify those groundwater bodies that are definitely not at risk, as far as the status and trend objectives are concerned. However, in many cases this will not be the case and risk screening values for the "at risk" assessment may have to be set a lower level than the reported TVs for groundwater bodies.

Whilst TVs may be a useful indicator for the risk assessment they should not be used in isolation. New substances may need attention, changes in land use may lead to new risks (or earlier risks may have been reduced), recent monitoring data may shed a new light on risks known before, and so on. The pressures and impact analysis from the previous planning cycle must be fully updated.

Special attention should be paid to the way Article 7 is included in the risk assessment. Since the Groundwater Directive also sets objectives for the human uses of a groundwater body, this should be part of the risk assessment. For abstractions within a groundwater body the groundwater quality in the abstraction wells should be evaluated in relation to the standards of the Drinking Water Directive and the risk of deterioration, by trend assessment (Article 7.3) (ref. to Guidance on DWPAs).

5.4 Risk assessment, measures and exemptions

It is important to highlight that this chapter is focused on the relation of the RA and exemptions for 2021 and not for the 2015 period.

The 1st risk assessment (2004) based on Pressures and Impacts Analysis was prepared principally without benefit of a status assessment and with little knowledge of limits and methods of groundwater body's classification. Status assessment, the derivation of TVs and trend assessment was conducted in the second half of 2008. The forecast of exemptions in 2015 (groundwater bodies failing the environmental objectives in spite of planned measures) was also needed. The time period between characterisation and the publication of the River Basin Management Plan (RBMP) was long enough to enable the collection of more data and the development or refinement of the assessment methods including exemptions.

Risk assessment for the 2nd RBMP should not be the same as for the first RBMP (2004). We have better knowledge, new methods and more data. The role of risk assessment is also different.

The same steps are required by the WFD in the 2nd river basin planning cycle but the time available for assessment is shorter: the results of river basin characterisation should be available by the end of 2013 and the status assessment and list of exemptions in 2021 must be prepared by the end of 2014 (see figure 1). GWBs which will not reach their environmental objectives by 2021 must be listed even where measures have been applied. The justification of proposed exemptions is an obligatory part of the RBMP according to the WFD requirements.

The time schedule has not been the only reason for paying more attention on role of RA in further exemptions assessment. The main characteristic of the risk assessment is the forecast of the groundwater status at the end of the management plan period. This is also the basis of the exemptions assessment. In 1st RBMP 4 years between the risk assessment (2004) and the status assessment (2008) allowed time to get both more quantitative and qualitative data. In the 2nd RBMP only 1 year is available for the same exercise.

Another main difference between the initial risk assessment and the list of exemptions in the next planning cycles is probably the uncertainty of status assessment results and planned measures. The low degree of the reliability and high level of uncertainty in the impact of planned measures in 1st Planning cycle are the most important gaps. Data from monitoring, using new approaches and methodology from the start of the second planning cycle can reduce such gaps.

Risk assessment in the 2nd planning cycle can, as a part of characterisation, reflect status assessment results from 2008-2009 but clearly cannot use the results from the second status assessment (due in 2015). On the other hand water bodies identified as being at risk (2nd cycle) are all the bodies where environmental objectives will not be met in 2021 without measures. Exemption assessment will be focused on water bodies in poor status (or with significant upward trend etc.) where we have to evaluate whether or not the planned measures will be effective. For this purpose, information about status assessment or other environmental objectives from 2014–2015 and the list of planned measures will be available. This means the same tool (or approach) can be used for risk assessment as for exemption assessment. Figure 9 presents the relation between the RA, exemptions and programmes of measures. The planning process should be made in an integral manner, since each part of the cycle influences other parts. Programmes of measures should be based on the risk assessment results, while using the conceptual models and other relevant tools increases the reliability in predicted outcomes.

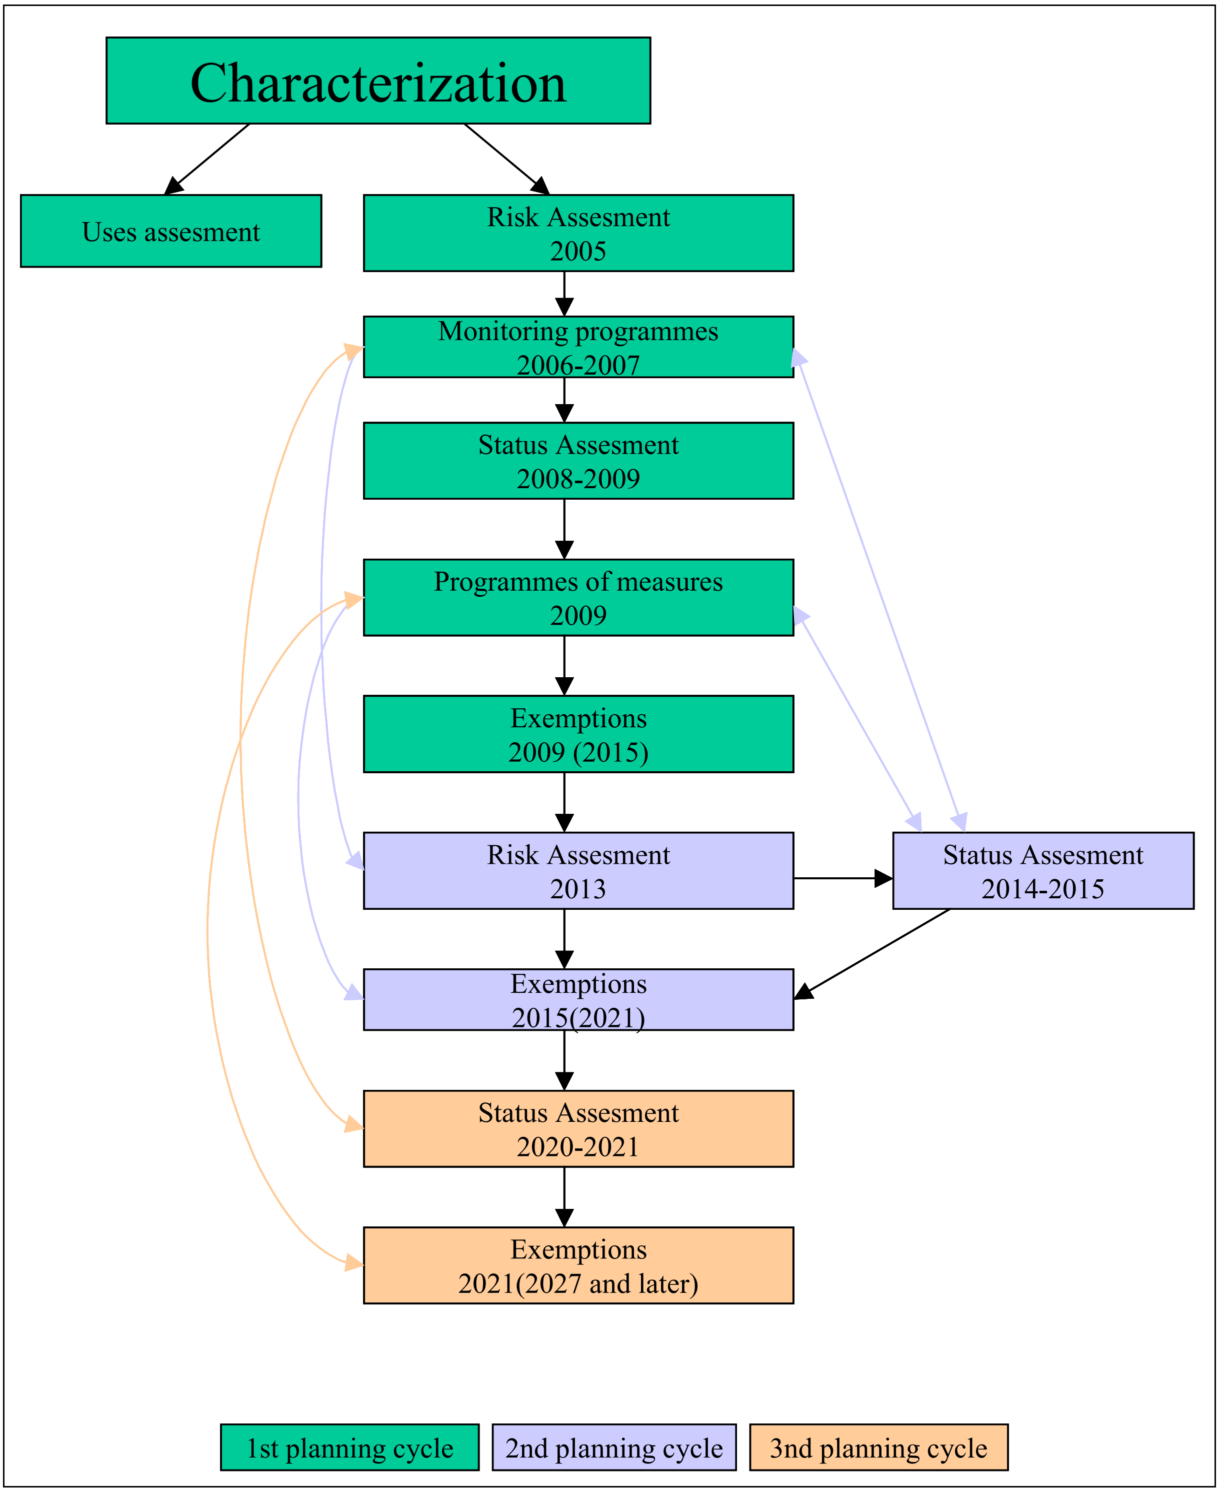

Figure 9: Relation between the RA, exemptions and programmes of measures

The RA is indirectly mentioned in the Guidance on exemptions (No. 20, 2009). The separate approach has been described in the text as well as in figures (e.g. figures 10). The figures also take into account the link between the measures and different types of exemptions. The list of exemptions should be reviewed every 6 years in the RBMP.

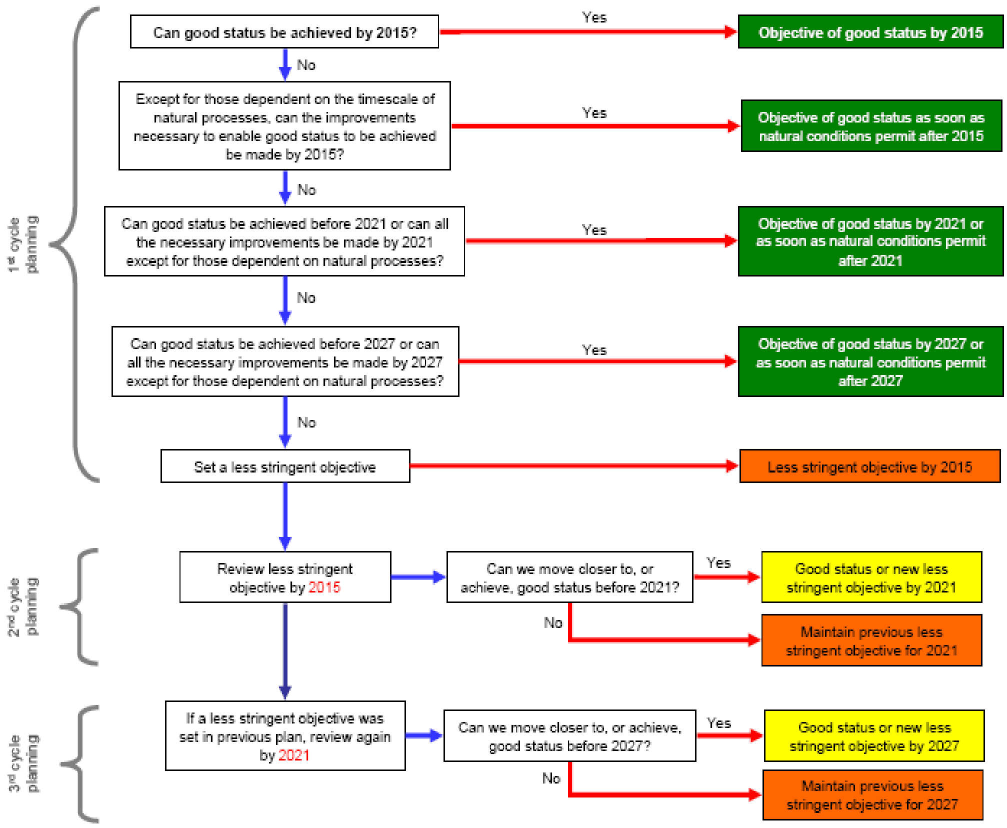

Figure 1: Stepwise thinking process for the considerations of exemptions from good status. The orange boxes refer to Art 4.5, the green except the first box to Art 4.4. For water bodies designated as heavily modified or artificial, references in the Figure to 'good status' should be taken to mean 'good ecological potential and good surface water chemical status*[16]*. Note, if the objective of "good status" is aimed for (green boxes), the achievement of "good status" needs to be confirmed by monitoring data.

Figure 10: Scheme of the exemptions requirements and requirements of current RA (Link between measures and exemptions) (Guidance Document No. 20)

ANNEX I

SUMMARY OF QUOTATIONS RELATED TO "RISK" IN THE WATER FRAMEWORK DIRECTIVE

WFD	Quotation	Related topic	Related documents
Recital (44)	In identifying priority hazardous substances, account should be taken of the precautionary principle, relying in particular on the determination of any potentially adverse effects of the product and on a scientific assessment of the risk.	Prevent and limit	Guidance Document No 17 - Direct and indirect inputs
Article 11 l)	any measures required to prevent significant losses of pollutants from technical installations, and to prevent and/or to reduce the impact of accidental pollution incidents for example as a result of floods, including through systems to detect or give warning of such events including, in the case of accidents which could not reasonably have been foreseen, all appropriate measures to reduce the risk to aquatic ecosystems.	Prevent and limit	Guidance Document No 17 - Direct and indirect inputs
Article 16.1	The European Parliament and the Council shall adopt specific measures against pollution of water by individual pollutants or groups of pollutants presenting a significant risk to or via the aquatic environment, including such risks to waters used for the abstraction of drinking water. For those pollutants measures shall be aimed at the progressive reduction and, for priority hazardous substances, as defined in Article 2(30), at the cessation or phasing-out of discharges, emissions and losses. Such measures shall be adopted acting on the proposals presented by the Commission in accordance with the procedures laid down in the Treaty.	Prevent and limit Priority substances	Guidance Document No 17 - Direct and indirect inputs
Article 16.2	The Commission shall submit a proposal setting out a list of priority substances selected amongst those which present a significant risk to or via the aquatic environment. Substances shall be prioritised for action on the basis of risk to or via the aquatic environment, identified by	Priority substances Non-specific for groundwaters	
Article 16.2 a)	risk assessment carried out under Council Regulation (EEC) No 793/93 (1), Council Directive 91/414/EEC (2), and Directive 98/8/EC of the European	Priority substances	Council Regulation (EEC) No 793/93 (1), Council Directive

WFD	Quotation	Related topic	Related documents
	Parliament and of the Council (3)	Non-specific for groundwaters	91/414/EEC (2), and Directive 98/8/EC of the European Parliament and of the Council (3)
Article 16.2 b)	targeted risk-based assessment (following the methodology of Regulation (EEC) No 793/93) focusing solely on aquatic ecotoxicity and on human toxicity via the aquatic environment.	Priority substances Non-specific for groundwaters	Regulation (EEC) No 793/93)
Article 16.2	When necessary in order to meet the timetable laid down in paragraph 4, substances shall be prioritised for action on the basis of risk to, or via the aquatic environment, identified by a simplified risk-based assessment procedure based on scientific principles taking particular account of	Priority substances Non-specific for groundwaters	
Annex II 2.1	Member States shall carry out an initial characterisation of all groundwater bodies to assess their uses and the degree to which they are at risk of failing to meet the objectives for each groundwater body under Article 4. Member States may group groundwater bodies together for the purposes of this initial characterisation. This analysis may employ existing hydrological, geological, pedological, land use, discharge, abstraction and other data but shall identify:	Risk assessment	Technical report on groundwater body characterisation issues as discussed at the workshop of 13th October 2003
Annex II 2.2	Following this initial characterisation, Member States shall carry out further characterisation of those groundwater bodies or groups of bodies which have been identified as being at risk in order to establish a more precise assessment of the significance of such risk and identification of any measures to be required under Article 11. Accordingly, this characterisation shall include relevant information on the impact of human activity and, where relevant, information on:	Risk assessment	Technical report on groundwater body characterisation issues as discussed at the workshop of 13th October 2003
Annex II 2.3	For those bodies of groundwater which cross the boundary between two or more Member States or are identified following the initial characterisation undertaken in accordance with paragraph 2.1 as being at risk of failing to meet the objectives set for each body under Article 4, the following information shall, where relevant, be collected and maintained for each groundwater body:	Risk assessment	Technical report on groundwater risk assessment issues as discussed at the workshop of 28th January 2004

Annex V 2.4.2	bodies identified as being at risk following the characterisation exercise undertaken in accordance with Annex II, Bodies which are identified in accordance with Annex II as being at significant risk of failing to achieve good status shall also be monitored for those parameters which are indicative of the impact of these pressures	Chemical status	Guidance Document N°15_Groundwater Monitoring Guidance Guidance Document No 18 - Groundwater Status and Trend Assessment
Annex V 2.4.3	establish the chemical status of all groundwater bodies or groups of bodies determined as being at risk Operational monitoring shall be carried out for all those groundwater bodies or groups of bodies which on the basis of both the impact assessment carried out in accordance with Annex II and surveillance monitoring are identified as being at risk of failing to meet objectives under Article 4. The selection of monitoring sites shall also reflect an assessment of how representative monitoring data from that site is of the quality of the relevant groundwater body or bodies.	Chemical status Chemical status	Guidance Document N°15_Groundwater Monitoring Guidance Guidance Document No 18 - Groundwater Status and Trend Assessment

SUMMARY OF QUOTATIONS RELATED TO "RISK" IN THE GROUNDWATER DIRECTIVE

GWD	Quotation	Related topic	Related documents
Recital (4)	Decision No 1600/2002/EC of the European Parliament and of the Council of 22 July 2002 laying down the Sixth Community Environment Action Programme (5) includes the objective to achieve water quality levels that do not give rise to significant impacts on, and risks to, human health and the environment.	General	
Recital (14)	It is necessary to distinguish between hazardous substances, inputs of which should be prevented, and other pollutants, inputs of which should be limited. Annex VIII to Directive 2000/60/EC, listing the main pollutants relevant for the water environment, should be used to identify hazardous and non-hazardous substances which present an existing or potential risk of pollution.	Prevent and Limit	Guidance Document No 17 - Direct and indirect inputs
Article 3 b	threshold values to be established by Member States in accordance with the procedure set out in Part A of Annex II for the pollutants, groups of pollutants and indicators of pollution which, within the territory of a Member State, have been identified as contributing to the characterisation of bodies or groups of bodies of groundwater as being at risk, taking into account at least the list contained in Part B of Annex II.	Chemical status	Guidance Document No 18 - Groundwater Status and Trend Assessment
Article 3.6	Threshold values can be removed from the list when the body of groundwater concerned is no longer at risk from the corresponding pollutants, groups of pollutants, or indicators of pollution.	Chemical status	Guidance Document No 18 - Groundwater Status and Trend Assessment
Article 4 2 c i)	on the basis of the assessment referred to in paragraph 3 of Annex III, the concentrations of pollutants exceeding the groundwater quality standards or threshold values are not considered to present a significant environmental risk, taking into account, where appropriate, the extent of the body of groundwater which is affected;	Chemical status	Guidance Document No 18 - Groundwater Status and Trend Assessment
Article 5.1	Member States shall identify any significant and sustained upward trend in concentrations of pollutants, groups of pollutants or indicators of pollution found in bodies or groups of bodies of groundwater identified as being at risk and define the starting point for reversing that trend, in accordance with Annex IV.	Chemical status	Guidance Document No 18 - Groundwater Status and Trend Assessment

GWD	Quotation	Related topic	Related documents
Article 5.2	Member States shall, in accordance with Part B of Annex IV, reverse trends which present a significant risk of harm to the quality of aquatic ecosystems or terrestrial ecosystems, to human health, or to actual or potential legitimate uses of the water environment, through the programme of measures referred to in Article 11 of Directive 2000/60/EC, in order progressively to reduce pollution and prevent deterioration of groundwater	General	
Article 5.3	Member States shall define the starting point for trend reversal as a percentage of the level of the groundwater quality standards set out in Annex I and of the threshold values established pursuant to Article 3, on the basis of the identified trend and the environmental risk associated therewith, in accordance with Part B, point 1 of Annex IV.	Environmental risk	
Article 5.5	Where necessary to assess the impact of existing plumes of pollution in bodies of groundwater that may threaten the achievement of the objectives in Article 4 of Directive 2000/60/ EC, and in particular, those plumes resulting from point sources and contaminated land, Member States shall carry out additional trend assessments for identified pollutants in order to verify that plumes from contaminated sites do not expand, do not deteriorate the chemical status of the body or group of bodies of groundwater, and do not present a risk for human health and the environment	Prevent and limit	Guidance Document No 17 - Direct and indirect inputs
Article 6.1.b	for pollutants listed in Annex VIII to Directive 2000/60/EC which are not considered hazardous, and any other non hazardous pollutants not listed in that Annex considered by Member States to present an existing or potential risk of pollution, all measures necessary to limit inputs into groundwater so as to ensure that such inputs do not cause deterioration or significant and sustained upward trends in the concentrations of pollutants in groundwater. Such measures shall take account, at least, of established best practice, including the Best Environmental Practice and Best Available Techniques specified in the relevant Community legislation.	Prevent and limit	Guidance Document No 17 - Direct and indirect inputs
Article 6.3.e i)	measures that would increase risks to human health or to the quality of the environment as a whole; or	General	

GWD	Quotation	Related topic	Related documents
Article 10	Without prejudice to Article 8, the Commission shall review Annexes I and II to this Directive by 16 January 2013, and thereafter every six years. Based on the review, it shall, if appropriate, come forward with legislative proposals, in accordance with the procedure laid down in Article 251 of the Treaty, to amend Annexes I and/or II. In its review and in preparing any proposal, the Commission shall take account of all relevant information, which might include the results of the monitoring programmes implemented under Article 8 of Directive 2000/60/EC, of Community research programmes, and/or of recommendations from the Scientific Committee on Health and Environmental Risks, Member States, the European Parliament, the European Environment Agency, European business organisations and European environmental organisations.	General	
Annex I.2	The results of the application of the quality standards for pesticides in the manner specified for the purposes of this Directive will be without prejudice to the results of the risk assessment procedures required by Directive 91/414/EEC or Directive 98/8/EC.	Risk assessment	Directive 91/414/EEC and Directive 98/8/EC
Annex II A	Member States will establish threshold values for all pollutants and indicators of pollution which, pursuant to the characterisation performed in accordance with Article 5 of Directive 2000/60/EC, characterise bodies or groups of bodies of groundwater as being at risk of failing to achieve good groundwater chemical status. Threshold values will be established in such a way that, should the monitoring results at a representative monitoring point exceed the thresholds, this will indicate a risk that one or more of the conditions for good groundwater chemical status referred to in Article 4(2)(c)(ii), (iii) and (iv) are not being met. all pollutants which characterise bodies of groundwater as being at risk, taking into account the minimum list set out in part B;	Chemical status	Guidance Document No 18 - Groundwater Status and Trend Assessment
Annex II C	information on the number of bodies or groups of bodies of groundwater	Chemical status	Guidance Document No 18 -

GWD	Quotation	Related topic	Related documents
	characterised as being at risk and on the pollutants and indicators of pollution which contribute to this classification, including the observed concentrations/ values; information on each of the bodies of groundwater characterised as being at risk, in particular the size of the bodies, the relationship between the bodies of groundwater and the associated surface waters and directly dependent terrestrial ecosystems, and, in the case of naturally-occurring substances, the natural background levels in the bodies of groundwater;		Groundwater Status and Trend Assessment
Annex III	The assessment procedure for determining the chemical status of a body or a group of bodies of groundwater will be carried out in relation to all bodies or groups of bodies of groundwater characterised as being at risk and in relation to each of the pollutants which contribute to the body or group of bodies of groundwater being so characterised	Chemical status	Guidance Document No 18 - Groundwater Status and Trend Assessment
Annex III 4 e)	The risk from pollutants in the body of groundwater to the quality of water abstracted, or intended to be abstracted, from the body of groundwater for human consumption	DWPAs	Guidance No 16 - Groundwater in DWPAs
Annex IV A	Member States will identify significant and sustained upward trends in all bodies or groups of bodies of groundwater that are characterised as being at risk in accordance with Annex II to Directive 2000/60/EC, taking into account the following requirements:	Trend assessment	Guidance Document No 18 - Groundwater Status and Trend Assessment
Annex IV B 2	once a starting point has been established for a body of groundwater characterised as being at risk in accordance with Section 2.4.4 of Annex V to Directive 2000/60/EC and pursuant to point 1 above, it will not be changed during the six-year cycle of the river basin management plan required in accordance with Article 13 of Directive 2000/60/EC;	Trend assessment	Guidance Document No 18 - Groundwater Status and Trend Assessment

ANNEX II

Setting up Conceptual Models for Groundwater Systems

1. INTRODUCTION TO THE CM ANNEX

In the new Groundwater Directive as well as in several Guidance Documents, the use of 'conceptual models' is mandatory or recommended, for various purposes. The term 'conceptual model' is not defined in the Groundwater Directive.

In this Annex an approach to set up conceptual models for purposes related to the WFD and GWD and assist in groundwater management is described.

Definition of conceptual model

In the context of this guidance, a conceptual model is a means of describing and optionally quantifying systems, processes and their interactions. A hydrogeological conceptual model describes and quantifies the relevant geological characteristics, flow conditions, hydrogeochemical and hydrobiological processes, anthropogenic activities and their interactions. The degree of detail is based on the given problems and questions. It is one of the basic steps for the management of groundwater bodies.

Depending on the specific problems/questions to be addressed for groundwater, a conceptual model (I) is an evolving system that is starting simple and may grow in complexity and (II) starts with a basic descriptive approach of structures and processes and may reach up to their parameterization. The CM is a knowledge based approach that is evolving during development and use.

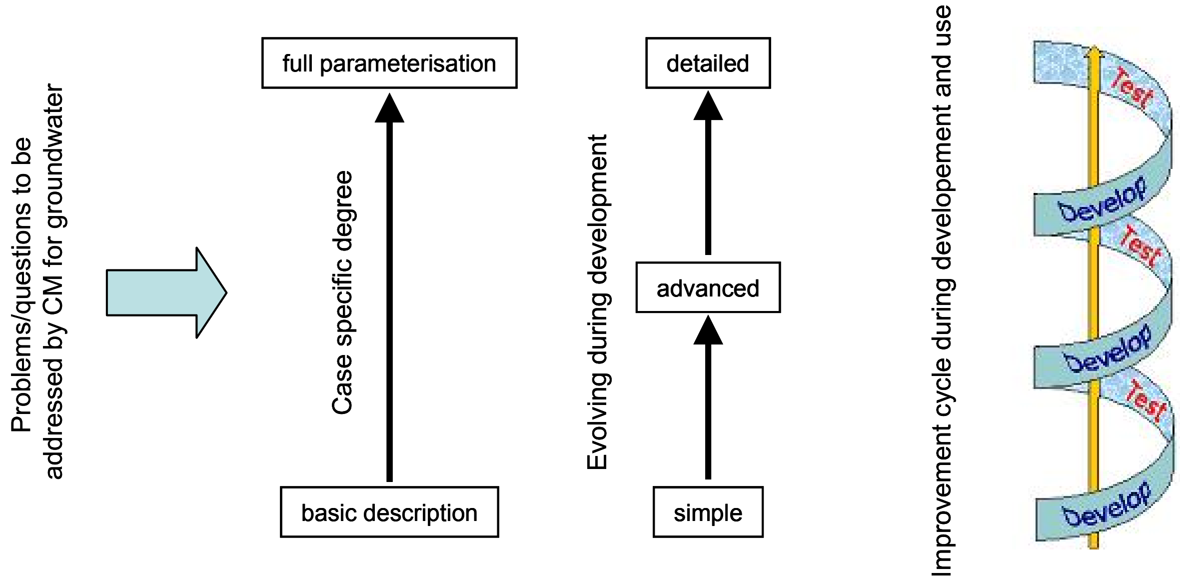

Figure 1: The application requirements determine the CM's degree of parameterization and complexity.

It can be concluded that the use of conceptual models is recommended for various purposes. Its cyclic nature (stepwise approach) is emphasized: start simple, refine later if necessary.

2. BASIC PROCEDURE

For many purposes CM in different degrees of elaboration and complexity are already existing. Mostly, they are a good basis to build on. Nevertheless, the complete procedure of setting up a CM is described here.

To address the different aims for Conceptual Models a stepwise approach is suggested. Within the steps there is a follow up of a qualitative description (e.g. what structures, processes are there) and a quantitative description of parameters (e.g. flow rates, concentrations):

Step 1, basic CM for the groundwater body

- Step 1a, qualitative CM
- Step 1b, Quantification of parameters in the CM

Step 2, to include risk assessment aspects into the CM[11]

- Step 2a, qualitative description of impacts (anthropogenic)
- Step 2b, quantitative description of impacts

Step 3, to include risk management aspects into the CM

- Step 3a, description of effects of existing measures
- Step 3b, prediction of effects of existing and future measures

Dependent on the aims a consequent follow up of these steps is not mandatory.

[11] Step 2, especially the quantitative consideration is quite similar to the assessment of groundwater bodies

3. INITIAL CONSIDERATIONS FOR SETTING UP A CONCEPTUAL MODEL

3.1 Scope and questions to be answered by a CM

The management of groundwater systems holds by its nature various steps in a continuous cycle (see figure 6 chapter 3.2 in the main document). Within the cycle of groundwater management conceptual models can be used in different phases with a different purpose. Each step gives rise to different questions to be answered. For instance:

- *Information and communication*: To allow an integration of and communication to no expert stakeholders
- *Status assessment*:
    - What is the interaction between groundwater and ecosystems?
    - How can MS inform risks and the effect of action plans to the public?
    - Do the groundwater bodies meet the environmental objectives of the WFD (Article 4)?
- *Monitoring*: What is the best design of a monitoring network within the frame of the WFD?
- *Risk assessment*: What is the risk of not meeting the environmental objectives of the WFD (Article 4)?
- *Risk management*: Where to initiate which measures and what are their effects in time and space.

Depending on the questions to be addressed different degrees of detail and complexity are required in the development of a CM (see figure 1).

The questions to be answered by a conceptual model also set demands upon the scale in time and space to be considered. For instance when evaluating the effect of inputs on abstractions, one typically studies a local scale, while for the design of monitoring network a regional scale is in place. It should be kept in mind that independent from the scale of interest, in all considerations for a conceptual model, hydrogeological boundaries determine the extension of the areas to be considered. For instance, for studying again the effect of inputs on abstractions, the catchment area should be taken into account when setting up the conceptual model.

3.2 Spatial scale

The whole system of aquifers, aquicludes, unsaturated zone, etc. is under consideration in this guidance. This approach covers e.g. the surface water interaction and unsaturated zone interaction.

For the delineation of a conceptual model it is obligatory to move from an overview scale like groundwater bodies to a detailed scale considering several aspects, e.g. the recharge area of a sampling site: In the first case, the groundwater body as a whole is the area of the conceptual model. In many cases only parts of a groundwater body are the origin of poor status (depending on e.g. high abstraction areas, land use). It is helpful to define the water balance for the area covered by the conceptual model. If parts of the groundwater bodies are negatively influenced e.g. by point sources, only those areas that might be affected have to be considered in the CM more detailed. The smallest scale of CM is the catchment area of a sampling point.

In general this means that different scales have to be considered when setting up a CM. A varying depth of data is needed, from only basic data in the overview scale to more specific data in the detailed scale where the CM should provide a reliable basis for description, risk-assessment and -management. This allows to reduce data needs in areas that are not affected.

3.3 Temporal scale

Temporal scale is very important in the CM elaboration, because it touches e.g. basic information on groundwater dynamics (like infiltration rates, geogenic changes of physical/chemical groundwater properties).

Temporal aspects can be distinguished into natural variations (e.g. seasonal effects) and anthropogenic influences like rising concentrations, decreasing groundwater levels).

3.4 Main points during CM set-up

Based on the previous considerations in chapter 2 and 3 the following main points can be summarized:

Basic delineation

- Scope and questions to be answered determine the degree of details and complexity of the CM (chapter 3.1).
- Definition of the investigation area based on the regional hydrogeological situation including relevant geological and tectonic structures, characterisation of main groundwater and surface water catchment areas (chapter 3.2)
- Definition of the balance and target area, based on sufficient geohydraulic boundary conditions (chapter 3.2)
- Vertical and horizontal structuring units (hydrogeological units) have to be defined. Formations with comparable hydrogeological characteristics (see chapter 5.1) have to be combined and important heterogeneous areas have to be kept.

Description, parameterisation and quantification

- Description and Quantification of important hydraulic, geochemical and hydrochemical parameters where possible and necessary. They have to be transferred from point to areas of parameter zones, without misrepresenting driving processes and interactions.
- Consideration of processes with slow kinetics (e.g. solution processes, unsaturated zone flow, changes in surface conditions, climate variations…)
- Description of the most important climatic and unsaturated zone parameters
- Delineation of land use distribution
- Identification of emerging areas that could pose a potential risk (chapter 5.2)
- Evaluation and assessment of potential uncertainties, variability, and representatives in data and structures (chapter 5.2).

Cyclic approach

- The setting up of a CM is not a static process, it requires several iteration steps during development (e.g. by aligning it with new field data), application (e.g. a numerical model serves to verify whether complex interacting processes are appropriately described), and maintenance (see Figure 2).
- Be aware that it might be necessary in one of the CM development steps, e.g. step 2b (chapter 5.2) to get back in one of the previous steps in case it turns out that actual data show that the CM is no longer consistent or shows new gaps.

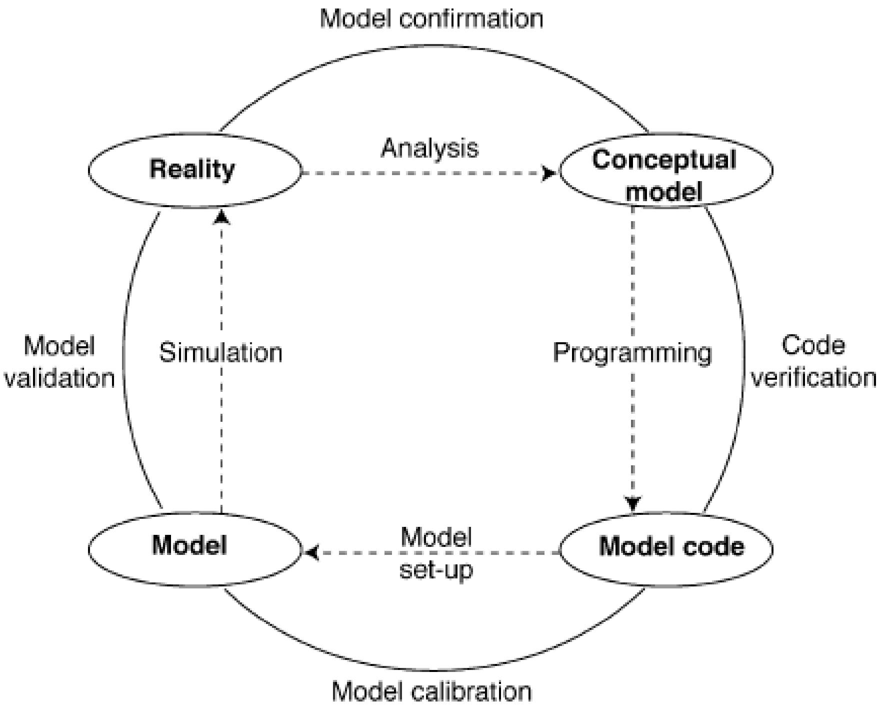

Figure 2: Cyclic approach for developing a conceptual model[12]

[12] Refsgaard, J. C., Henriksen, H. J. r. (2004). Modeling guidelines - terminology and guiding principles. Advances in Water Resources, vol. 27, no. 1, pp. 71-82.

4. DATA

During setting up a CM the requirements defined in chapter 3 determine the need for screening existing data from various sources or to collect new data.

It is important to be aware that, in addition to the WFD and GWD, groundwater monitoring data are collected for the purposes of other European and national programmes or Directives. These data can be used within the CM. They can be very valuable, as they provide quite often long lasting existing data sets and as future data out of these programmes can be integrated in the CM as well. Their use also avoids an unnecessary collection of new data. Thus a wide range review of existing data and data collection activities is very important.

Setting these data in the context of a CM gives an added value to them.

4.1 Data check list

The data checklist provides a comprehensive overview of information that might be needed. In practice, depending on the questions to be answered (chapter 3.1), only a limited selection of these data is needed. Tables with examples (without claiming completeness) for the data needed are given below.

Step 1, basic CM for the groundwater body

Step 1a Qualitative CM:

Step 1a is to give an overview on the aquifer geometry and basic characteristics. It has to consider topographic information, geology and hydrogeology in a qualitative, descriptive way.

Step 1b Quantification of parameters

Step 1b quantifies the elements described in step 1a. It considers e.g hydraulic, geochemical hydrochemical and soil data and values. It may occur that for this quantification step further detailed data of step 1a are useful.

Table 1: Conceptual Model – qualitative description (step 1a)

Topography • Morphology • Surface waters (stream flows, lakes, springs) • Surface water catchment areas	**Geology** • Lithology • Tectonics • Stratigraphy
	Hydrogeology • Groundwater catchment area • Aquifer geometry • Hydrogeological units Aquifer type (porous, fissured, karst etc.) Geochemical type (silicious, calcareous etc.) Permeability (rough estimation high, medium low) Confined/unconfined Consolidated/unconsolidated rock • Groundwater (chemical) typology • Single/multi-aquifer system • Unsaturated zone • Estimation of flow directions • Local uses of groundwater

Table 2: Conceptual Model – quantification of parameters (step 1b)

Geochemical data • Clay content • Organic carbon content (in soil/aquifer matrix) • Mineralogical composition of soil/aquifer matrix	**Hydraulic data** • Hydraulic conductivity • Porosity (total/effective) • Groundwater levels • Hydraulic gradients • Direct recharge (rainfall) • Indirect recharge/discharge (interaction with surface waters, drainage and sewers)
Basic hydrochemical data • Temperature • pH • Conductivity • Redox potential • Alkalinity • Dissolved oxygen • Dissolved organic carbon • Mineral content (Ca^{2+}, Mg^{2+}, Na^{+}, K^{+}, NH_4^{+}, HCO_3^{-}, Cl^{-}, SO_4^{2-}, NO_3^{-})	**Specific hydrochemical data** • Compounds related to age determination (e.g. ^{3}H) • Trace compounds
Soil (pedology) • Soil type distribution • Depth of development	

Step 2, to include risk assessment aspects into the CM[13]

Step 2a Qualitative description of impacts (anthropogenic)

Step 2a is to delineate different types of land use, receptors and potential impacts/risks.

Table 3: Conceptual Model – qualitative description of impacts (step 2a)

Land use and potential stress factors and risks[14], e.g. • Agriculture • Industry • Infrastructure • Abstraction and infiltration points • Heat storage or extraction points	**Receptors e.g.** • Protective zones (e.g. water supply facilities, wetlands, ecotopes)

[13] Step 2, especially the quantitative consideration is quite similar to the assessment of groundwater bodies

[14] For an overview on land use distribution maps based on CORINE land use data, NATURA 2000, etc. can be used

Step 2b Quantitative description of impacts

Step 2b is to quantify emission, immissions and uses.

Table 4: Conceptual Model – quantitative description of impacts (step 2b)

Emission of anthropogenic sources	**Inputs to groundwater by anthropogenic sources**
• Agriculture (e.g. N surplus) • Industry • Infrastructure • Mining (including mines, tailing dams and spoil heaps) • Waste management activities • Diffuse soil contamination (e.g. caused by atmospheric deposition)	• Case-specific pollutants (e.g. CHC, TPH, BTEX, oxygenates, HM, PAHs, pesticides, creosotes, nitrate, sulphate, ammonia) • Corresponding degradation products • Additional potential electron acceptors and nutrients ($Mn^{2+/4+}$, $Fe^{2+/3+}$, P) • Indicators of biodegradation (Mn^{2+}, Fe^{2+}, CH_4) • metals
Groundwater use • Abstraction or infiltration rates • Heat storage or extraction	

Step 3, to include risk management aspects into the CM

Step 3a Description of effects of existing measures

In step 3a existing data of groundwater quality and quantity are used to derive information on parameters (e.g. travel times) that impact the effects of existing measures. This might be information that results out of the interpretation of time dependent data (e.g. nitrate travel times calculated out of concentration peaks in two monitoring wells). For measures related to groundwater quantity effects on groundwater level and groundwater related ecosystems due to changes in an abstraction regime can be calculated.

Table 5: Conceptual Model – description of existing measures and effects (step 3a)

Measures for groundwater quality	**Measures for groundwater quantity**
• existing concentration data rows for calculation (in relation to river basin management plan) of travel times in unsaturated/saturated zone • temporal and spatial development of anthropogenic input (e.g. fertilizer) • results of tracer tests • calculated/measured degradation/reaction rates	• existing data on groundwater/surface water levels • existing data on groundwater abstraction • results of tracer tests

Step 3b Prediction of effects in future of existing and future measures

Step 3b has to provide data that allow the prediction of effects of existing and future measures. These data are based on the data collected for step 3a and also includes data collected in steps 1 and 2, especially the quantifying data. Thus step 3b marks the transition from the conceptual model to the mathematical and numerical model.

Table 6: Conceptual Model – forecast on effects due to measures (step 3b)

Future effects of measures for groundwater quality	**Future effects of measures for groundwater quantity**
• calculated (in relation to river basin management plan) travel times in unsaturated/saturated zone • calculated degradation/reaction rates • scenarios of climate development • scenarios of future developments in land use, population and water demand	• calculated effects to groundwater level and groundwater related ecosystems by changes in abstraction regime • scenarios of climate development • scenarios of future developments in land use, population and water demand

4.2 Data review

By implementing or following several national and European programs and guidelines related to groundwater, soil, surface water and related fields a large data base is available that should be considered carefully before initiating new data collection activities.

When comparing or combining data out of different sources a quality check e.g. in terms of collection method, scale and temporal aspects should be made.

4.3 Data collection/acquisition

New data should only be collected, if, after careful consideration, existing data turned out not to be sufficient related to the target group to be addressed and the questions to be answered. (See also Chapter 3 of main document)

5. CONCEPTUAL MODEL DEVELOPMENT

5.1 Basic CM for the groundwater body, step 1 qualitative and quantitative CM

Description of Step1a. qualitative parameters in the CM

The task is to define a first understanding of the spatial scale to be considered (chapter 3.2) based on topographical data and definition of surface water catchment area. This is followed by the development of a hydrogeological understanding out of geological data.

The main knowledge increase of this step is:

⇨ Definition of hydrogeological properties

⇨ Derivation of hydrogeological units.

These outcomes allow a refinement of the investigation area and a first estimation of the groundwater balance area as interface to step 1b.

At the end of step 1a a first overview on the hydrogeological system should already be possible (principle maps/sketches)

The results of this step can be shown as e.g. cross sections, maps, block diagrams, providing:

- Spatial distribution/delineation of hydrogeological units in the area delineated for the CM
- Description of monitoring network (see Monitoring guidance)
- Integrate information on groundwater flow (directions)

Description of Step1b, Quantification of parameters in the CM

Hydraulics:

The hydraulic characteristics are described by integrating measured soil (pedological) and hydraulic data (e.g. groundwater levels, gradients, permeabilities, recharge, discharge, level of drainage)

The main knowledge increase of this step is:

⇨ Groundwater balance for draft balance area

⇨ Adjustment of balance area related to groundwater balance

⇨ A first estimation if the existing monitoring network is sufficient

The results of this step can be shown as e.g. cross sections, maps, block diagrams, providing:

- Quantified Water balance, split to different components of discharge and recharge
- GW flow directions
- Depth to GW table
- Travel times of seepage and groundwater
- Other refined products of step 1a.

Hydrochemistry:

The aim is to elaborate a spatial and temporal distribution of basic and, specific (where necessary) hydrochemical data (natural groundwater composition).

The main knowledge increase of this step is:

⇨ understanding and quantification of natural hydrochemical processes

⇨ e.g. allows to identify natural background level (according to Guidance on Groundwater Status and Trend Assessment)

⇨ further confirmation of balance area

⇨ further confirmation of flow regime

The results of this step can be shown as e.g. maps, diagrams, providing:

- Groundwater chemistry characterisation in time and space
- Natural background levels
- Refined products of step 1a and 1b hydraulics.

5.2 Risk based requirements – step 2, including risk assessment aspects

Description of Step 2a, qualitative description of impacts (anthropogenic)

In this step, different types of land use and receptors are delineated (according to Guidance on Groundwater Status and Trend Assessment and Guidance on the application of the term 'direct and indirect inputs' in the context of the Groundwater Directive 2006/118/EC).

Also, a delineation of risks is done by identifying specific points or areas that could pose a risk and the identification of types of actual or potential inputs (direct/indirect, point/diffuse, actual/historical, permanent/periodic) has to be done in this step.

The main knowledge increase of this step is:

⇨ Identification of the location of anthropogenic inputs (hazards)

⇨ Identification of the location of (potential) receptors

⇨ Identification of plausible pathways between hazards and receptors

⇨ Identification of actual risks (magnitude and probability of unacceptable impacts at receptors)

The results of this step can be shown as e.g. maps, providing:

- Distribution of different types land use
- Distribution of different anthropogenic impacts
- Distribution of different receptors

Description of Step2b, quantitative description of impacts

Emissions, immissions and uses are described in this step. Aims are the definition of monitoring data requirements, (type of parameter characterising the impacts, where to measure, frequency of measurements) and the temporal and spatial distribution of substances measured in the groundwater caused by anthropogenic impacts (e.g. landfill contamination plume). For groundwater quantity, temporal and spatial variations of anthropogenic influences on the hydraulic system (e.g. drinking water abstraction) are to be considered.

The main knowledge increase of this step is:

⇨ the spatial delineation of concentrations and fluxes

⇨ the variability of concentrations and fluxes in time

⇨ identification (quantification?) of mobility relevant processes (attenuation, dilution, see Guidance on Groundwater Status and Trend Assessment)

The results of this step can be shown as e.g. maps and diagrams, providing:

⇨ the delineation of areas and receptors affected

⇨ the reconstruction of the impacts from past events until today

⇨ first predictions of the future development of the impacts

5.3 Risk management based requirements (step 3)

In step 3, the CM development process is directly linked to the program of measures of the WFD. It is necessary to distinguish measures regarding groundwater quality and quantity.

Description of Step3a, description of effects of existing measures

Measures for GW quality:

With the help of time series analysis, the effects of existing measures can be described by estimations of travel times in the unsaturated and saturated zone and by delineating the impact on the kinetics of degradation and attenuation processes. The impact of measures addressing temporal and spatial development of past anthropogenic inputs can be described.

This is the basic instrument for the understanding of the processes described in step 2 and the knowledge base to provide a basis for the prediction of future processes in step 3b.

Measures for GW quantity:

Here, a description of past and ongoing measures (e.g. changes in abstraction regime) and their effects to groundwater level and groundwater related ecosystems is made.

The main knowledge increase of this step is:

- an understanding of the effects of measures on groundwater quantity and quality.
- a knowledge base to decide, if a good status can be achieved in principle?

The results of this step can be shown as:

- maps of the spatial and timely development in impact areas, where measures have been taken already
- diagrams of the development of risk related parameters due to existing measures.

Description of Step3b, description of effects of existing measures

Based on the information in Step 3a, step 3b provides data sets for future scenarios that can feed into mathematical or numerical models.

Measures for GW quality:

With the help of calculations of travel times in the unsaturated and saturated zone it is possible to compare the effects of measures in time and space to deadlines defined in river basin management plans. In this step, also scenarios considering the future climate and land use development, population and water demand can be elaborated.

Measures for GW quantity:

Mainly, the effects to groundwater level and groundwater related ecosystems by different scenarios of measures focusing on the abstraction/infiltration regime is calculated. Like for groundwater quality, scenarios considering the future climate and land use development, population and water demand can/should be elaborated.

The main knowledge increase of this step is:

- if proposed/planed measures in principle are sufficient to reach the RBMP goals
- the time of reaching a trend reversal
- the time of reaching a good status/natural background level
- advise, if there is a need for prolongation of deadlines or less stringent environmental objectives

The results of this step can be shown as diagrams and maps together with a text description.

5.4 Documentation/Visualisation

It is important to have aggregated documentation of all steps of a CM. It should be clearly shown, where improvement loops are situated. The complexity of the visualisation is dependent on the scoping questions and the people addressed. Data sources used have to be documented.

Appropriate media for publishing are e.g. pictures, diagrams, maps, block diagrams, cross sections, text, Slide shows, Web Map Services, viewer.

6. VALIDATION OF CM, QUALITY ASSURANCE

6.1 Introduction

A conceptual model is dynamic, evolving with time as new data are obtained and as the model is tested. Its development and refinement should adopt an iterative approach. Before the conceptual model can be used, it has to be calibrated. Before re-characterisation takes place, the conceptual model should be evaluated, refined and validated. All data concerning the nature of the groundwater body collected during the characterisation process should be tested against the conceptual model, both to refine the model and to check for data errors. In doing so, the distance to target should be kept in mind: the closer a groundwater body gets toward a good status the more accurate the conceptual model should be in order to carry out a correct compliance test. If there is uncertainty about the reliability of the results, the groundwater body is at-risk beforehand.

Four types of data will have to be included in the calibration and validation process:

1. process data: e.g. groundwater to surface water interactions, steady state or transient state
2. structure : e.g. geological structure, boundary conditions
3. inputs: e.g. rainfall, groundwater recharge, evapotranspiration
4. parameters: e.g. permeability, storage coefficient

The main difference between calibration and validation is the timing when those processes take place:

- Calibration is executed before the conceptual model can be considered finished : it is the process where the values of all the parameters that can vary have been chosen in such a way that the calculated groundwater levels, velocities, concentrations,… are as close as possible to the real ones;
- Validation is executed after the conceptual model is finalised an when a significant set of new data is obtained; in this stage one can check if the new data are well predicted; if not one should restart the calibration process.

The validation of a conceptual model can be based on monitoring data if there is sufficient data available. Quite often this is not the case. Then an analysis of the characteristics of the pressures and receptors combined with monitoring data can be a suitable validation method. Following the approach applied to the selection of relevant substances (Guidance no. 3, 2003), one can analyse the pressures on a groundwater body (top-down), analyse the observed effects on receptors (bottom-up), and compare these, certainly taking into account a travel time distribution. This comparison offers insight in the validity of the conceptual model.

In general it is important to plan and log the validation steps that will be carried out, taking into consideration aspects such as availability of data and the distance to the target.

6.2 Validation of conceptual models

Within CM setup the first step in validation is to put existing data consistently together to a conceptual model. As CM is not a static image, new information that can feed into the CM appears over time (e.g. monitoring data, information construction measures…) when these new information can be constantly put into your CM this validates that the actual design of the CM is right. In case of conflicts, both the conceptual model design and the quality of the new information have to be reviewed, to come up with a consistent solution. The validation by monitoring data and new information is the most common way.

Besides this validation by monitoring data, it is also possible to make use of mathematical models (usually computer based) for validation. A first way is, if the existing conceptual model can be reproduced by a mathematical model (e.g. reproduction of measured groundwater levels or hydrographic curves). A second but more time consuming way is to compare the forecasting of CM based mathematical models with later monitoring data of the groundwater body.

6.3 Quality assurance

Errors in the development of a CM will be perpetuated throughout the other steps of setting up the CM and are likely to result in developing a sampling and analysis plan that may not achieve the data required to address the relevant issues. It is important to identify theories and assumptions underlying the CM to ensure adequate transparency. If the problem is complex, it may be considered breaking it into more manageable pieces, which might be addressed by separate studies. Priorities may be assigned to individual segments of the problem and the relationship between the segments examined.

There are two primary types of intended uses of the data: data for *decision making* and data necessary for *making estimations.* Models can be used to generalise point information to information for areas.

Decision problems

- Does the concentration of contaminants in groundwater exceed acceptable levels?
- Does the pollutant concentration exceed a standard?
- Does a contaminant pose a human health or ecological risk?
- Is the contaminant concentration significantly above background levels?
- Etc.

Estimation problems

- What is the average rate of groundwater flow in the aquifer?
- What is the distribution of pollutant groundwater concentrations over space and time?
- What are the sizes of endangered species populations within the habitat of concern?
- How do the background contaminant concentrations vary over space and time?
- Etc.

In order to minimize the possibility of either making erroneous conclusions or failing to keep uncertainty in estimates to within acceptable levels *performance or acceptance* criteria should be derived that the collected data will need to achieve. *Performance* criteria, together with the appropriate level of common Quality Assurance practices, will guide the design of new data collection efforts, while *acceptance* criteria will guide the design of procedures to acquire and evaluate existing data relative to the intended use. Therefore, the method to use and the type of criteria to be set will, in part, be determined based on the intended use of your data.

The Data Quality Objective Process (Guidance on Systematic Planning Using the Data Quality Objectives Process EPA QA/G-4, February 2006) can be used to develop *performance* and *acceptance* criteria (or data quality objectives) and specify tolerable levels of potential decision errors that will be used as the basis for establishing the quality and quantity of data needed to set up a conceptual model.

The DQO Process is a series of logical steps that gives guidance to a plan for the resource-effective acquisition of environmental data. It is both flexible and iterative, and applies to both decision-making (e.g., compliance/non-compliance with a standard) and estimation (e.g., ascertaining the mean concentration level of a contaminant). The DQO Process is used to establish *performance* and *acceptance* criteria, which serve as the basis for designing a plan for collecting data of sufficient quality and quantity to support the goals of the study. Use of the DQO Process leads to efficient and effective expenditure of resources; consensus on the type, quality, and quantity of data needed to meet the project goal; and the full documentation of actions taken during the development of the project.

In general, *performance* criteria represent the full set of specifications that are needed to design a data or information collection effort such that, when implemented, generate newly-collected data that are of sufficient quality and quantity to address the project's goals. *Acceptance* criteria are specifications intended to evaluate the adequacy of one or more existing sources of information or data as being acceptable to support the project's intended use.

When evaluating scientific and technical information, the EPA recommends using the five General Assessment Factors (GAFs) documented in Table 7.

Table 7: EPA General Assessment Factors

Soundness: The extent to which the scientific and technical procedures, measures, methods or models employed to generate the information are reasonable for, and consistent with, the intended application.
Applicability and Utility: The extent to which the information is relevant for its intended use.
Clarity and Completeness: The degree of clarity and completeness with which the data, assumptions, methods, quality assurance and analyses employed to generate the information are documented.
Uncertainty and Variability: The extent to which the variability and uncertainty (quantitative and qualitative) in the information or the procedures, measures, methods or models are evaluated and characterized.
Evaluation and Review: The extent of independent verification, validation, and peer review of the information or of the procedures, measures, methods or models.

These general assessment factors can be used to describe the Quality Assurance of the conceptual model.

7. GLOSSARY

A comprehensive glossary of terms on Groundwater can be found on the webpages of “The Groundwater Foundation”:

ANNEX III - Examples

A CONCEPTUAL MODEL TO CHARACTERISE A GROUNDWATER BODY

GWB Leibnitzer Feld - Location and boundaries

The groundwater body "Leibnitzer Feld" is situated in the Austrian province of Styria to the south of Graz in southeast Austria. It is a single groundwater body in a porous medium, extending in a north-south direction and covering 103 km^2 at altitudes ranging between 157 and 340 m a.s.l. (above Adriatic Sea level).

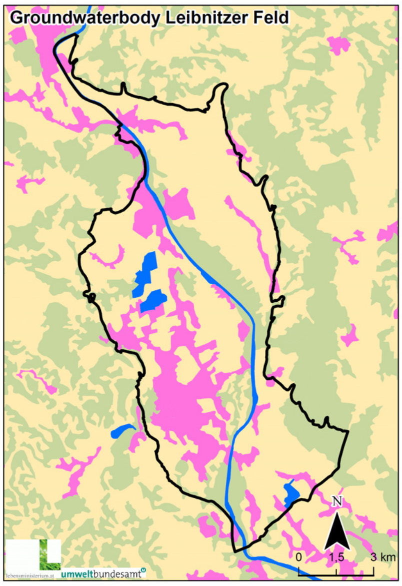
Morphologically, the groundwater body is clearly delineated by mountains to the north, east and west. To the south, the river "Mur" marks the delineation.

Land use and pressures

On the basis of evaluations of CORINE Landcover 2000 data (CORINE, 2000), the following distribution of land usage across the groundwater body Leibnitzer Feld was obtained, as shown in Table 1 (in % of total area). Main pressures are due to water abstraction, agriculture, industrial sites and contaminated sites (see also anthropogenic impact).

Table 1: Leibnitzer Feld - land use according to CORINE Landcover (2000).

Land use	***%***
Artificial surfaces	19.4
Agriculture	61.3
Forests and semi-natural areas	14.8
Surface waters	4.5



LEGEND:

Pink: artificial surfaces

Yellow: agricultural areas

Green: forests and semi-natural areas

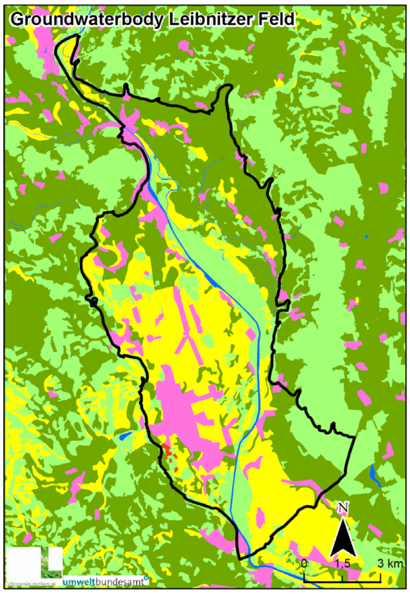
Light blue: wetlands

Blue: surface water

Figure 1: Land use according to CORINE (2000) in the groundwater body Leibnitzer Feld (Data source: Water Quality Monitoring Ordinance, Federal Legal Gazette No. 479/2006 as amended; Federal Ministry of Agriculture, Forestry, Environment and Water Management, Department VII/Unit 1 National Water Management; Offices of the Provincial Governments, Umweltbundesamt GmbH)

Overlying strata

Confining layer and depth to groundwater table: More than 75% of the groundwater body is covered with confining layers, mostly clays of varying thickness. The thickness of the overlying strata varies in dependence of the surface morphology, ranging from less than 2 m in the valley floodplains to more than 8 m on the upper terraces in the northeast. In the west of the Leibnitzer Feld the thickness of the overlying strata varies between 4 and 7 m at mean groundwater levels. The confining layers in the Mur area are characterised by low nitrate retention (see figure 2), as are large parts in the south and southwest of the groundwater body.



LEGEND:

Red: Very low nitrate retention capabilities (i.e. highest risk for groundwater)

Yellow: Low nitrate retention capabilities

Green: Medium to high nitrate retention capabilities

Blue; surface waters

Lime: Forest; partly-forest

Pink: Settlement

Figure 2: Nitrate retention capabilities of the confining layers in the Leibnitzer Feld (Data source: Water Quality Monitoring Ordinance, Federal Legal Gazette No. 479/2006 as amended; Federal Ministry of Agriculture, Forestry, Environment and Water Management, Department VII/Unit 1 National Water Management; Offices of the Provincial Governments – Nitrate retention: Institute for Land and Water Management Research, Petzenkirchen (IKT)).

Characteristics of soils

Table 1: Soil types in the Leibnitzer Feld according to FAO Soil Type Units classification (H2O-Fachdatenbank [H2O database], 2009).

FAO - Soil Type Units	%
Be - Eutric Cambisol	77.6
Je - Eutric Fluvisol	5.8
Wd - Dystric Planosol	9.2
We - Eutric Planosol	7.4

Geological characteristics

Water level of the aquifer: unconfined.

Petrography of the aquifer: The average thickness of the Quaternary gravel terraces (sandy gravel with fractured rock) is 6-10 m. Most of the lower terrace is composed of slightly silty, sandy gravel and fractured rock. The Mur floodplains are also composed of slightly silty and sandy gravel, which is – in contrast to the lower terrace – overlain by an alluvial clay layer with a thickness of 1.5 to 3 m. The thickness of the sediments of the floodplain layer ranges mostly between 4 and 6 m. Small channels, filled with fine sediment, are a common characteristic of the areas near the Mur.

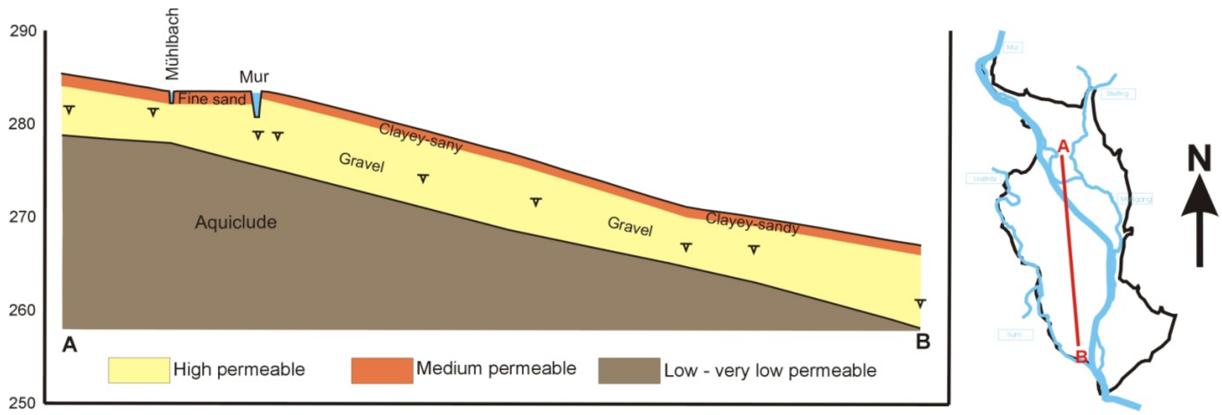


Figure 3: Schematic cross-section through the groundwater body Leibnitzer Feld

Thickness of the groundwater body: At mean groundwater levels, the thickness of the shallow Quaternary groundwater body varies between less than 2 m in boundary areas near bedrock and more than 8 m in small-scale areas near the Mur (see figure 3). A groundwater thickness of more than 4 m is only reached in the northeast of the Leibnitzer Feld and in the west of the Leibnitzer Feld (H20-Fachdatenbank, 2009).

Aquiclude: The configuration of the relief underlying the Quaternary bedrock valley sediments is relatively consistent, and the gradient corresponds more or less to today's course of the river Mur. The flat undulating bedrock relief with zones of consistently shallow and wide depressions shows only a few signs of hollows consistent with the character of deep chutes. The pre-Quaternary underground is mostly composed of silty-sandy rocks or clayey rocks dating from the Neogene. In the northeast of the Leibnitzer Feld Leitha limestone below the Quaternary gravel were detected.

Hydrogeological characteristics

Groundwater flow directions: The northeast part of the Leibnitzer Feld is characterised by groundwater flow in the southeast direction (parallel to the Mur). At the eastern boundary of the Leibnitzer Feld groundwater flowing down from surrounding slopes gains more and more importance. The flow direction in this area is from northeast to southwest, coinciding with the groundwater flow parallel to the Mur river. The flow direction in the western part of the Leibnitzer Becken is, in general, from northwest to southeast. In some of the westernmost parts the Lassnitz and Sulm rivers become the receiving waters for the groundwater.

Hydraulic conductivity – flow velocities: Overall, differences in hydraulic conductivity tend to be small in the groundwater body, ranging mainly between 2E-3 and 7E-3 m/s except in some local zones, with generally higher permeability in the valley floodplains of the Mur and Sulm. The usable porosity of the terraces varies between 6 and 9%, and between 9 and 18% in the floodplains (*H2O-Fachdatenbank*, 2009). Flow velocity ranges between 0.4 and 8.5 m/d.

Groundwater balance: At mean groundwater level, the groundwater flux at the level of the town of Leibnitz (in the southwest) is 125 l/s (Fank, 1998).

Precipitation: Total long-term annual mean precipitation in the Leibnitzer Feld is 902 mm, ranging between 848 and 939 mm. The proportion of winter precipitation is low (*H20-Fachdatenbank*, 2009).

Surface water interaction and recharge

Interaction between surface waters and groundwater: There are strong interactions between different rivers, streams and the groundwater. In many parts of the floodplains, surface waters drain the shallow groundwater. Some surface waters are of vital importance for groundwater recharge in the northeast of the Leibnitzer Feld, with groundwater alimentation strongly depending on the flow conditions in the surface waters. Bank filtrate of the Mur is considerably alimenting groundwater.

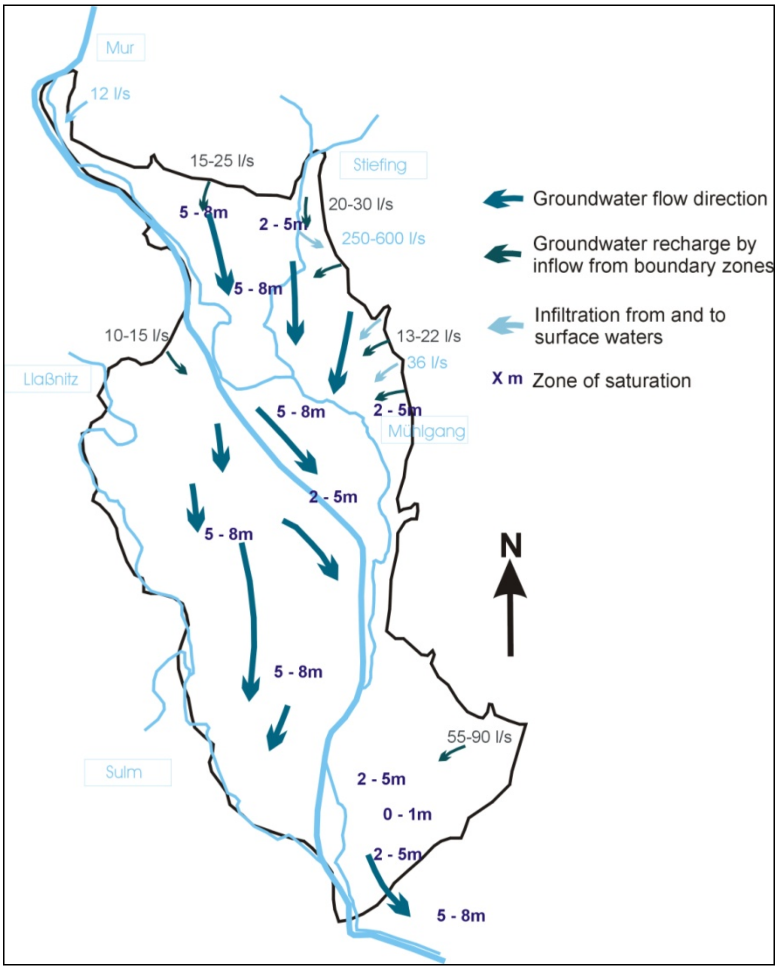

Figure 5: Groundwater body Leibnitzer Feld - Schematic illustration of hydrogeological characteristics, surface water interaction and recharge.

Groundwater recharge: According to the groundwater model “Leibnitzer Feld” (simulation period 1987), recharge from percolating precipitation (340 mm/a, average value for the years 1971-1990) amounts to about 28 million m3 (71%), followed by infiltration from surface waters (18%) and inflow (groundwater) from boundary zones with 4.4 million m3 (11%).

With a total area of 103 km2, an assumed mean groundwater thickness of 4 m and a storage coefficient of about 13%, the groundwater volume is about 54.6 million m3. The average volumetric discharge of flow through groundwater recharge within the Leibnitzer Feld is 10 l/s km2 (*H2O-Fachdatenbank*, 2009).

Groundwater chemistry and anthropogenic impacts

Groundwater chemistry: Geochemistry in the groundwater body is silicate/carbonate dominated (*H2O-Fachdatenbank*, 2009).

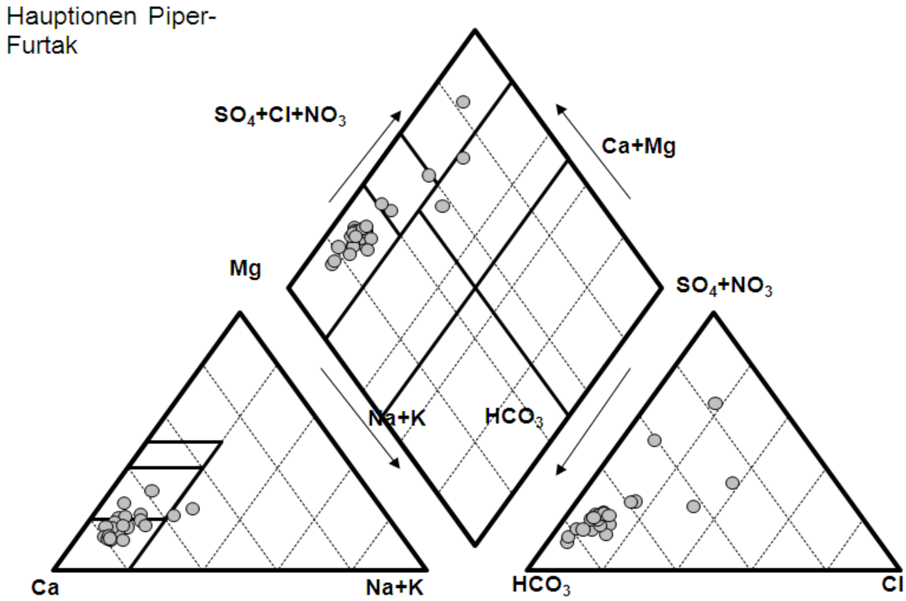

Figure 4: Major ions illustrated in a Piper-Furtak diagram.

Anthropogenic impacts: Anthropogenic impacts on groundwater include water abstraction, constructions, industrial sites and designated contaminated sites, as well as tourism, agriculture and forestry (H2O-*Fachdatenbank*, 2009). Groundwater is used on a large scale for drinking water and also for commercial purposes. Major interference with the former flow regime along the Mur due to power stations is evident.

Due to a number of drinking water and other uses particular efforts to protect groundwater resources are necessary and established.

B Drinking Water Protection File: an approach for risk assessment on a local scale

Introduction

The Water Framework Directive sets, among others, objectives for water intended for human consumption (Article 7). These objectives hold both preserving the current status of the resource quality as well as an aimed improvement of quality in time, all in relation to the quality standards of the Drinking Water Directive (98/83/EC). The characterization of water bodies therefore holds an assessment of the risk of failing to meet the drinking water objectives. The Netherlands developed an instrument named the Drinking Water Protection File with the aim to carry out such a risk assessment for an abstraction site on a local scale. This instrument was developed two years ago and has since then been tested for several sites. The experiences with the instrument have led to the intention to implement it on a nationwide scale. The results should contribute to the program of measures of the second implementation cycle of the WFD (2015-2021).

Description of a DWPF

In a Drinking Water Protection File (DWPF) all information is collected that is relevant for the water quality at the abstraction site now and in the future. Based on this information measures can be developed that are effective with respect to water quality and costs of measures. The DWPF complements the existing protection policy and offers an instrument to implement Article 7 of the WFD. Decisions upon the measures to be carried out will be taken by the competent authorities, laid down in their plans and consequently summarized in the river basin management plans. In the preparation of a DWPF the relevant stakeholders are involved, such as water managers (provinces and water boards), water companies, and municipalities. The provinces are leading this process. The number of parties involved depends upon the type of abstraction (surface water or groundwater) and the location and size of the catchment area.

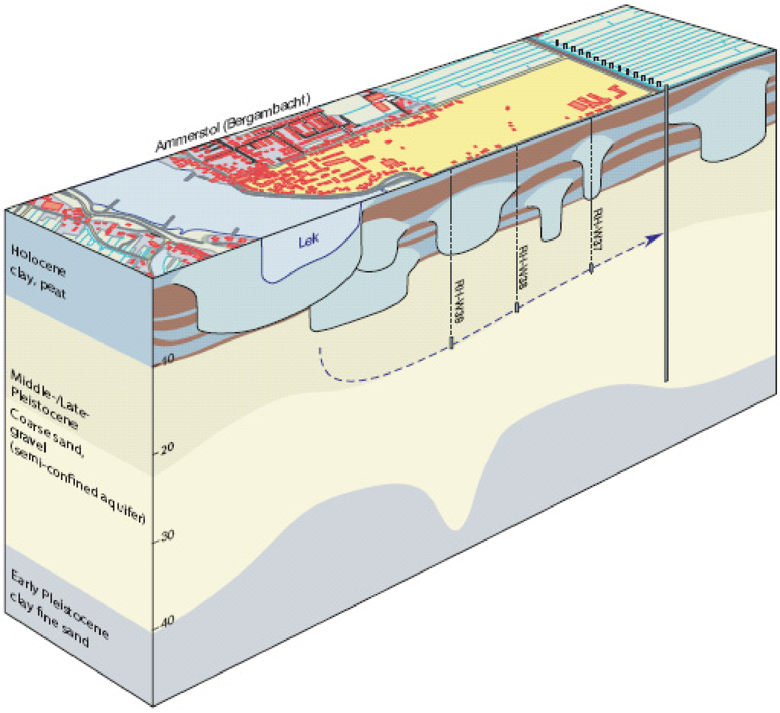
A Drinking Water Protection File holds at least the following elements:

- Information on the abstraction itself and the water system (quality and quantity);
- Information on activities that influence water quality (pressures);
- Identification of relevant substances. What are possible pollution sources?
- Current protection policies and practices. Where are the bottlenecks?
- What are the most (cost) effective measures for dealing with relevant substances?

Example

The DWPF-instrument has been tested for several abstraction sites. In this case we present an overview of the DWPF for the Bergambacht abstraction site. The Bergambacht site supplies drinking water to 280,000 consumers in the Netherlands. Surface water from the Lek river (a Rhine branch) infiltrates to the groundwater and is abstracted at 500-1000 m from the river bank. The soil passage ensures attenuation and dilution of substances present in the subsurface water. The quality of the abstracted water is primarily determined by the quality of the infiltrated river water (80-90%) and for the remaining 10-20% by the groundwater quality of the surrounding polder (Bergambacht). For groundwater intended for human consumption no specific standards are in place. In the DWPF the abstracted water is therefore compared to the drinking water standards. This does not mean that groundwater abstracted for human consumption has to comply to the drinking water standards. In the Netherlands all water companies have a facility in place to treat the water up to the drinking water standards.

In the current situation the car fuel additive MTBE, the solvent diglyme and volatile chlorinated hydrocarbons, are found in the abstracted groundwater in concentrations exceeding Dutch standards for drinking water. In order to meet the standards, the water company applies water treatment by activated carbon filtration.



In addition, concentrations of other substances, such as several pharmaceuticals and pesticides, appear to be rising, although not yet exceeding drinking water quality standards. Water quality data from local surface water, the river Lek and the upstream Rhine indicate that the pollutants originate from industrial and sewage effluent, storm water overflow spills and agriculture in both the Netherlands and upstream countries. The DWPF demonstrates that it is important to discuss these substances on a river basin level, but that there are possibilities for improvement within the Rhine Delta as well. Possible measures are more stringent regulation with respect to pesticides, reduction of spills of untreated sewage water, adjustment of effluent discharge permits and high-performance sewage water treatment.

With the in-depth analysis provided by a DWPF, a common understanding is created of the risks at drinking water abstraction sites. From there, actions supported by the relevant parties can be formulated.

Common Implementation Strategy
for the Water Framework Directive (2000/60/EC)

Guidance Document No. 27

Technical Guidance For Deriving Environmental Quality Standards

FOREWORD

The EU Member States, Norway, and the European Commission in 2000 have jointly developed a common strategy for implementing Directive 2000/60/EC establishing a framework for Community action in the field of water policy (the Water Framework Directive). The main aim of this strategy is to allow a coherent and harmonious implementation of the Directive. Focus is on methodological questions related to a common understanding of the technical and scientific implications of the Water Framework Directive. In particular, one of the objectives of the strategy is the development of non-legally binding and practical Guidance Documents on various technical issues of the Directive. These Guidance Documents are targeted to those experts who are directly or indirectly implementing the Water Framework Directive in river basins. The structure, presentation and terminology are therefore adapted to the needs of these experts and formal, legalistic language is avoided wherever possible.

Under the WFD Common Implementation Strategy, an Expert-Group (EG) on Environmental Quality Standards (EQS) was initiated in 2007 to produce guidance on establishment of the EQSs in the field of water policy. This activity was led by UK and the Joint Research Centre and supported by the Working Group E (WG-E). The Working Group E is chaired by the Commission and consists of experts from Member States, EFTA countries, candidate countries and more than 25 European umbrella organisations representing a wide range of interests (industry, agriculture, water, environment, etc.).

The enclosed Technical Guidance has been developed to support the derivation of EQSs for priority substances and for river-basin-specific pollutants that need to be regulated by Member States according to the provisions of the WFD. The Commission intends to use the Technical Guidance to derive the EQSs for newly identified priority substances and to review the EQSs for existing substances.

Article 16 of the Water Framework Directive (WFD, 2000/60/EC) requires the Commission to identify priority substances among those presenting significant risk to or via the aquatic environment, and to set EU Environmental Quality Standards (EQSs) for those substances in water, sediment and/or biota. In 2001 a first list of 33 priority substances was adopted (Decision 2455/2001) and in 2008 the EQSs for those substances were established (Directive 2008/105/EC or EQS Directive, EQSD). The WFD Article 16 requires the Commission to review periodically the list of priority substances. Article 8 of the EQSD requires the Commission to finalise its next review by 2011, accompanying its conclusion, where appropriate, with proposals to identify new priority substances and to set EQSs for them in water, sediment and/or biota.

The Scientific Committee on Health and Environmental Risks (SCHER) adopted its opinion on Technical Guidance for Deriving Environmental Quality Standards in October 2010[1]. The Water Directors endorsed the Guidance during their informal meeting under the Hungarian Presidency in Budapest (26-27 May 2011).

This Guidance Document is a living document that will need continuous input and improvements as application and experience build up in all countries of the European Union and beyond. The Water Directors agreed to make publicly available the Guidance in its current form in order to present it to a wider public as a basis for carrying forward ongoing implementation work.

The Water Directors would like to thank the leaders of the activity and the members of the Working Group E for preparing this high quality document. The Water Directors also commit themselves to assess and decide upon the necessity for reviewing this document in the light of scientific and technical progress and experiences gained in implementing the Water Framework Directive and Environmental Quality Standards Directive.

1. INTRODUCTION

1.1 Environmental Quality Standards (EQSs) under the Water Framework Directive

Article 16 of the Water Framework Directive (WFD) (EC 2000) sets out the strategy against chemical pollution of surface waterbodies. The chemical status assessment is used alongside the ecological status assessment to determine the overall quality of a waterbody. Environmental Quality Standards (EQSs) are tools used for assessing the chemical status of waterbodies. The EQS Directive (EC 2008a) establishes the maximum acceptable concentration and/or annual average concentration for 33 priority substances and 8 other pollutants which, if met, allows the chemical status of the waterbody to be described as 'good'.

EQSs for the 33 substances identified by the EU as Priority Substances (PSs) and Priority Hazardous Substances (PHSs) are derived at a European level and apply to all Member States. They are also referred to as Annex X substances of the WFD.

In addition, the WFD (Annex V, section 1.2.6) establishes the principles to be applied by the Member States to develop EQSs for Specific Pollutants that are 'discharged in significant quantities'. These are also known as Annex VIII substances of WFD. Compliance with EQSs for Specific Pollutants forms part of the assessment of ecological status (Figure 1-1). EQSs are therefore key tools in assessing and classifying chemical status and can therefore affect the overall classification of a waterbody under the WFD (Figure 1.1). In addition, EQSs will be used to set discharge permits to waterbodies, so that chemical emissions do not lead to EQS exceedance within the receiving water.

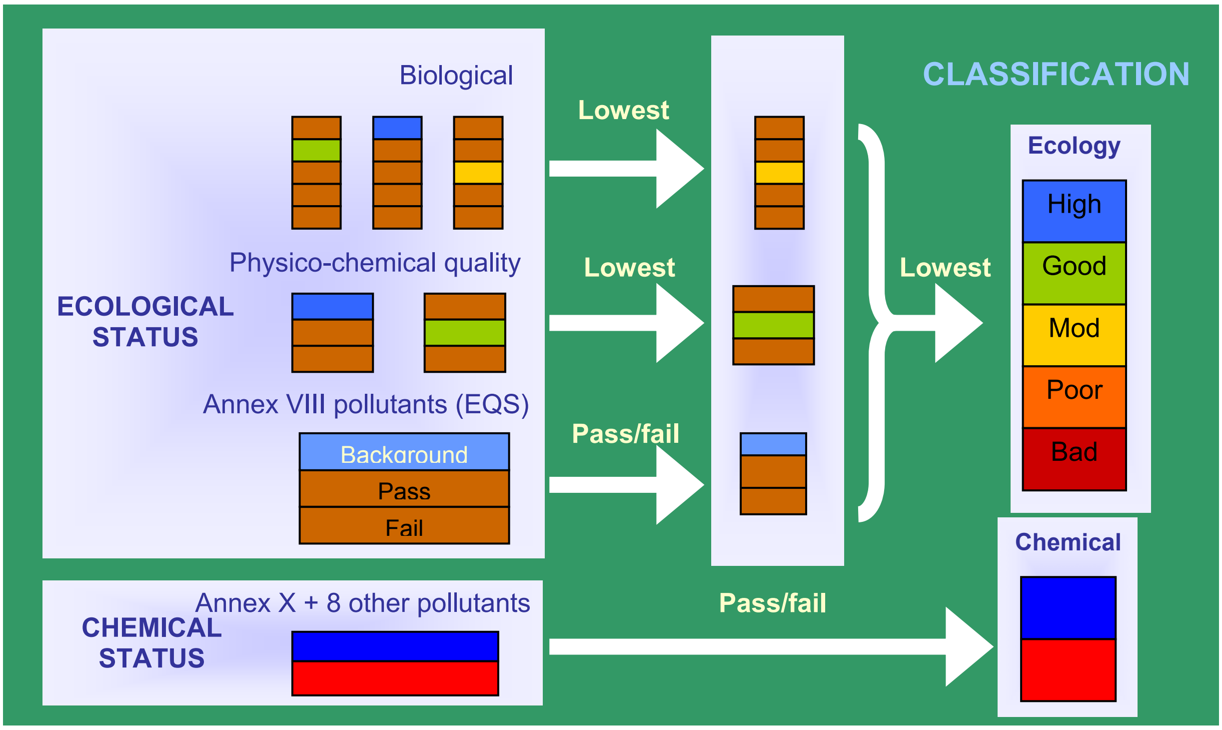

Figure 1.1 Role of EQSs in waterbody classification

Whilst establishing the principles of EQS derivation, Annex V, Section 1.2.6 of the Water Framework Directive does not provide the necessary detail for practitioners to develop EQSs in a consistent manner, or cover all the scientific issues that may be encountered.

In 2005, a technical guidance document was prepared (Lepper, 2005) for the purpose of EQS derivation. This covered many of the key technical issues involved in deriving EQSs however the science has since moved on requiring the need for an update of the guidance.

The risk assessment paradigm on which the technical guidance for EQS derivation is based (ECHA, 2008) relies on worst-case assumptions. Whilst this is entirely legitimate within a tiered assessment framework, to ensure environmental protection, when this paradigm is applied to EQS derivation it can lead to unworkable and/or unrealistically low EQS values (CSTEE[2], 2004; Lepper 2005). One of the factors leading to unmanageable water column standards is the very low concentrations that arise for some substances with low water solubility, or a tendency to bioaccumulate through the food web. If these substances pose a significant risk through indirect toxicity (i.e. secondary poisoning resulting from food chain transfer), and their analysis is more feasible in other environmental matrices, such as biota and/or sediments, then a biota standard or sediment standard may be required alongside, or instead of, the water column EQS, as referred to in the EQS Directive 2008/105/EC (Art 3, para 2). For this reason, guidance on the derivation of biota and sediment EQSs is required. There is also a need for further guidance on setting EQSs for metals in ways that allow speciation and bioavailability to be accounted for. Furthermore, we are now in a position to refine the guidance for the derivation of water column standards in the light of technical advances and experience of EQS setting gained in recent years. These issues are amongst those covered in this new guidance.

1.2 Scope of the guidance

This guidance document addresses the derivation of environmental quality standards for water, sediment and biota. It addresses the need for further guidance highlighted above and responds to comments made by the Scientific Committee on Toxicity, Ecotoxicity and the Environment (CSTEE, 2004) and by the Scientific Committee on Health and Environmental Risks (SCHER) in 2010. It also takes account of the principles highlighted in a SETAC (Society for Environmental Toxicology and Chemistry) workshop on environmental standards that took place in 2006 (SETAC, 2009) so that the latest scientific thinking on setting and implementing environmental standards is reflected.

This guidance applies to the derivation of EQSs for PSs, PHSs and Specific Pollutants. The guidance focuses on the steps required to derive EQSs that comply with the requirements of Annex V of the WFD. It assumes that the chemicals for which EQSs are required have been identified, i.e. the guidance does not cover chemical prioritisation. However, it does address some aspects of the way an EQS is implemented, where this has a direct bearing on the way an EQS is derived and expressed, e.g. assessing compliance with an EQS. The guidance does not cover issues relating to sampling and chemical analysis: these are covered by separate guidance on monitoring (EC, 2010).

The quantity of data available for deriving an EQS can vary. Where an EQS can be derived on the basis of a large dataset there may be only small uncertainties in the final outcome. If, however, only a very small dataset is available, the residual uncertainties can be large. Uncertainty is accounted for by the use of assessment factors (AFs) but, clearly, there is a considerable difference in the robustness and reliability of such EQSs compared to those

[2] Scientific Committee on Toxicity, Ecotoxicity and the Environment

based on extensive data sets, and it may even be inadvisable to implement such EQSs**.** This technical guidance does not recommend when uncertainties are so large that an EQS should not be implemented, or used in only an advisory capacity. That decision is for policymakers but this could come under review as we gain more experience in setting and using environmental standards for the WFD. However, **the scientist has an important role in advising the policymaker about the major uncertainties and key assumptions involved in deriving an EQS. This is particularly important for EQSs which are to be applied across Europe (e.g. for Priority Substances or Priority Hazardous Substances)**. It is also important to highlight to the policymaker the practical steps which might be taken to reduce uncertainty (e.g. generation of additional ecotoxicity data) and the benefits these would have e.g. reducing the size of AFs. The scientist should also advise policymakers when uncertainties are small and the resulting EQS is correspondingly robust. With this in mind, a proforma technical report is appended (Appendix 2) to prompt the assessor for the information that should be reported, including advice to policymakers.

A further point to add is that confidence about regulatory decisions involving EQSs can also be affected by the way in which an EQS is implemented, eg how compliance is assessed. Although detailed monitoring guidance lies outside the scope of this guidance, it is useful to consider implementation issues during EQS setting. Although the final decision about EQS values should reflect the scientific risk, those responsible for EQS derivation are encouraged to discuss implications for water management practices with policy makers and those responsible for implementing an EQS. These might include, for instance, implications for permitting and emission controls, sampling (e.g. whole water vs filtered samples), statistical aspects of compliance assessment, availability of suitable analytical methods, the impact of residual uncertainty in the EQS and a threshold for the relevance of a specific pollutant for which an EQS is needed (e.g. exceedance of 50% of the EQS).

This guidance is intended for use by environmental scientists with an understanding of the principles of risk assessment. A detailed appreciation of the principles and practice of environmental chemistry and ecotoxicology is also recommended. Much of this guidance will be familiar to those used to dealing with effects assessments under REACH (Registration, Evaluation and Authorisation of Chemicals) (Regulation (EC) 1907/2006).

1.3 Links to chemical risk assessment

It is important to highlight some conceptual differences between EQS derivation and the estimation of a PNEC (Predicted No Effect Concentration) from chemical risk assessment or TER (Toxicity Exposure Ratio) for a pesticide. For example:

- the concept of an overall threshold (Sections 2.3 and 2.4) that protects all receptors and routes is a feature of EQS derivation that does not normally apply in chemical risk assessment

- whereas there are opportunities to refine a risk assessment in the light of new data, this is often not the case in EQS derivation; although additional data may sometimes be voluntarily provided, we cannot usually demand the commissioning of new studies so have to utilise what is available to us

- an exceedance of the EQS will not normally trigger a refinement of the standard

- an underlying requirement of the WFD is to protect the most sensitive waters in Europe. For metal EQSs, where bioavailability is to be accounted for (Section 2.10) there is therefore a requirement to protect a higher proportion of waterbodies than for PNECs estimated as part of a risk assessment

- in EQS derivation, field and mesocosm data have an important role as lines of evidence in helping define the standard (through helping reduce uncertainty) but would not be regarded as 'higher tier' data that would replace laboratory-based ecotoxicity data as done in the assessment of the impact of pesticides.

A PNEC derived as part of a risk assessment will provide a key step in the derivation of an EQS and, in some cases, the PNEC from a risk assessment will be identical to the EQS. However, for the reasons outlined above, it will not be sufficient to simply adopt the PNEC as the EQS as a matter of course. Nevertheless, the process of deriving environmental standards is similar to that used in the effects (i.e. hazard) assessment that is required for a risk assessment for chemicals. For the purposes of the WFD, short and long-term effects are of concern, though greater emphasis is placed on risks from long-term or continuous exposure. Authoritative guidance on effects assessment for chemicals has been developed, notably the technical guidance developed for industrial chemicals (now under REACH (ECHA, 2008)) and pesticides under Directive 91/414/EEC. Annex V of the WFD refers directly to the methodology described for the Existing Substances Regulation (ESR) (now under REACH). Furthermore, the guidance for undertaking risk assessment of pesticides allows for short term impacts and recovery. As far as possible, the technical guidance for EQSs described here is consistent with the guidance for effects assessments performed for chemical risk assessment under REACH.

1.4 Structure of guidance

Generic issues and principles that apply to the derivation of EQSs across all media and receptors are outlined in Section 2. The guidance is separated into sections dealing with different environmental media, ie derivation of EQSs for the water column are considered in Section 3, those for biota in Section 4 and those for sediment in Section 5. Risks from metals pose particular challenges and the guidance reflects the latest scientific developments for taking account of speciation and bioavailability in deriving thresholds and assessing compliance with these EQSs. Detailed guidance for deriving EQSs for metals in water, biota and sediment is given in the respective Sections. Recognising the growing importance of computational and non-testing methods in the estimation of environmental hazard, guidance on the use of such methods when deriving EQSs is given in Section 6. Finally, Section 7 outlines how to estimate EQSs for mixtures.

At various points in the guidance, we refer to Appendices and scientific background documents to accompany the guidance. These are intended to provide more detailed explanations for the technical advice given here.

2. GENERIC ISSUES

2.1 Use of EQSs in waterbody classification

The WFD establishes a framework for protection of all surface waters and groundwaters, with an obligation to prevent any deterioration of status, and to achieve good status, as a rule by 2015. The overall good status is reached for a certain waterbody if both ecological and chemical status are classified as good.

EQSs established at EU level by the EQS Directive (2008/105/EC) for the 33 priority substances and 8 other pollutants are used within the WFD to assess the chemical status of a waterbody. Good chemical status is achieved where a surface waterbody complies with all the environmental quality standards listed in Part A of Annex I of EQS Directive and applied according with the requirements set in Part B of Annex I of the same directive. If not, the waterbody shall be recorded as failing to achieve good chemical status.

For Annex VIII substances (Specific Pollutants), each Member State shall establish their EQSs according to Annex V, Section 1.2.6 of WFD. Specific Pollutants are supporting parameters for biological quality elements, thus they contribute among other parameters to the ecological status classification. If the EQSs for these substances are not met, the waterbody can not be classified as either 'Good' or 'High'status, even if the biological quality is 'Good' or 'High' (Figure 1.1).

2.2 Overview of the steps involved in deriving an EQS

Figure 2.1 illustrates the key steps that are involved in deriving an EQS, irrespective of the compartment or receptor at risk. The key steps are broadly consistent across all media/receptors. However, the detail within each step can differ markedly between compartments and receptors.

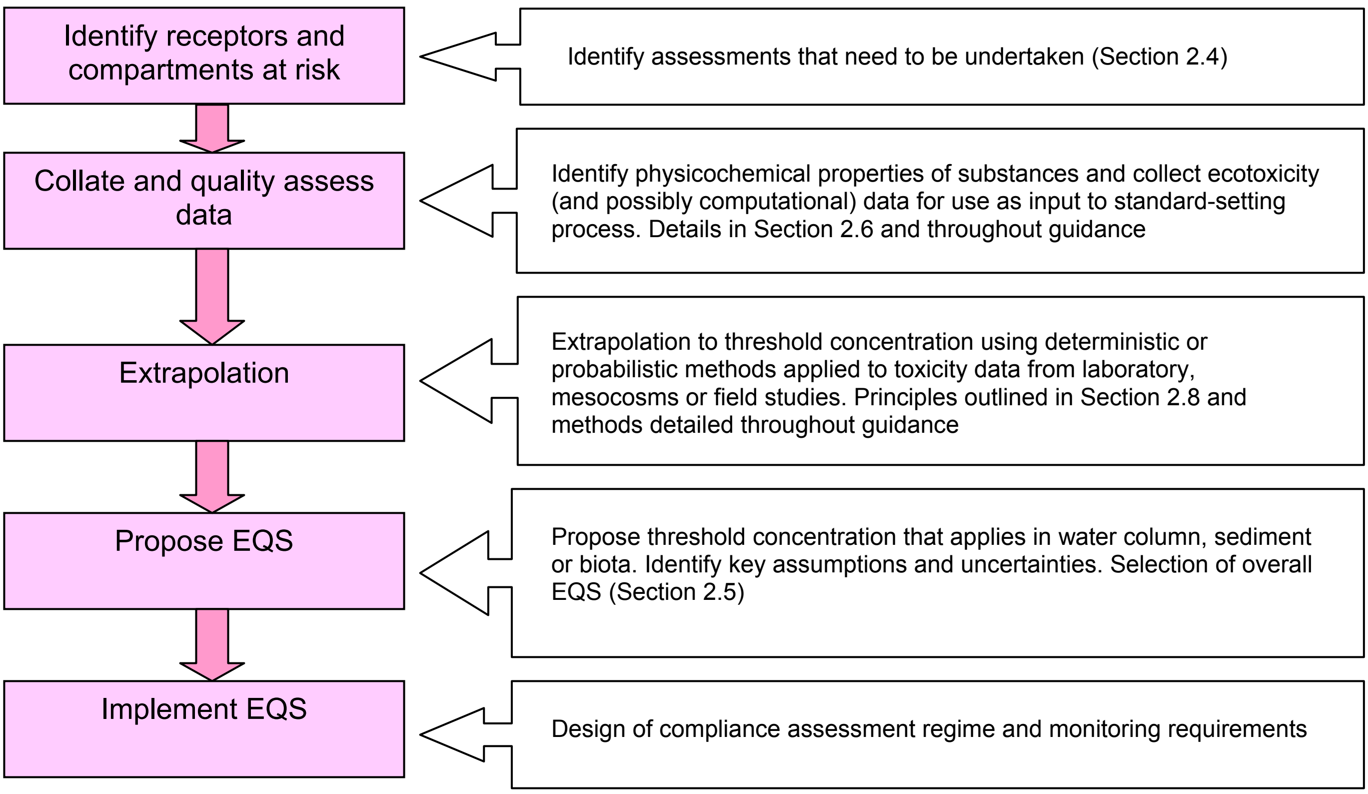

Figure 2.1 Key steps involved in deriving an EQS

2.3 Receptors and compartments at risk

EQSs should protect freshwater and marine ecosystems from possible adverse effects of chemicals as well as human health via drinking water or ingestion of food originating from aquatic environments. Several different types of receptor therefore need to be considered, i.e. the pelagic and benthic communities in freshwater, brackish or saltwater ecosystems, the top predators of these ecosystems and human health.

The receptors and media of concern to EQS setting covered in this guidance are illustrated in Figure 2.2.

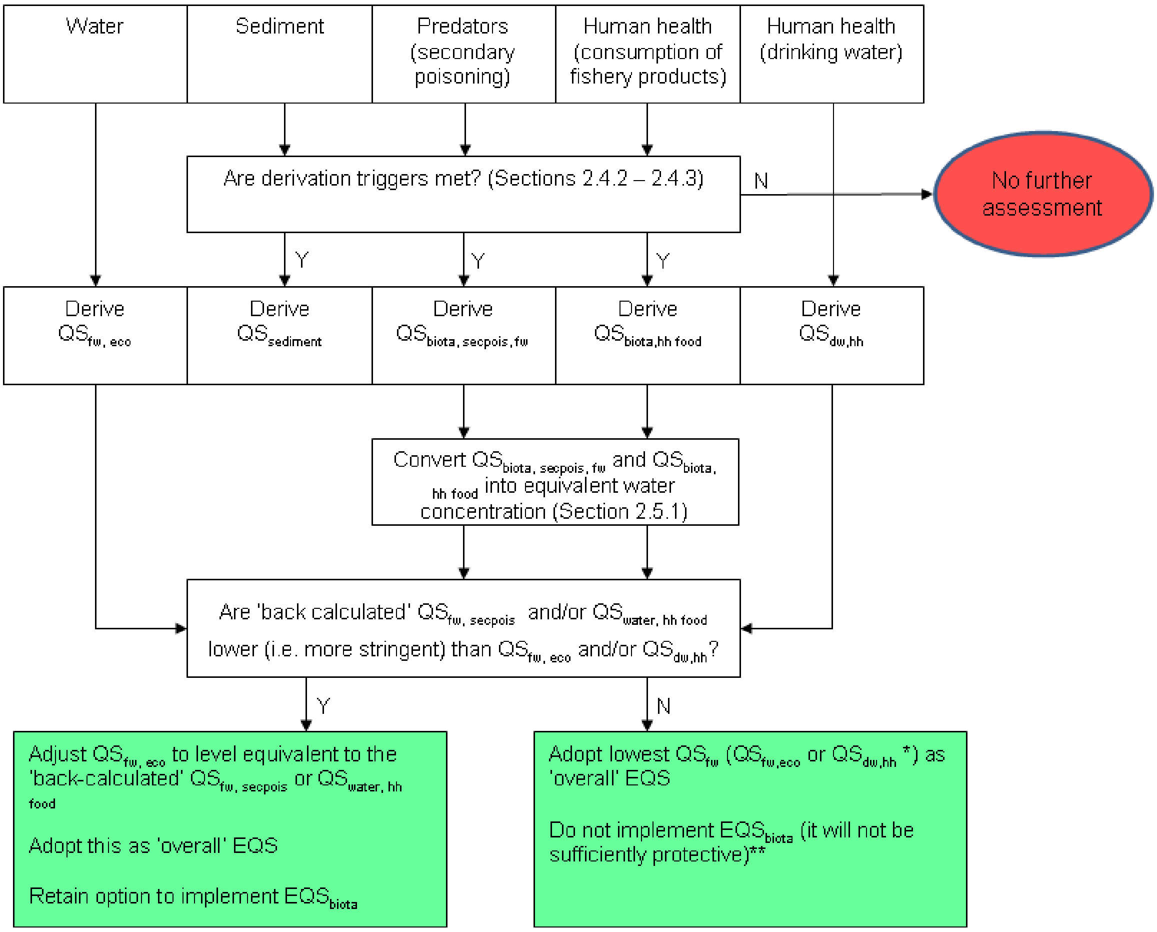
		Environmental compartment		
		Water	**Sediment**	**Biota**
Receptor(s) at risk	**Humans**	**Yes**	**No**	**Yes (consumption of fish products)**
	Sediment dwelling biota	**No**	**Yes**	**No**
	Pelagic biota	**Yes**	**No**	**Yes (secondary poisoning)**
	Top predators (birds, mammals)	**Yes**	**No**	**Yes (secondary poisoning)**

Figure 2.2 Receptors for which an assessment may be required

Yes = potential risks to receptor need to be considered in EQS derivation
No = risks do not need to be addressed in EQS derivation

Not all receptors need to be considered for every substance. This depends on the environmental fate and behaviour of the substance i.e. if a substance does not bioaccumulate (or doesn't have high intrinsic toxicity), there is no risk of secondary poisoning and so a biota standard is not required. However, where a possible risk is identified, quality standards should be derived for that receptor (Figure 2.3). Criteria to help identify which of the assessments are needed for a particular substance are given in Section 2.4. Where several assessments are performed, the lowest (most stringent) of the thresholds will be selected as an 'overall' EQS as illustrated in Figure 2.3 and detailed in Section 2.5.

In this way, all relevant protection objectives should be taken into account. Moreover, all direct and indirect exposure routes in aquatic systems i.e. exposure in the waterbody via water and sediment or via bioaccumulation, as well as possible exposure via drinking water uptake, are accounted for. Figure 2.3 presents the routes taken into account for the freshwater compartment, similar routes are considered for the saltwater compartment, but indicated with different subscripts (fw is replaced by sw in the figure below) See appendix 6 for clarification of the temporary standards used during EQS derivation.



* $QS_{dw,hh}$ can only be adopted as the lowest QS_{water} for waters intended for drinking water use

** unless monitoring in biota is strongly preferred. Under these circumstances, calculate QS_{biota} that is equivalent to lowest (i.e. most protective) QS_{water} and select this value as EQS_{biota}

Figure 2.3 Overview of assessments needed and selection of an 'overall' EQS

The mode of toxic action for a chemical is not always known but, when carrying out an assessment, all relevant modes of toxicity need to be considered. No plausible toxicological hazard should be excluded from consideration. Stressors for which an EQS could be derived, but do not act by chemical toxicity (e.g. temperature, pH) may require a different approach than that described here. Such physical stressors lie outside the scope of this guidance.

2.4 Identifying the assessments to be performed (receptors at risk)

According to Article 3 of the EQS Directive, quality standards shall apply to contaminant concentrations in water, sediments and/or biota. As illustrated in Figure 2-3, **an assessment for several compartments is needed when a substance could pose a risk through direct toxicity in the water column, to predators through the food chain, or to benthic (sediment-dwelling) biota.** On the other hand, **a QS is not required if a substance will not pose a risk to a particular compartment**. For instance, a quality standard for sediment is not necessary if the substance is unlikely to partition to, or accumulate in, sediment. Similarly, quality standards for biota are not required if a substance does not bioaccumulate (or doesn't have high intrinsic toxicity), in which case it is reasonable to conclude that there is no risk of secondary poisoning of top predators, or to human health from consumption of fishery products.

The criteria for identifying which assessments are required are outlined below.

2.4.1 Water column

An assessment to protect pelagic (i.e. water column) organisms from direct toxicity to chemicals is always undertaken. A drinking water threshold is also required for waters used for drinking water abstraction. For these waters, existing health-based standards from either the Drinking Water Directive 98/83/EC or World Health Organization (WHO) could be used, if available, as the basis for the QS derivation, as described in Section 3.9. If no existing standards are available, an assessment of risks to human health from drinking water will be required. However, a QS to protect waterbodies designated for drinking water abstraction is required only when it is lower (i.e. more stringent) than the water column QS to protect aquatic life. A derivation is not required if existing drinking water standards are less stringent (i.e. higher) than the water column QS to protect aquatic life.

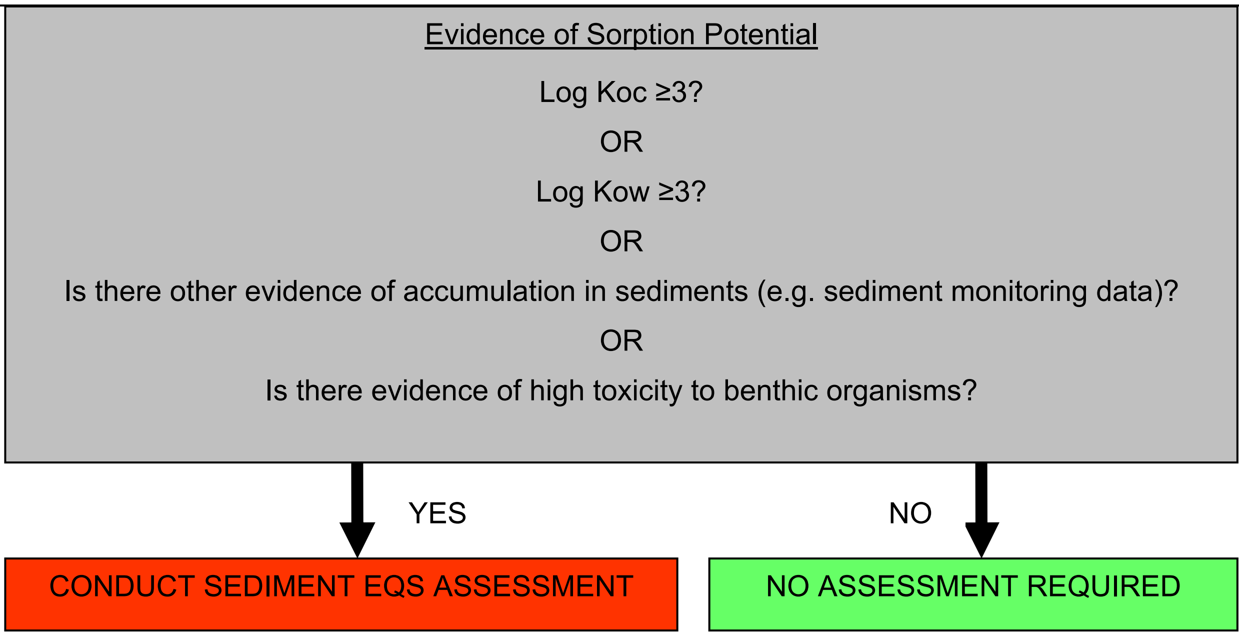
In the derivation of QSs to protect human health two major exposure routes are considered (consumption of fishery products and consumption of drinking water). There may be other routes of exposure, such as exposure during recreation (dermal exposure, ingestion of water). These routes are of minor importance compared to the other routes considered (see for example Albering *et al*, 1999) and are therefore not considered in this guidance.

2.4.1.1 EQSs for transitional waters

Separate EQSs are recommended for freshwaters and saltwaters. However, transitional (e.g. estuarine) waters are intermediate in salinity which can vary on a diurnal cycle. For waters with a low salinity, supporting communities that are closely related to freshwater ecosystems, the freshwater scheme is more appropriate. At salinity levels between 3 and 5‰ there is a minimum number of species present and this can be considered as a switch from communities that are dominated by freshwater species to communities that are dominated by saltwater species. Therefore, EQSs in this document are not reported for 'transitional ánd marine waters', but either for freshwaters or saltwaters. As a default, we recommend a salinity of 5‰ as the cutoff unless other evidence suggests a different cutoff is appropriate for a particular location. For instance, Bothnian Sea (inner BalticSea) is a brackish water body that has a salinity of around 5‰, and has, so far, been treated as a saltwater system.

2.4.2 Sediments

Not all substances require an assessment for a sediment standard. The criteria for triggering an assessment are consistent with those under REACH Regulation (EC) No 1907/2006 (ECHA, 2008, Chapter R.7b). In general, substances with an organic carbon adsorption coefficient (K_{oc}) of <500–1000 $l \cdot kg^{-1}$ are not likely to be sorbed to sediment. Consequently, a log K_{oc} or log K_{ow} of ≥3 is used as a trigger value for sediment effects assessment. Some substances can occur in sediments even though they do not meet these criteria so, in addition, evidence of high toxicity to aquatic organisms or sediment-dwelling organisms or evidence of accumulation in sediments from monitoring, would also trigger derivation of a sediment EQS.



2.4.3 Biota

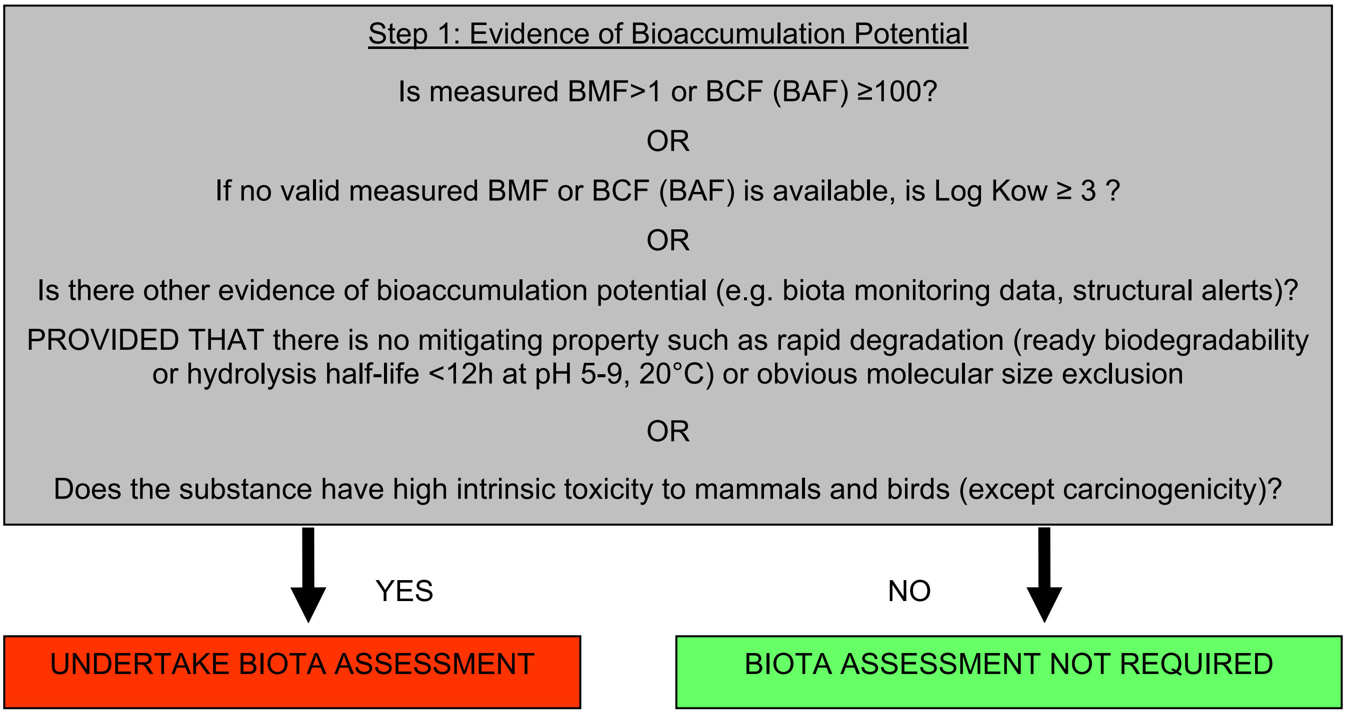
The criteria determining whether or not a biota standard is needed are more complex. A standard would be required if there was a risk of secondary poisoning of predators (e.g. mammals or birds) from eating contaminated prey ($QS_{biota,secpois}$), or a risk to humans from eating fishery products ($QS_{biota,\ hh\ food}$).

The triggers are based on those used to determine whether a secondary poisoning assessment is necessary for a substance under REACH Regulation (EC) No 1907/2006 (ECHA, 2008)[3]. The triggers for derivation of a $QS_{biota,\ hh\ food}$ are dominated by hazard properties whereas a $QS_{biota\ sec\ pois}$ is triggered by the possibility of accumulation in the food chain in conjunction with hazard properties. There are differences between how metals and organic substances are dealt with, and these are highlighted below.

[3] The criteria used to determine whether a substance is Persistent, Bioaccumulative and Toxic (PBT) or very Persistent and very Bioaccumulative (vPvB) under Annex XIII of REACH are more stringent and not suitable for use as a screening decision tree since a substance meeting the PBT/vPvB criteria would require stricter management control than standard setting.

2.4.3.1 *Protection of predators from secondary poisoning*

(1) Organic substances



The assessor should determine whether the substance has the potential to accumulate through food chains and thus expose top predators via their diet. The biomagnification factor (BMF) is the ratio of the concentration of a substance in an organism compared to the concentration in food (prey) items. The bioconcentration factor (BCF) is the ratio of the concentration of a substance in an organism to the concentration in water. A BMF greater than 1 or, in the absence of this information, a BCF greater than or equal to 100 is used as an indication of the potential for bioaccumulation. **When both BMF and BCF data are available, the most reliable should be used, not necessarily the worst case (highest) value**. Usually this will be the BCF data, except for metals, where BCF data can be influenced by the water concentration used in the study (See Section 2.4.3.1 (2)).

If neither BMF or BCF data are available, the octanol–water partition coefficient (K_{ow}), can be used as a surrogate for bioaccumulation potential. A log K_{ow} of ≥3 would be expected to capture substances with a BCF of ≥100. Other evidence of bioaccumulation potential should also be taken into account where available, such as structural features of the molecule or monitoring data from top predators. In addition, factors mitigating bioaccumulation potential should be considered. These include rapid degradation and molecular size. Rapid degradation may lead to relatively low concentrations of a substance in the aquatic environment and thus low concentrations in aquatic organisms. Information on molecular size can be an indicator of limited bioaccumulation potential of a substance as very bulky molecules will pass less easily through cell membranes. Further guidance on molecular size and its impact on bioaccumulation potential is available in the REACH guidance (ECHA, 2008).

(2) Metals

Biomagnification of metals in aquatic organisms is rarely observed and, if it does occur, it usually involves the organo-metallic forms of metals (e.g. methyl mercury) (Brix *et al*., 2000). However, the assessor should examine their potential to biomagnify or cause secondary poisoning in food chains, even for inorganic metal forms. It is especially important to look for evidence of organo-metallic species being formed in some compartments, or if the range over which homeostasis occurs is relatively small (e.g. selenium). Therefore, a useful first step is to review the information available for the metal in question in order to assess whether an in-depth secondary poisoning assessment is needed.

A lack of biomagnification should not be interpreted as lack of exposure or no concern for trophic transfer. Even in the absence of biomagnification, aquatic organisms can bioaccumulate relatively large amounts of metals and this can become a significant source of dietary metal to their predators (U.S. EPA 2007; Reinfelder *et al*. 1998).

For metals, a BCF should not be used. This is because the model of hydrophobic partitioning, giving a more or less constant ratio C_{biota}/C_{water} with varying external concentration, does not apply to metals. For a number of metals an inverse relationship between BCF and external (water-) concentration is observed (McGeer *et al*., 2003). Consequently, BCFs and BAFs are not constant with water concentration. Furthermore, some metals are essential for life and many organisms possess mechanisms for regulating internal concentrations, especially essential metals such as copper and zinc.

Instead, a case-by-case evaluation of the possibility of dietary toxicity is required:

- Information on metal mode of action and homeostatic (internal regulation) controls
- Information on essentiality
- Information on biomagnification (BMF). An example of a study relevant in addressing this question is Ikemoto et al (2008a)
- Information on major toxicities i.e. whether main risks are through direct toxicity to pelagic organisms or secondary poisoning. With regards to the potential for secondary poisoning the assessment of the mode of toxic action in both prey and predator is a key consideration. If there is no evidence of biomagnification (i.e. BMF<1) and no specific toxicity in birds and mammals compared to fish (on a dose based approach), the QSwater, eco should be protective for birds and mammals as well as pelagic organisms.

If the balance of evidence points to a risk of secondary poisoning then an assessment is required.

2.4.3.2 Protection of humans from consuming fishery products

For humans, the derivation of a biota standard is triggered solely on the basis of the hazardous properties of the chemical of interest. The available mammalian and bird toxicity data is used to give an indication of possible risks to top wildlife predators as well as humans since there is usually standard mammalian toxicity data available for well-studied chemicals. Effects on reproduction, fertility and development are of particular concern since these are long-term effects which could impact on populations of organisms.

Specific triggers[4] are as follows:

- a known or suspected carcinogen (Cat. I-II, R-phrases R45 or R40) or
- a known or suspected mutagen (Cat. I-II, R-phrases R46 or R40) or

[4] In accordance with Directive 67/548/EEC.

- a substance known or suspected to affect reproduction (Cat. I-III, R-phrases R60, R61, R62, R63 or R64) or

- possible risk of irreversible effects (R68) or

- the potential to bioaccumulate (see protection of top predators) plus danger of serious damage to health by prolonged exposure (R48) or harmful/toxic/fatal when swallowed (R22/R25/R28).

Note that applicability of these toxicological triggers should follow from R or H phrases, but information obtained from evaluation of toxicological data not necessarily reflected in classification and labelling phrases should not be neglected. It may warrant derivation of a risk limit for human health based on the consumption of fishery products.

The H-statements will soon replace the R-phrases in EU chemicals legislation via the Classification, Labelling and Packaging Regulation (2008) (EC, 2008). The conversion between H and R phrases is provided below. Check the status of the R and H phrases. For those substances where R or H phrases have not been harmonised at the EU-level, consultation with (a) human toxicological expert(s) is needed.

R22 H302: Harmful if swallowed

R25 H301: Toxic if swallowed

R28 H300: Fatal if swallowed

R40 H351: Suspected of causing cancer

R45 H350: May cause cancer

R46 H340: May cause genetic effects

R48 H373: May cause damage to organs through prolonged or repeated exposure

R60 H360: May damage fertility or the unborn child

R61 H360: May damage fertility or the unborn child

R62 H361: Suspected of damaging fertility or the unborn child

R63 H361: Suspected of damaging fertility or the unborn child

R64 H362: May cause harm to breast-fed children

R68 H341: Suspected of causing genetic effects

2.5 Selecting an overall standard

Standards for water, sediment and biota are derived independently and they should all be made available for possible implementation. Where several assessments are performed for the same compartment (e.g. water: protection of pelagic species, protection of human health from drinking water; biota: protection of biota from secondary poisoning, protection of human health from consuming fisheries products), **the lowest standard calculated for the different objectives of protection will normally be adopted as the overall quality standard for that compartment**. An exception will be when the drinking water route results in the lowest (most stringent) QS but a waterbody is not designated as a source of drinking water. It is not sufficient to simply report the 'overall' EQS; the assessor must make available all the relevant QSs and their derivations. Standards for freshwater and saltwaters will be derived independently so the overall $EQS_{saltwater}$ may be different to the overall $EQS_{freshwater}$.

To select an overall EQS, quality standards will need to be expressed in the same units (i.e. mass/volume). This means that biota standards must be 'back-calculated' to the corresponding water concentration. This is referred to in Figure 2-3 and further guidance is given in Section 2.5.1. Finally, sediment QSs are dealt with independently of water column and biota standards. This leads to selection of a separate, overall $EQS_{sediment}$.

2.5.1 Converting biota standards into an equivalent water concentration

Procedures for converting biota standards into water column concentrations are given in Section 4.7.2. It should be noted that the conversion from a biota standard into an equivalent water concentration can introduce uncertainty, especially for (a) highly lipophilic substances and (b) metals.

(a) Where it is necessary to convert a biota QS into an equivalent water column concentration for a highly lipophilic substance, the uncertainties may be taken into account by performing the conversion for extreme BAF values as well as the typical BAF value. If the QS for water lies within the range of possible extrapolated values of the QS for biota, when considering the uncertainties of the extrapolation, it is not possible to determine with high confidence which is the 'critical' QS. These should be reported as key uncertainties, outlining the implications for implementing an EQS.

As explained in Section 2.4.3.1, BCF data for metals may be unreliable. Instead, BAF or BMF data are preferable. To compare a biota standard with water column standards, refer to Section 4.7.1.2.

(b) For an organic substance, if the log $K_{OW} \geq 3$ criterion is met, but no experimental evidence is available on BCF or BMF then the assessor should estimate BCF or BMF from log K_{OW} and translate the biota standard to a water concentration for comparison with water column standards (Section 4.7.1.2). If the estimated QS for biota is the most stringent (i.e. lowest) value, then further investigation to improve BCF and BMF values would be necessary, otherwise there is a risk of developing an unrealistically low QS value for water.

2.6 Data – acquiring, evaluating and selecting data

Comprehensive and quality assessed data are key inputs to QS derivation. Indeed most of the resource required for QS derivation is expended on collecting and assessing data. Appendix 1 provides detailed guidance on how to locate relevant data, evaluate the data to assess their suitability for QS derivation, and select data that will be used to determine a QS.

A brief summary of the main types of data required for deriving QSs is provided below (Section 2.6.1), along with details of the quality assessment of data (Section 2.6.2), and the identification of 'critical' and 'supporting' data (Section 2.6.3).

2.6.1 Types of data required for deriving QSs

2.6.1.1 <u>Data on physical and chemical properties</u>

Properties which can be very important when interpreting laboratory and field ecotoxicity are water solubility, vapour pressure, photolytic and hydrolytic stability, and molecular weight (when assessing risks of bioaccumulation). Such data will make it clear when steps to control exposure concentrations in ecotoxicity experiments are particularly important. This, in turn, helps assess how reliable a toxicity study is (Section 2.6.2). In addition, partition coefficients are needed when deriving a sediment QS when derived using EqP, to conduct transformation calculations (e.g. from mass/volume [mg/L] to mass/mass [mg/kg]). These coefficients (K) include, for example: Koctanol-water (K_{ow}), K suspended particulate matter – water ($K_{susp-water}$), K sediment – water ($K_{sed-water}$), K organic carbon (K_{oc}).

2.6.1.2 Ecotoxicological data

According to Annex V of the WFD, the base set of taxa that should be used in setting quality standards for water are algae and/or macrophytes, *Daphnia* (or representative invertebrate organisms for saline waters), and fish in relation to water column standards. For sediment QSs, the range of species should be expanded to include benthic species (Section 5). However, for the purpose of quality standard setting, the data should not be restricted to this base set. **All available data for any taxonomic group or species should be considered, provided the data meet quality requirements for relevance and reliability** (Section 2.6.2). This may include data for alien species and even exotic species[5], although care should be taken with data generated from experiments using species from extreme environments (e.g. thermophiles, halophytes).

If there are indications of endocrine activity (e.g. bioassays), but not studies are available that allow assessment of adverse effects through this mechanism, this should be highlighted as an uncertainty in the technical report.

Often, multiple data are available for the same species and endpoint (e.g. several studies assessing acute toxicity to *Daphnia*). Unless there is a clear reason for differences between toxicity (e.g. different test conditions, different exposure periods, different life stages or forms of the substance tested, like different metal species), any variation in toxicity may simply reflect random error and the valid data may be aggregated into a single value for each species and endpoint. Detailed guidance on data aggregation is given in Appendix 1

Finally, using ecotoxicological data to derive QSs for metals requires additional considerations. These are dealt with in detail in the relevant sections.

2.6.1.3 Mammalian toxicity data

QSs to protect human health utilise information about effects on mammals from oral exposure, repeated dose toxicity, carcinogenicity, mutagenicity and effects on reproduction, typically No Observable Adverse Effect Level (NOAEL), Acceptable Daily Intake (ADI) and Tolerable Daily Intake (TDI) values identified in the human health section of risk assessments performed under the REACH regime. Oral Reference Doses (RfD), ADI or TDI values adopted by national or international bodies such as the World Health Organization may also be used. For some substances, a threshold level cannot be established (e.g. some genotoxic carcinogens). For these, risk values corresponding to an additional risk of, e.g., cancer over the whole life of 10^{-6} (one additional cancer incident in 10^6 persons taking up the substance concerned for 70 years) may be used, if available.

To assess the risk of secondary poisoning of predators, bird and mammal toxicity data are also used. Further details are to be found in Appendix 1.

---

[5] This is because test species not only represent species that occur in European waterbodies but to ensure a range of sensitivities is represented in the dataset with the result that any resulting QS is more likely to protect the range of species sensitivities found in nature.

2.6.1.4 Data on bioaccumulation

Data on bioaccumulation (bioconcentration, biomagnification and/or the octanol-water partition coefficient (K_{ow})) are required if a substance has a potential to bioaccumulate (i.e. it exceeds the trigger-values given in Section 2.4.4). Where data are available that give different indications of bioaccumulation potential, preference should be given to field observations on bioaccumulation and biomagnification factors (BAFs, BMFs) or experimentally derived BCFs and BMFs (and TMFs – Trophic Magnification Factor), if available.

Further details on how to obtain and evaluate data on bioaccumulation can be found in Appendix 1.

2.6.2 Quality assessment of data

A rigorous assessment of the data is needed to ensure that data are **reliable** and **relevant**. This will normally entail a review of the original study report, especially for critical data that are likely to have a major impact on the QS (Section 2.6.3).

Reliability refers to the inherent quality of the method used to conduct the test. A reliable study requires all relevant details about the test to be described. **Relevance** means the extent to which a test provides useful information about the hazardous properties of a chemical. **Only reliable, relevant data should be considered valid for use in setting a quality standard.**

2.6.2.1 Reliability

Guidance on the principles of data validation and the aspects to be considered is given in Appendix 1, based on REACH guidance. Data are assigned a score according to the reliability of the study.

Further assessment of data generated or assessed under Community legislation such as Regulations (EC) 793/93 and 1488/94 (existing chemicals) or Directives 91/414/EC (plant protection products) or 98/8/EC (biocides) is required unless the data published in the risk assessment reports under these legal frameworks have already been subjected to data quality assurance controls and peer-review. The same applies to peer-reviewed data or guidance values (e.g. Tolerable Daily Intakes or Drinking Water values) published by (inter)national organisations such as the World Health Organization (WHO), the United Nations Food and Agriculture Organization (FAO), the Organisation for Economic Development (OECD) or the OSPAR Convention for the Protection of the Marine Environment of the North-East Atlantic;

Studies on pesticides may be performed on technical material or formulated product. Preference is given to data using technical material because toxicity of the active ingredient is less prone to modification by other formulation ingredients, but specific guidance on treatment of ecotoxicological data for pesticides when formulations have been tested is given in Appendix 1. Not all studies on plant protection properties are suitable for EQS derivation because the exposure regimes are sometimes very short to simulate specific exposure scenarios (mesocosm studies for example).

Studies that have been performed to 'Good Laboratory Practice' (GLP), to international (e.g. OECD) test guidelines and submitted under a regulatory regime may be taken at 'face value' without further review. This is because they have already been reviewed by a competent authority and there is a precedent for their acceptability. An exception to this would be if ecotoxicity studies submitted as part of a regulatory dossier have been performed in such a way that they might not be relevant to QS derivation e.g. unusual exposure regimes or very short test durations.

Detailed guidance for the selection of data to be used for standard setting is provided in Appendix 1, but the following principles are highlighted here:

1. Only data that can be considered as valid may be used, irrespective of the source of the data. **Admissible data are not confined to GLP studies**.

2. Data should be collated in a database with quality scores clearly assigned to each datum. **Only those considered as valid (see Appendix 1, section "Toxicity data") should be used as 'critical' data (Section 2.6.3) in deriving an EQS**.

3. If a QS for a particular receptor cannot be derived because the required data are lacking, this should be flagged.

Again, metals data require additional considerations and these are covered in Section 2.10.

2.6.2.2 Relevance

A study can be well conducted and fully reported but the test endpoint may have little ecological significance. Studies used for EQS derivation should be those where the test endpoint can be related to ecologically significant hazards. For practical purposes, this means effects that can be linked to population sustainability and particularly:

a. survivorship of adults

b. time taken to develop (particularly to reach reproductive age)

c. reproductive output

Most standard test methods include one or more of these endpoints. However, the assessor may be faced with data from studies describing endpoints that do not include direct measurements of survival, development or reproduction but, rather, describe e.g. behavioural effects, anatomical differences between control and treatment groups, effects at the tissue or sub-cellular level, such as changes in enzyme induction or gene expression. Generally these are unsuitable as the basis for EQS derivation. However, some other endpoints are relevant. For example, anatomical changes to gonad development that would prevent successful reproduction, or changes in behaviour if the effect described would impair competitive fitness may be relevant. Avoidance reactions may also be relevant if populations are likely to avoid a contaminated habitat where they would normally be present. Further examples are given in Appendix 1 .

2.6.3 'Critical' and 'supporting' data

Not all data have an equal influence on QS derivation. **Critical data** are ecotoxicity data (typically NOECs/EC10s or LC/EC50) for sensitive species and endpoints that are used as the basis for extrapolation and hence determine – or strongly influence - the value of the QS. Section 3 details the various approaches for extrapolation in particular deterministic and probabilistic methods. Critical data play a key role where a deterministic approach to extrapolation is used (i.e. an AF is applied) because the AF is applied to the lowest credible NOEC/EC10 or LC/EC50 (the critical datum). If a species sensitivity modelling approach is adopted, a distinction between critical and supporting data does not apply. This is because all the data are used in the model extrapolation and so, all the data can be regarded as critical (as long as they are reliable and relevant).

Supporting data are those data that are not described as critical data. They include data that are not among the most sensitive species/endpoints, studies that have estimated a non-standard summary statistic e.g. a LOEC is reported but no NOEC, field or mesocosm experiments that are difficult to interpret, or where a study might be sound but is not fully reported. Supporting data are not used directly for QS derivation when using the deterministic approach but can help inform the derivation of the QS by, for example, identifying sensitive taxa, determining if freshwater and saltwater datasets can be combined for QS derivation, averaging or aggregating the data in order to identify the critical data, and selecting an appropriate AF. All reliable and relevant data are used when deriving a QS using the probabilistic approach, ie SSDs. **Experiments that are clearly flawed should not be used in any way, even as supporting data.**

It is essential that all available toxicity data, both critical and supporting , are subject to rigorous quality assessment and are comprehensively reported as all data may be used, eg in the derivation of an SSD, for aggregation of data for the same species and end point and for comparison of fresh and saltwater data. Further guidance can be found in Appendix 1.

2.6.4 Data gaps - non testing methods

A lack of experimental data can lead to high uncertainty in the derivation process, possibly resulting in over-precautionary QSs. Whilst the generation of well-targeted experimental data can be critical in helping reduce uncertainty, it can be expensive and time-consuming. Under these circumstances there is a useful role for computational methods to fill data gaps, including quantitative structure–activity relationships (QSARs) for predicting toxicity and quantitative structure-property relationships (QSPRs) for estimating physicochemical properties. 'Read across' approaches can also be useful to infer the properties of chemicals for which data are absent, based on the properties of closely related analogues. Such approaches are now recommended in chemical risk assessment (ECHA 2008). Chemical regulation activity and the effort to reduce animal testing under REACH may lead to an increased regulatory acceptance of this type of information and new tools for deriving non-test data. The use of QSARs to predict toxicity has been examined in the following European research projects:

DEMETRA (Emilio Benfenati: Quantitative Structure-Activity Relationships (QSAR) for Pestide Regulatory Purposes; Elsevier 2007, ISBN: 978-0-444-52710-3): Prediction of five eco-toxicological endpoints: Acute toxicity trout, daphnia, quail (oral and dietary exposure), and bee

- CAESAR http://www.caesar-project.eu/: Prediction of five toxicological endpoints: Bioconcentration factor, skin sensitisation, carcinogenicity, mutagenicity, developmental toxicity

Detailed guidance on non-testing approaches is given in Section 6 but possible applications are briefly summarised below.

2.6.4.1 *Predictive models (QSARs, QSPRs)*

The most likely application for computational methods is to fill non-critical data gaps (Section 2.6.3) in the dataset for acute aquatic toxicity, especially when a deterministic assessment is to be followed. It is vital that computational methods are used within their legitimate operating domains; further guidance on QSARs and their use is given in Section 6.

2.6.4.2 *Analogue approaches*

Further non-testing methods include 'read across' and 'category' approaches. The most likely application of read-across is to fill data gaps, when the setting of a QS for mixtures, eg polyaromatic hydrocarbons (PAHs) is preferred compared to the QS for individual substances (Section 2.6.5).

Section 6 outlines another approach for inferring the properties, including ecotoxicological properties, of substances for which data are lacking. Essentially, it uses a category building approach in which chemical analogues are arranged by some physicochemical property (e.g. log Kow) and data from close neighbours are used to fill data gaps by interpolation. The approach can have value in demonstrating that additional AFs are not justified when using data for one substance to derive a QS for another closely related one. However, the following criteria must be met:

- There is a consistent and reliable trend within a category that is relevant to the endpoint of interest (e.g. log K_{ow} increases as ecotoxicity increases)

- If toxicity is the endpoint of interest, reliable measured toxicity is needed to identify the most sensitive trophic group

- Reliable measured data for the endpoint of interest, allowing interpolation to a value for the substance of interest (i.e. where there is a data gap)

- QSARs may be used to support read across but cannot be used to replace measured values

Predictive and analogue methods may be used for generating supporting data but are not suitable for predicting toxicity to be used as critical data. Furthermore, the range of substances to which these models can be applied is limited to chemicals with certain physicochemical and mode of action properties and are not suitable for all substances.

2.7 Calculation of QSs for substances occurring in mixtures

Some mixtures are intentionally emitted with a known and largely constant composition, but change after entry into environment, for example pesticide and biocide preparations. Other mixtures are released with a partly unknown, reasonably constant composition, but change after entry into the environment. In such circumstances an EQS for mixtures of substances may be preferable to deriving EQSs for the individual constituent substances. Section 7 provides guidance on the approaches that can be adopted if a mixture based approach is preferred.

2.8 Using existing risk assessments

In the interests of economy and consistency, it is sensible to utilise existing assessments, or at least the data on which they are based. As noted in section 1, the effects assessments conducted for chemical and pesticide risk assessments share many of the same principles and practices as those used to estimate an QS. Sections 2.8.1 and 2.8.2 provide guidance on the use of such assessments as a basis for deriving QSs, when they are available.

2.8.1 Risk assessments under Existing Substances Regulations (ESR)

For some industrial chemicals, detailed evaluations and risk assessments will already have been prepared under Regulation (EC) No. 793/93 or Directives 98/8/EC, and published in Risk Assessment Reports (RARs). We recommend that the Predicted No Effect Concentrations (PNECs) derived from this process are normally adopted as QSs because the assessments and associated data will have undergone thorough peer review. This also promotes consistency between chemical assessment and control regimes.

However, there are some circumstances that could prompt a review of the RAR PNEC, including:

- If new, potentially critical, ecotoxicity data (i.e. sensitive species or endpoints) has become available since the publication of the RAR.

- If there is new evidence for a mode of toxic action that was not considered in the RAR e.g. new evidence of endocrine disrupting properties.

- Where species sensitivity distribution modelling has been used for extrapolation, there can sometimes be finely balanced arguments about the size of the AF applied to the HC5 to account for uncertainty. For example, where the PNEC for a metal is close to background levels, this would encourage a review of uncertainties and how best to account for them so that a compliance assessment regime for the EQS can be practically implemented.

2.8.2 Pesticide risk assessments under 91/414/EEC

Many pesticides currently on the EU market have been reviewed under the Plant Protection Products Directive (91/414/EEC) which includes an assessment of freshwater ecotoxicity data. The data are peer-reviewed by a competent authority, they usually follow standard (OECD) test methods, and are performed to GLP so the studies are fully auditable. Non-regulatory data, ie data that do not conform to GLP and were not covered by the dossier submitted to the regulatory body may also be included in the review. However, some aspects of risk assessment under 91/414/EEC are different to the approaches taken under REACH to derive PNECs and on which the derivation of EQSs is based. For example:

- The 91/414/EEC assessment is based on a field margin ditch scenario close to the point of application, which would not normally apply under the WFD: the WFD seeks to provide protection to all waterbodies, including lakes, rivers, transitional and coastal waters.
- The 91/414/EEC assessment makes an allowance for recovery from impacts. This does not feature at all in the Annex V methodology under WFD
- Under 91/414/EEC the risk is expressed as a Toxicity Exposure Ratio (TER), based on a direct comparison of toxicity values (without assessment factors) to predictions of concentrations in the environment (PEC). Hence risk assessment under 91/414/EEC does not use AFs applied to the toxicity side of the risk equation, but to the risk quotient, yielding a TER.
- Algal toxicity data are dealt with differently under REACH and 91/414/EEC. This can lead to different outcomes when algae are the critical data determining the threshold (Lepper, 2005).
- Under 91/414/EEC, acute toxicity data are never used to extrapolate to chronic toxicity values; risk assessment for chronic exposure is carried out using only chronic toxicity data because this is a minimum requirement for registration.

Although a risk assessment under 91/414/EEC should not be used directly to set a QS, the list of endpoints produced for the review process and published on the internet by the Commission, provides a valuable data set. These data must, however, be supplemented with other ecotoxicity data where they are available, and also meet quality criteria.

2.9 Extrapolation

Derivation of all QSs requires some form of extrapolation from the available data to estimate a threshold that takes account of uncertainties such as inter- and intra-species variation and laboratory to field extrapolation.

Two main approaches are possible, the deterministic and probabilistic methods. Essentially the deterministic approach takes the lowest credible toxicity datum and applies an AF (which may be as low as 1 or has high as 10000) to extrapolate to a QS, the AF allowing for the uncertainties in the available data. Probabilistic methods adopt species sensitivity distribution (SSD) modelling in which all reliable toxicity (usually NOEC) data are ranked and a model fitted. From this, the concentration protection a certain proportion of species (typically 95%) can be estimated (the HC5).

Laboratory and (where available mesocosm) data are used to derive QSs that account for direct toxicity of chemicals to pelagic and sediment-dwelling organisms. Where there are insufficient data for a probabilistic approach, a deterministic approach is adopted (Section 3). Where there are sufficient data, both deterministic and probabilistic approaches to extrapolation will normally be performed (Section 3). Species sensitivity distribution models explicitly account for differences in sensitivity between species but, as Section 3 explains, a further AF is applied to the HC5 arising from model extrapolation to account for 'residual' uncertainties that are not accounted for by the SSD model. In a deterministic approach, larger AFs are typical, depending on the quantity and type of data available.

The purpose of these AFs is to account for the uncertainty that is not accounted for already in the experimental toxicity data or modelling (in the case of a probabilistic assessment). A basic principle of extrapolation is that, where uncertainty is high, larger AFs are necessary. Guidance on the size of these AFs is given in Section 3. The REACH guidance makes clear the possibility of flexibility in the size of the AF but any change from the 'default' AF (either to increase it, making the QS more stringent or to decrease it, making the QS less stringent) should be justified.

Useful lines of evidence that may be used to inform the extrapolation (and possibly influence the size of AF applied) include mode of action data, effects data from the field, and background concentration data for naturally occurring substances as outlined below.

2.9.1 Mode of action

If there are indications of adverse effects via endocrine activity (e.g. bioassays) or other specific effects that have not been adequately reflected in bird or mammals studies used to derive the NOAELoral (e.g. only 28day studies are available), an additional assessment factor may be considered to cover the anticipated effects.

On the other hand, uncertainty is reduced when there are relevant test endpoints from ecotoxicity studies that are highly relevant to a substance's mode of toxic action. An example would be fish life cycle studies for a chemical that is known to affect the reproductive physiology of vertebrates. Similarly, if a substance has a specific mode of toxic action, and reliable data for taxa that would be expected to be particularly sensitive are available (e.g. data for a range of insects for an insecticide that acts by inhibiting acetyl cholinesterase activity, or data for blue-green algae when dealing with chemicals that have bactericidal properties) then, again, an important aspect of uncertainty is reduced. Under these conditions, a smaller AF than the default value may be justified.

It follows that uncertainty may be increased if data for sensitive taxa are missing when dealing with substances with a specific mode of action like insecticides, herbicides or antibiotics.

2.9.2 Field and mesocosm data

Annex V of the WFD states that:

> *"…the standard thus derived should be compared with any evidence from field studies. Where anomalies appear, the derivation shall be reviewed to allow a more precise safety factor to be calculated."*

Field data, whilst rarely being suitable as the critical data for deriving a QS, can be used to corroborate (or challenge) the choice of AF. Crane et al. (2007), describe techniques for estimating a field threshold based on chemical exposure and biological data from matched locations and sampling occasions in the field. Field data also have a key role in deriving sediment standards (Section 5.2.1.3). In principle, where there is evidence of a mismatch, this would prompt consideration of the reasons why there is a discrepancy between the QS derived using laboratory data and experience in the field. Given the variability in field data (and indeed in laboratory ecotoxicity data), small differences between a laboratory-based QS and field data should not be given undue weight. We suggest that differences larger than an order of magnitude would, however, warrant further investigation and, if justified, a revision of the AF.

Mesocosm studies usually employ only a single contaminant stressor but biological impacts seen in the field may be attributable to several stressors, including non-chemical stressors. This can impair interpretation of matched chemical and biological data. However, if a 'one-sided' analysis is undertaken, i.e. calculate the maximum concentration that still permits good biological quality, the resulting threshold will be a conservative estimate. Analysis of mesocosm or field data may suggest the laboratory-based QS is over-protective (the QS based on laboratory data is lower than the field threshold). However, if the laboratory data do not include species that are known to be sensitive to the contaminant, a reduction of the AF cannot be justified.

2.9.3 Background concentrations

Another line of evidence that could affect the final QS is information about background levels for naturally occurring substances e.g. metals and some organics which occur widely in nature e.g. polycyclic hydrocarbons and some cyanides. The size of the AF should not normally result in a QS that is below the natural background level unless an 'added risk' approach to compliance assessment is to be adopted (Section 3.5). However, if uncertainties in the extrapolation are largely responsible for the QS being below the background level (e.g. an AF > 50 is required), this must be highlighted in the datasheet as a key uncertainty for the policymaker.

2.10 Dealing with metals

2.10.1 Why metals are different

Unlike most organic substances, metals are neither created nor destroyed by biological or chemical processes. Rather, they are transformed from one chemical form to another. Because metals are naturally occurring, many organisms have evolved mechanisms to regulate their accumulation and storage. Moreover some metals are essential nutrients so, when they are not present in sufficient concentrations, can limit growth, survival and reproduction of the organisms. Excess amounts of certain metals, on the other hand, are potentially toxic. Table 2-1 summarises the essentiality status for some environmentally relevant metals.

These features, along with the fact that metals naturally occur as inorganic forms in environmental compartments (e.g. sediments) and are cycled through the biotic components of an ecosystem, complicate the evaluation of toxicity data for inorganic metal substances and have a major influence on the way we derive QSs for metals.

Table 2.1 Essentiality of metals and metalloids to living organisms

Essential	Non-essential
Cr, Co, Cu, Fe, Mn, Mo, Ni, Se, Zn	As, Sb, Cd, Pb, Hg, Tl, Ag, Sn

When evaluating toxicity data to derive quality standards for metals, total metal concentrations are not usually directly related to ecotoxicological effects because many abiotic and biotic processes can modify the *availability* of metals, even rendering them unavailable for uptake. This means that the fraction available for uptake and toxicity may be a very small part of the total metal present. Due to several physicochemical processes, metals exist in different chemical forms which might differ in (bio)availability. Thus, the (bio)availability of metals in both laboratory tests and in the 'real" environment may be affected by several physicochemical parameters such as the pH, hardness of water and the dissolved organic carbon (DOC). Organic carbon (OC) and sulphides levels are key influencing factors for the sediment compartment. As geographically distinct watersheds show distinct geochemical characteristics, the degree to which different aquatic systems can safely accommodate metal loadings will vary. For this reason, ecotoxicity data, derived for the same species and same endpoint may vary widely when artificial/natural waters or sediments are used as test media.

The Water Framework Directive explicitly acknowledges the issues of (bio)availability and naturally occurring concentrations for metals. The Daughter Directive to the WFD on EQSs (2008/105/EC) (EC, 2008) states in Annex I, part B.3:

Member States may, when assessing the monitoring results against the EQS, take into account:

> *(a) natural background concentrations for metals and their compounds, if they prevent compliance with the EQS value; and*
>
> *(b) hardness, pH or other water quality parameters that affect the bioavailability of metals.*

Ideally, the derivation of QSs for metals requires an explicit consideration of (bio)availability using speciation models or, failing that, to utilise dissolved concentrations instead of total concentrations. Background concentrations may also need to be taken into account. Guidance on both bioavailability and backgrounds is provided in more detail in the Sections dealing with specific media (See Section 3.5, 4.7 and 5.2).

Guidance on deriving EQSs for metals is provided in Section 3.5.

2.11 Expression and implementation of EQSs

2.11.1 Accounting for exposure duration

Depending on the release pattern of a chemical and its environmental fate, chemical exposure may occur over long periods - or even continuously - in biota, in sediments, and even in the water column. In the water column, exposure may also occur intermittently for short periods e.g. coinciding with storm events or short periods of chemical use.

In order to cover both long- and short-term effects resulting from exposure, two water column EQSs will normally be required:

(i) a long-term standard, expressed as an annual[6] average concentration (AA-EQS) and normally based on chronic toxicity data

and

(ii) a short-term standard, referred to as a <u>m</u>aximum <u>a</u>cceptable <u>c</u>oncentration EQS (MAC-EQS) which is based on acute toxicity data.

Where EQSs are derived for biota and sediment, they are always expressed as a long-term standard. **It is not appropriate to derive a short-term standard for these compartments because exposure will typically be over long periods of time.**

2.11.2 Including aspects of water management and monitoring into the final decision about EQSs

Although uncertainty is taken into account during extrapolation through the use of modelling and/or AFs applied to critical data, small datasets invariably lead to greater uncertainty in the EQS. Under

[6] When the exposure pattern for a substance is known to be episodic e.g. many pesticides, the averaging period may be a shorter period than a year. This is case-specific but is determined by the expected exposure pattern, not toxicology (EC 2000/60/EC)

some circumstances, the policymaker responsible for implementing a standard may decide that a standard is too uncertain to be used in a statutory context, i.e. the policymaker may decide the risks of implementing an imprecise standard outweigh any benefits, or that it is only appropriate to use the EQS in an advisory context. As explained earlier, the role of the scientist deriving an EQS is to advise the policymaker on the nature and importance of unresolved uncertainties, and the steps that could be taken to resolve them (e.g. conducting further ecotoxicity tests), so that decisions about how to implement the standard can be made in an informed way.

2.11.3 Expression of EQSs for water

The overall EQS for water that is derived as described above is expressed as a dissolved concentration. Water column EQSs may also be expressed as a total (dissolved + particulate) concentration or concentration associated with SPM. In most cases the dissolved concentration will be preferred. However, for substances that are highly adsorbed to suspended matter the EQS might be based on suspended matter concentrations, which can be more appropriate for calculating substance fluxes in river systems. For such substances, this may be preferable to expressing the EQS as a total water concentration because this is dependent on the highly variable suspended matter concentration in water (which is a function of seasonality, turbidity and so on) and so may be highly uncertain. Emission controls are usually based on total concentrations in discharges too. When faced with such situations, the assessor should agree thepreferred method of EQS expression/compliance assessment with policy makers or river basin managers.

3 STANDARDS TO PROTECT WATER QUALITY

3.1 General approach

QSs for the protection of **pelagic communities** (organisms inhabiting the water column) are required for all substances. This Section covers the protection of freshwater and saltwater pelagic communities from both long-term and short-term exposure, as well as those in transitional waters. In addition, this Section also covers the assessment of **risks to human health from drinking water**.

For the water column, four different QS values can be derived:

- A QS based on direct ecotoxicity ($QS_{fw, eco}$ or $QS_{sw, eco}$ (Section 3.2),
- A QS based on secondary poisoning of predators ($QS_{biota\ sec\ pois\ fw}$ or $QS_{biota\ sec\ pois\ fw}$)[7] (Section 4.4),
- A QS based on human consumption of fishery products ($QS_{biota,\ hh\ food}$)[7] (Section 4.5)

and

- A QS for human consumption of drinking water ($QS_{dh,hh}$) (Section 3.9)

As explained in Section 2.4.3, the $QS_{biota,\ sec\ pois}$ and $QS_{biota,\ hh}$ only need to be derived if specific trigger values are met. The lowest of these values is set as the overall EQS, although the drinking water standard is only adopted as an overall standard for waters intended for drinking water abstraction.

As explained in Section 2.5.1, in order to select an overall EQS, it will be necessary to translate biota and human health standards (ie biota, hh) into an equivalent water concentration, so they can be compared directly with other water column QSs. Some jurisdictions may also prefer to assess compliance with these standards by sampling the water column rather than biota. The conversion of biota QSs into their equivalent water column concentrations is covered in Section 4.7.2.

The particular requirements for deriving water column standards for metals are dealt with in Section 3.5.

3.2 Derivation of QSs for protecting pelagic species

3.2.1 Relationship between water column QS and MAC-QS

As explained in Section 2.11, two QSs are required for the water compartment to cover both long-term and short-term exposure to a chemical:

(i) an annual average concentration (QS) to protect against the occurrence of prolonged exposure, and

(ii) a maximum acceptable concentration (MAC-QS) to protect against possible effects from short term concentration peaks. The temporary standard during derivation is termed MAC-QS to distinguish this value from the QS mentioned in (i)

[7] The QS $_{biota,\ sec\ pois}$ and QS $_{biota,\ hh\ food}$ are based on biota standards and are unlikely to be implemented as annual average concentrations in practice. They may be converted to equivalent water concentrations e.g. to set an overall EQS or to enable compliance assessment using water samples instead of biota sampling.

Whilst derivation of the QS typically employs chronic toxicity data, the MAC-QS always relies on acute data. When data are sparse or the ratio between acute effects and chronic no-effects is narrow, the estimated MAC-QS can sometimes be more stringent than the QS. It is also possible that the effects observed in chronic studies are due to the initial contact with the test substance, rather than to prolonged exposure. In that case it is also reasonable that the MAC-QS and QS are similar. When the MAC-QS is lower than the QS, a further analysis should be presented in which the possible causes are discussed. When acute and chronic critical data for the QS derivation relate to the same species, and the acute L/EC50 is lower (more stringent) than the chronic NOEC, the data should be re-evaluated and justified, and/or an EC10 should be derived instead of a NOEC to derive the QS if the statistical analysis to derive the NOEC has insufficient discriminating power. Since effects of chronic exposure normally occur at lower concentrations than those of acute exposure, MAC-QS values below the QS make little toxicological sense.**Therefore, where the derivation of the MAC-QS leads to a lower value than the QS, the MAC-QS is set equal to the QS for direct ecotoxicity**. This is summarised below in Table 3.1.

Table 3.1 Summary of MAC-QS recommendation based on relationship with QS for direct ecotoxicity

Relationship between estimated AA and MAC	Recommendation
MAC-QS < QS	Set MAC-QS equal to AA-QS
MAC-QS > AA-QS	Derive MAC-QS.

3.2.2 Preparing aquatic toxicity data

Aquatic toxicity data are the key inputs to the derivation of water column standards for direct ecotoxicity. Before the assessor can derive QSs the available data must be properly assessed for reliability and relevance. This is because all data contribute to the final outcome, especially when a probabilistic analysis (SSD) is performed. Guidance on data quality assessment is detailed in Appendix 1.

Before starting the extrapolation steps, the following steps are also taken:

- Data are aggregated when there are multiple data for the same species and endpoint (Section 2.6.1.2);
- Analyses are performed to see whether freshwater and saltwater data can legitimately be combined. This is covered in detail in Section 3.2.3.

As an aid to properly understanding the available data, the assessor should plot all the data graphically so that he/she can develop (and communicate) an appreciation of the quantity of data and spread of species and effects over a range of concentrations. A convenient way to do this is to separate acute and chronic data for freshwater and saltwater species, rank effect concentrations or NOECs, and simply plot the cumulative ranks against concentration. This can be achieved simply in Excel (or using the ETX programme (Van Vlaardingen *et al.*, 2004)), ideally identifying the different taxonomic groups by different symbols so any particularly sensitive or tolerant taxa become immediately obvious. This presentation helps inform an understanding of acute: chronic ratios. It also identifies outliers and different sensitive groups, especially if groups are given different symbols.

3.2.3 Combining data for freshwater and saltwater QS derivation

3.2.3.1 Organic compounds

In principle, ecotoxicity data for freshwater and saltwater organisms should be pooled for organic compounds, if certain criteria are met. **Where the criteria for combining data are met (see below), the pooled datasets are then used to derive both freshwater and saltwater QSs, but with different assessment factors (see Sections 3.3.1 and 3.3.2).**

The presumption that for organic compounds saltwater and freshwater data may be pooled must be tested, except where a lack of data makes a statistical analysis unworkable. In those cases where there are too few data (either freshwater or saltwater) to perform a meaningful statistical comparison and there are no further indications (spread of the data, read-across, expert judgement[8]) of a difference in sensitivity between freshwater vs saltwater organisms, the data sets may be combined for QS derivation.

To enable a robust comparison, it is important that a comprehensive set of data is included. For compounds with a specific mode of action, this should include particularly sensitive taxonomic group(s). This reinforces the need for a search strategy for ecotoxicological data that is as wide as possible.

Where there are sufficient toxicity data in both the freshwater and saltwater datasets to enable a statistical comparison, the following procedure should be followed. The null hypothesis is that freshwater and saltwater organisms do not differ in their sensitivity to the compound of interest; *i.e.* they belong to the same statistical population:

1. All freshwater data are collected and tabulated (note: this data set contains one toxicity value per species). Next, a logarithmic transformation of each of these toxicity values is performed.
2. All saltwater data are collected and tabulated (note: this data set contains one toxicity value per species). Next, a logarithmic transformation of each of these toxicity values is performed.
3. Using an F-test, determine whether the two log-transformed data sets have equal or unequal variances. Perform the test at a significance level (α) of 0.05.
4. A test for differences between the data sets e.g. a two tailed t-test where the data are normally distributed (with or without correction for unequal variances, depending on the results of step 3), is performed. Perform the test at a significance level (α) of 0.05[9].
5. Especially for compounds with a specific mode of action, it is important to identify particularly sensitive taxonomic groups and perform a separate statistical analysis for this specific group. If enough data are available to make a comparison for individual or related taxonomic groups (e.g., insects, crustaceans, arthropods, fish, vertebrates), this may help to determine if there are differences between saltwater and freshwater species.

8 Information on a closely related compound(s) may be used (‘read across’) (See Section 6). The toxicity data of the related compound should not be used, but toxicological information or knowledge may be used to underpin conclusions. Any use of information from related compounds should be well documented. This can be especially useful when differences are expected for a compound but the dataset is too small to to perform a meaningful statistical comparison.

9 Beware of confounding factors. For example: (i) a specific group of organisms might be more sensitive than other organisms, (ii) over representation of results from one study or species from a specific taxonomic group in one of the two data sets might cause bias in the results. Results of statistical tests become increasingly meaningful with increasing sample size.

When a significant difference in sensitivity cannot be shown, the two data sets remain combined for QS derivation and the $QS_{fw, eco}$ and the $QS_{sw, eco}$ are derived using the same data set. However, different extrapolations should be used for the two compartments (detailed in Sections 3.3 and 3.4).

When a difference in sensitivity is demonstrated based on toxicity, the freshwater and saltwater data sets should not be pooled and QSs for both compartments should be derived using the respective data sets separately and the appropriate extrapolation method.

3.2.3.2 Metals

Freshwater and saltwater toxicity data for metals should be separated *a priori*. This is because differences in toxicity between freshwater and saltwater species are likely because of differences in metal speciation and bioavailability as well as (osmo)regulation. Datasets should only be combined when there is no demonstrable difference in sensitivity. If metals effects data are expressed as dissolved metal concentrations, freshwater and saltwater sensitivities can be compared to assess whether they can be combined, as described for organic substances (Section 3.2.3.1).

However, when metal bioavailability correction is being considered for the freshwater QS, such correction can not be extrapolated to the marine environment and therefore freshwater and marine NOECs can not be combined.

3.3 Deriving a $QS_{fw, eco}$

3.3.1 Derivation of a QS for the freshwater community ($QS_{fw, eco}$)

For the derivation of the $QS_{fw, eco}$ combined toxicity data sets (with one toxicity value per species) of freshwater and saltwater species may be used (see Section 3.2.3), if after evaluation of the freshwater and saltwater toxicity data it appears that the data can be pooled. Where data permit, the $QS_{fw, eco}$ is derived in three ways:

1. deterministic approach: assessment factor applied to the lowest credible datum ('AF method', Section 3.3.1.1)

2. probabilistic approach using species sensitivity distribution modeling ('SSD method', Section 3.3.1.2),

and

3. using results from model ecosystem and field studies (Section 3.3.1.3).

The methodology is consistent with the REACH provisions for effects assessment for substances that are released continuously. **If the conditions to use the SSD-method for the derivation of quality standards are met, it should always be used. However, a QS should also be derived using the AF method, and, where valid data exist, also using model ecosystems**. In all three methods, remaining uncertainty is taken into account by applying an assessment factor. This implicitly means that the resulting QS, whether it is derived using the AF method, the SSD method, or using model ecosystem studies, are all considered reliable. It is possible, however, that the results differ. These should be covered in the report on the derivation of the QS, with an explanation of possible discrepancies in the results and the reason for choosing the final method. If all methods can be performed, the final $QS_{fw, eco}$ should preferably be based on the results from the SSD method or the model ecosystem-studies, since these entail a more robust approach towards assessing ecosystem effects. It cannot be stated beforehand which method is preferred, the selection of the final $QS_{fw, eco}$ remains subject to expert judgement. The SSD gives a robust estimate of the range of sensitivities to be encountered in an ecosystem, but it is still based on single species data, and species-interactions at the ecosystem level are not covered. In the case of mesocosm studies, it is often not possible to disentangle the exact cause-effect relationships, but

they may point to long-term effects on the ecosystem that cannot be shown in single-species laboratory studies (*i.e.* indirect effects, predator-prey interactions). The relevance of the ecosystem structures of the available model ecosystem studies is an important consideration. In any case, both the SSD and mesocosm should include species that are likely to be sensitive. If sensitive species are not available, nor represented in the mesocosm studies, the deterministic approach may still be preferred, because it makes greater allowance for uncertainty.
Rarely, there may not be appropriate data for the water column available but there are suitable tests with benthic studies (e.g. only sediment tests with chironomids for an insecticide). In such a case it might be considered to apply the equilibrium partitioning method (section 5.2.1.2) in a reversed way from how it is usually applied. However, in such a case it must be considered whether exposure to the substance is primarily through the aqueous phase. This means that for highly hydrophobic substances, where food ingestion contributes significantly to the exposure, this approach could not be applied.

3.3.1.1 Extrapolation using assessment factor method

For substances with small datasets, the deterministic approach or assessment factor method (AF method) is the only realistic option because the data requirements of the SSD method (Section 3.3.1.2) are too demanding. The quantity and types of data available determines the assessment factors used (Table 3.2). The procedures for estimating an $AA\text{-}QS_{fw,\ eco}$ are the same as the aquatic effects assessment and the calculation of the PNEC (≈ $AA\text{-}QS_{water}$) described in the guidance prepared for REACH (ECHA, 2008).

If an assessment factor equal to or higher than 100 is used, this implies a high level of uncertainty and it should always be highlighted in a 'residual uncertainty' paragraph in the technical report describing the derivation of the $AA\text{-}QS_{freshwater,\ eco}$, together with possible ways to reduce this uncertainty (e.g. perform an additional toxicity test for a specific species).

When only short term toxicity data are available an assessment factor of 1000 will be applied to the lowest L(E)C50 of the relevant available toxicity data, irrespective of whether or not the species tested is a standard test organism (see notes to Table 3.2). A lower assessment factor will be applied to the lowest NOEC derived in long term tests with a relevant test organism.

The algal growth inhibition test of the base set is, in principle, a multigeneration test. However, for the purposes of applying the appropriate assessment factors, the EC50 is treated as a short term toxicity value. The NOEC from this test may be used as an additional NOEC when other long-term data are available. In general an algal NOEC should not be used unsupported by long term NOECs of species of other trophic levels. However if the short term algal toxicity test is the most sensitive of the short term tests, the NOEC from this test should be supported by the result of a test on a second species of algae. The investigations with bacteria (eg growth tests) are regarded as short term tests. Additionally, blue-green algae should be counted among the primary producers due to their autotrophic nutrition i.e. they assume the same status as green algae.

The assessment factors presented in Table 3.2 should be considered as general factors that under certain circumstances may be changed. In general, justification for changing the assessment factor could include one or more of the following:

- evidence from structurally similar compounds (Evidence from a closely related compound may demonstrate that a higher or lower factor may be appropriate);
- knowledge of the mode of action (some substances, by virtue of their structure, may be known to act in a non-specific manner);
- the availability of test data from a wide selection of species covering additional taxonomic groups other than those represented by the base-set species;
- the availability of test data from a variety of species covering the taxonomic groups of the base-set species across at least three trophic levels. In such a case the assessment factors

may only be lowered if these multiple data points are available for the most sensitive taxonomic group.

Specific comments on the use of assessment factors in relation to the available data set are given in the notes below Table 3.2.

Table 3.2 Assessment factors to be applied to aquatic toxicity data for deriving a $QS_{fw, eco}$

Available data	Assessment factor
At least one short-term L(E)C50 from each of three trophic levels (fish, invertebrates (preferred *Daphnia*) and algae) (i.e. base set)	1000 [a)]
One long-term EC10 or NOEC (either fish or *Daphnia*)	100 [b)]
Two long-term results (e.g. EC10 or NOECs) from species representing two trophic levels (fish and/or *Daphnia* and/or algae)	50 [c)]
Long-term results (e.g. EC10 or NOECs) from at least three species (normally fish, *Daphnia* and algae) representing three trophic levels	10 [d)]
Species sensitivity distribution (SSD) method	5-1 (to be fully justified case by case) [e)]
Field data or model ecosystems	Reviewed on a case by case basis [f)]

a) The use of a factor of 1000 on short-term toxicity data is a conservative and protective factor and is designed to ensure that substances with the potential to cause adverse effects are identified. It assumes that the uncertainties identified above make a significant contribution to the overall uncertainty. For any given substance there may be evidence that this is not so, or that one particular component of the uncertainty is more important than any other. In these circumstances it may be necessary to vary this factor. This variation may lead to a raised or lowered assessment factor depending on the available evidence. A factor lower than 100 should not be used in deriving an $QS_{fw, eco}$ from short-term toxicity data.
Variation from a factor of 1000 should not be regarded as normal and should be fully supported by accompanying evidence.

b) An assessment factor of 100 is applied to a single long-term result (e.g. EC10 or NOECs) (fish or Daphnia) if this result was generated for the trophic level showing the lowest L(E)C50 in the short-term tests.

If the only available long-term result (e.g. EC10 or NOECs) is from a species (standard or non-standard organism) which does not have the lowest L(E)C50 from the short-term tests, applying an assessment factor of 100 is not regarded as protective of other more sensitive species.. Thus the hazard assessment is based on the short-term data and an assessment factor of 1000 applied. However, the resulting QS based on short-term data may not be higher than the QS based on the long-term result available.
An assessment factor of 100 can also be applied to the lowest of two long-term results (e.g. EC10 or NOECs) covering two trophic levels when such results have not been generated from that showing the lowest L(E)C50 of the short-term tests. This should, however, not apply in cases where the acutely most sensitive species has an L(E)C50 value lower than the lowest long term result (e.g. EC10 or NOECs) value. In such cases the QS might be derived by using an assessment factor of 100 to the lowest L(E)C50 of the short-term tests
.

c) An assessment factor of 50 applies to the lowest of two long term results (e.g. EC10 or NOECs) covering two trophic levels when such results have been generated covering that level showing the lowest L(E)C50 in the short-term tests. It also applies to the lowest of three long term results (e.g. EC10 or NOECs) covering three trophic levels when such results have not been generated from that trophic level showing the lowest L(E)C50 in the short-term tests. This should however not apply in cases where the acutely most sensitive species has an L(E)C50 value lower than the lowest long term result (e.g. EC10 or NOECs) value. In such cases the QS might be derived by using an assessment factor of 100 to the lowest L(E)C50 of the short-term tests.

d) An assessment factor of 10 will normally only be applied when long-term toxicity results (e.g. EC10 or NOECs) are available from at least three species across three trophic levels (e.g. fish, Daphnia, and algae or a non-standard organism instead of a standard organism). When examining the results of long-term toxicity studies, the $QS_{fw,\ eco}$ should be calculated from the lowest available long term result. Extrapolation to the ecosystem can be made with much greater confidence, and thus a reduction of the assessment factor to 10 is possible. This is only sufficient, however, if the species tested can be considered to represent one of the more sensitive groups. This would normally only be possible to determine if data were available on at least three species across three trophic levels. It may sometimes be possible to determine with high probability that the most sensitive species has been examined, i.e. that a further long-term result (e.g. EC10 or NOECs) from a different taxonomic group would not be lower than the data already available. In those circumstances, a factor of 10 applied to the lowest long term result (e.g. EC10 or NOECs) from only two species would also be appropriate. This is particularly important if the substance does not have a potential to bioaccumulate. If it is not possible to make this judgment, then an assessment factor of 50 should be applied to take into account any interspecies variation in sensitivity. A factor of 10 cannot be decreased on the basis of laboratory studies.[10]

e) Basic considerations and minimum requirements as outlined in Section 2.6.1.2.

f) The assessment factor to be used on mesocosm studies or (semi-) field data will need to be reviewed on a case-by-case basis (see Section 3.3.1.3 for further guidance).

Not all circumstances can be dealt with in these footnotes and specific cases may require specific considerations with respect to the choice of the AF. Any deviation from the scheme should be explained. To help with some questions that might arise, further guidance is offered below:

1. *The base set (acute data for fish,* Daphnia, *algae*) *is complete, but chronic data are only available for one trophic level of the base set*: This relates to footnotes a and b because we have to decide whether to use an AF of 100 applied to chronic data or 1000 applied to acute data. An AF of 100 is applied to the lowest chronic NOEC or EC10 but (a) it has to be either *Daphnia* or fish and (b) the NOEC or EC10 should be from the same trophic level as that of the lowest acute L(E)C50. If (a) and (b) are not the case, an AF of 1000 is applied to the lowest L(E)C50 and the two results are compared: lowest L(E)C50/1000 versus NOEC (or EC10)/100; the lowest value is selected as $QS_{fw,\ eco}$.

2. *The base set is complete, but chronic data are only available for two trophic levels from the base set*: This relates to footnotes b and c. An assessment factor of 50 is applied to the lowest chronic NOEC or EC10, if such chronic data are available from two trophic levels from the base set. The trophic levels of the NOECs and/or EC10s should include the trophic level of the lowest acute L(E)C50. If the trophic level for the lowest acute L(E)C50 is not included in the chronic data (NOECs and/or EC10s) then:
   - an assessment factor of 100 is applied to the lowest NOEC or EC10 if the lowest L(E)C50 is higher than the lowest NOEC or EC10;
   - an assessment factor of 100 is applied to the lowest L(E)C50 if the lowest L(E)C50 is lower than the lowest NOEC or EC10.

3. *The base set is complete and chronic data for each of the trophic levels of the base set are available*:
   This relates to footnote c and d. An assessment factor of 10 is applied to the lowest chronic NOEC or EC10 if chronic data are available from all three trophic levels of the base set. The trophic levels

[10] However, this only refers to the deterministic approach. If the SSD approach is used, which is also based on laboratory data, a lower assessment factor than 10 can be used (1-5).

of NOECs and/or EC10s should include the trophic level of the lowest acute L(E)C50. If acute toxicity data are available for trophic levels not covered in the chronic toxicity data, and the trophic level of the lowest L(E)C50 is not included in that of the NOECs and/or EC10s then:

- an assessment factor of 50 is applied to the lowest NOEC or EC10 if the lowest L(E)C50 is higher than the lowest NOEC or EC10;
- an assessment factor of 100 is applied to the lowest L(E)C50 if the lowest L(E)C50 is lower than the lowest NOEC or EC10.

4. *The base set is not complete, because data are missing*
   Although the table refers specifically to *Daphnia*, any reliable data for small crustaceans would be acceptable. In practice, Daphnia data will be the most readily available, but other species such as *Ceriodaphnia*, *Gammarus*, or *Acartia*, the latter in the case of the marine environment, can be considered to fill the gap when data for *Daphnia* are missing. A similar approach can be followed when data for algae or cyanophytes are missing, but macrophyte data are present. If there is evidence that the missing trophic level would not be the potentially most sensitive species (*e.g. Daphnia* in case of a herbicide) or when it can be assumed that the available species are potentially sensitive (*i.e.* insect and *Daphnia* data in case of an insecticide, where algae are missing), the assessment scheme can be followed as if the base set were complete.

5. *Insect growth regulators*
   For this specific type of pesticides, *Daphnia* may not be the most sensitive species. Within the context of pesticide authorisation, it is advised that insects should be tested when for an insecticide the toxicity to *Daphnia* is low (i.e. 48 h EC50 > 1 mg/L, 21 d NOEC > 0.1 mg/L; EC, 2002). This means that where the presence of acute and chronic data for algae, *Daphnia* and fish normally allows for an AF of 10, in this case additional information from insects is considered necessary.

In line with the REACH guidance (ECHA, 2008), data for bacteria representing a further taxonomic group may only be used if non-adapted pure cultures were tested. Studies with bacteria (e.g. growth tests) are regarded as short-term tests. **Consequently, NOECs or EC10 values derived from bacterial studies may not be used in the derivation of the $QS_{fw,\ eco}$ using assessment factors. EC50 values from bacterial tests may be used but they cannot substitute any of the other trophic levels (acute data on algae, *Daphnia*, fish) for completion of the base set**. The same principle applies to toxicity data using protozoans. Nevertheless, NOECs or EC10 values from bacterial studies are valuable and should be tabulated amongst the toxicity data because they are relevant as inputs in an SSD.

Blue-green algae should be counted among the primary producers due to their autotrophic nutrition (ECHA, 2008). Thus, cyanobacteria (blue-green algae or Cyanophyta) belong to the trophic level of primary producers. **This means that data from (both chronic and acute) tests with cyanobacteria are considered as additional algal data and are treated in the same way (*i.e.* if they represent the lowest endpoint, the AF will be based on cyanobacteria, even when data for green algae are present). They can also be used to complete the base set where there are no algal data**.

When there are indications that a substance may cause adverse effects via disruption of the endocrine system of mammals, birds, aquatic or other wildlife species, the assessor should consider whether the assessment factor would be sufficient to protect against effects caused by such a mode of action, or whether a larger AF is needed (Section 2.9.1).

Use of non-testing methods to reduce uncertainty

Emphasis is placed on experimental toxicity data for deriving an EQS. However, non-testing methods (e.g. QSARs, read-across methods) are also available which can be used to predict toxicity of certain organic chemicals and endpoints. They should not be used to generate critical data to derive an EQS, but predicted data can play a role in reducing uncertainty and thereby influence the size of AF chosen for extrapolation. Detailed guidance on the use of non-testing methods is given in Section 6.

3.3.1.2 Extrapolation using SSDs

Statistical extrapolation in line with the provisions of the REACH guidance (ECHA, 2008), namely the species sensitivity distribution method (SSD), can be used for the derivation of EQSs for water. Extensive information on the backgrounds and use of SSDs is given in Posthuma *et al.* (2002).

To construct an SSD, toxicity data are log-transformed and fitted to a distribution function from which a percentile (normally the 5th percentile; often referred to as the HC5) of that distribution is used as the basis for an EQS. Several distribution functions have been proposed. The US EPA (1985) assumes a log-triangular function, Kooijman (1987) and Van Straalen and Denneman (1989) a log-logistic function, and Wagner and Løkke (1991) a log-normal function. Aldenberg and Slob (1993) and Aldenbeg and Jaworska (2000) further refined the way to estimate the uncertainty of the 95th percentile by introducing confidence levels. The log-normal distribution is a pragmatic choice from the possible range of distributions because its mathematical properties are well-described (methods exist that allow for most in depth analyses of various uncertainties) although others are permissible

Data requirements

For estimating a $QS_{fw,\ eco}$ the input data to the SSD should be quality-assessed chronic NOEC or EC10 data according to the criteria recommended in Section 2.6.2. As for deterministic extrapolation, data should first be aggregated to one toxicity value per species, and statistical comparisons undertaken to decide if freshwater and saltwater data can be pooled. In practice, the same dataset is used for both the deterministic and probabilistic methods.

Ideally the dataset for an SSD should be statistically and ecologically representative of the community of interest (Posthuma *et al*., 2002). An EQS should be protective for the wide range of surface waters and communities that can occur within Europe. Given this broad scope of protection of the WFD, the requirements of the REACH guidance with respect to the number of taxa and species to be included in the dataset (ECHA, 2008) are followed, ie the output from an SSD-based QS is considered reliable if the database contains preferably more than 15, but at least 10 NOECs/EC10s, from different species covering at least 8 taxonomic groups. For estimating a $QS_{fw,\ eco}$, the following taxa would normally need to be represented:

- Fish (species frequently tested include salmonids, minnows, bluegill sunfish, channel catfish, etc.)
- A second family in the phylum Chordata (e.g. fish, amphibian, etc.)
- A crustacean (e.g. cladoceran, copepod, ostracod, isopod, amphipod, crayfish etc.)
- An insect (e.g. mayfly, dragonfly, damselfly, stonefly, caddisfly, mosquito, midge, etc.)
- A family in a phylum other than Arthropoda or Chordata (e.g. Rotifera, Annelida, Mollusca, etc.)
- A family in any order of insect or any phylum not already represented
- Algae
- Higher plants

SSDs for substances with a specific mode of action

For a substance exerting a specific mode of action, SSDs should be constructed using

(a) the entire dataset (i.e. all taxa, so that the relative sensitivities of taxa can be examined) and

(b) only those taxa that are expected to be particularly sensitive (e.g. for a herbicide acting by photosynthetic inhibition, this would be data for higher plants and algae).

In other words, the minimum requirements to perform an SSD should be also be met for a compound with a specific mode of action, in order to be able to demonstrate deviations from the expected distribution. If there is clear evidence of a 'break' in the distribution between the sensitive and other species, or poor model fit, the HC5 should be estimated using only data from the most sensitive group, provided that the minimum number of 10 datapoints is present. If other evidence is available that indicates there might be a specific sensitive group of species, for example, 'read-across' data from a structurally similar substance, this could also be used.

Testing goodness of fit

Different parametric distributions e.g. log-logistic, log-normal or others may be used. For example, the Anderson–Darling goodness of fit test can be used in addition to the Kolmogorov-Smirnov-test, to help choose a parametric distribution for comprehensive data sets, because it gives more weight to the tails of the distribution. Further details are given in REACH guidance (ECHA, 2008). The following guidance is offered:

Whatever the model fitted to a distribution, results should be discussed with regards to the graphical representation of the species distribution and the different p-values (~probability value: the likelihood of wrongly rejecting a statistical hypothesis when it is true) obtained with each test. ($p < 0.05$ means a probability of < 5%).

The choice of a distribution function other than the log-normal or log-logistic distribution should be clearly explained.

If the data do not fit any distribution, the left tail of the distribution (the lowest effect concentrations) should be analysed more carefully. If a subgroup of species is particularly sensitive and, if there are sufficient data, an SSD may be constructed using only this subgroup. However, this should be underpinned if possible by some mechanistic explanation e.g. high sensitivity of certain species to this particular chemical.

The SSD method should not be used in cases where there is a poor data fit to all available distributions.

Calculating the HC5

The method of Aldenberg and Jaworska (2000) is considered most appropriate because it enables the calculation of a confidence interval (normally the 90% interval) for the HC5. This method is used in the ETX-computer program (Van Vlaardingen *et al*., 2004).
The HC5 according to Aldenberg and Jaworska is calculated as follows:

$$\text{Log HC5} = Xm - k*s$$

Where:

Xm = mean of log-transformed NOEC and EC10 data

k= extrapolation constant depending on protection level and sample size (according to Aldenberg and Jaworska, 2000)

s=standard deviation of log-transformed data

The extrapolation constant k is taken from Aldenberg and Jaworska (2000). Three values are given for k. The 5%ile cu-off value (HC5) is calculated with the median estimate for k and, in addition, the confidence limits are calculated using the upper and lower estimates of k.

The median estimate of the HC5 (sometimes denoted as HC5-50) is used as the basis of the QS. SSD modelling deals explicitly with differences in sensitivity between species. According to the requirements set out above, an SSD can only be constructed when data are plentiful but there may still be some residual uncertainty that needs to be accounted for in the final QS. For this reason, the HC5 is divided by an additional AF:

QS = HC5 / AF

Choice of AF applied to HC5

An AF of 5 is used by default but may be reduced where evidence removes residual uncertainty. The exact value of the AF depends on an evaluation of the uncertainties around the derivation of the HC5. As a minimum, the following points have to be considered when determining the size of the assessment factor (ECHA, 2008):

- the overall quality of the database and the endpoints covered, e.g., if all the data are generated from “true” chronic studies (e.g., covering all sensitive life stages);
- the diversity and representativity of the taxonomic groups covered by the database, and the extent to which differences in the life forms, feeding strategies and trophic levels of the organisms are represented;
- knowledge on presumed mode of action of the chemical (covering also long-term exposure). Details on justification could be referenced from structurally similar substances with established mode of action;
- statistical uncertainties around the HC5 estimate, e.g., reflected in the goodness of fit or the size of confidence interval around the 5th percentile, and consideration of different levels of confidence (e.g. by a comparison between the median estimate of the HC5 with the lower estimate (90% confidence interval) of the HC5);
- comparisons between field and mesocosm studies, where available, and the HC5 and mesocosm/field studies to evaluate the level of agreement between laboratory and field evidence.

3.3.1.3 Use of field and mesocosm studies for derivation of the $QS_{fw,\ eco}$

Field studies and simulated ecosystem studies such as microcosm and mesocosm experiments (e.g. ponds and streams) are frequently used to assess the environmental risks posed by pesticides. They can be a valuable tool to assess the impact of a chemical on populations or communities of aquatic ecosystems under more realistic environmental conditions than is achievable with standard single-species laboratory studies. If such studies are available, and they fulfil the criteria regarding reliability and relevance as defined below, they may be used either as the basis of $QS_{fw,\ eco}$ derivation or, when an SSD is used, to help select the size of AF applied to the HC5. This section specifically deals with the use of mesocosm studies for derivation of the $QS_{fw,\ eco}$. The use of mesocosm data for derivation of the MAC-QS is addressed in Section 3.4.1.3.

Mesocosms

For more detailed guidance on the conduct and evaluation of micro- or mesocosm studies see e.g. Hill *et al*. (1994), Giddings *et al*. (2002) and De Jong *et al*. (2008). The following criteria should be addressed when assessing mesocosm data:

- Adequate and unambiguous experimental set-up
- Realistic community
- Adequate description of exposure patterns, especially in the compartment of interest e.g. water column
- Sound statistical evaluation

- Sensitive endpoints that are in accordance with the mode of action of the chemical

Irrespective of the framework under which the studies were originally conducted, these basic principles apply to all simulated ecosystem studies. However, there may be some features that are of particular importance to QS derivation since the objectives of risk assessment under Council Directive 91/414/EEC and QSs under the WFD are not entirely compatible. The following points are particularly important:

1. For $QS_{fw,\ eco}$ derivation, exposure in the test system must be properly characterised. Therefore a prerequisite for using a field or mesocosm study is that the concentration of the substance is measured over the course of the experiment so that time-weighted average concentrations (TWA) within a well-defined time window can be calculated for persistent active ingredients.

2. All effects observed (and all NOECs derived), must be related to the respective TWA concentration. It is not acceptable to use the initial concentration as the basis for assessment unless there is evidence that this level of exposure has been maintained.

3. This means that, for $QS_{fw,\ eco}$ derivation, mesocosm studies with rapidly dissipating compounds (with half-lives of hours) cannot be used unless steps have been taken to replenish the test substance at intervals consistent with the substance's half-life in the environment. For experiments with a repeated pulse application it should be evaluated on a case-by-case basis whether long-term exposure can be considered to be maintained.

4. In risk assessment of plant protection products, the potential for recovery following removal of the chemical stressor is normally taken into account. This principle does not apply in QS derivation i.e. a temporary impact is not normally tolerated, especially when deriving a $QS_{fw,\ eco}$ which is intended to protect against long-term exposure when recovery conditions might never actually occur.

5. The scope of protection of an EQS under the WFD is broader than that of the "acceptable concentration" in the risk assessment of pesticides. The EQS must be protective for all types of surface waters and communities, not just the type covered by a particular mesocosm or field study. We therefore need to assess whether the test system can be considered as representative for the full range of waterbodies that might be subject to pesticide exposure. Higher tier (e.g. mesocosm) studies in the context of the pesticide risk assessment are normally focused on shallow, eutrophic, waterbodies occurring in the immediate vicinity of agricultural areas. An EQS under the WFD, however, must also assure protection for waterbodies that differ significantly from this paradigm, for instance those with a wide range of flow regimes, subject to point source inputs of plant protection products (e.g. formulation plants), occurring in different climatic zones, or with different trophic status. Preferably, the available (semi-)field data should cover this wide range of water types, but in reality this is not the case and therefore the guidance presented here should be considered when deciding on the choice of the AF (see below).

6. In general, the more similar the test system is to the field situation, the higher its relevance for risk assessment and EQS setting. Differences between experimental mesocosms and the field can result in either an over- or underestimation of the response of the field ecosystem.

   - Species composition: more relevant NOECs are likely to arise when the species composition in a mesocosm is representative of that found in the field. This does not mean that the species composition in a micro- or mesocosm experiment should be exactly the same as that in the field; it is more important that a sufficient number of representatives of sensitive taxonomic groups are present, especially taxa that are expected to be sensitive given the substance's mode of action (e.g. insect larvae in a study with an insecticide that acts by disrupting moulting). Maltby *et al*. (2005) showed that taxonomy plays a more important role than habitat and geographical region in predicting the sensitivity of water organisms to pesticides with a specific toxic mode of action. Furthermore, the representativeness of the biological traits of the tested species is important. In general, vertebrates are not incorporated in mesocosm studies. If laboratory data suggest vertebrates belong to the most sensitive group, little weight should be given to a mesocosm study without vertebrates.

- Avoidance and drift: examples are known from the literature (for example, *Gammarus pulex*; see Schulz and Liess, 1999) of organisms that detect and avoid toxic substances by moving to areas with lower concentrations. Sessile organisms cannot avoid exposure. Although avoidance and drift are relevant endpoints, in general, laboratory and mesocosm studies do not accommodate avoidance reactions.

<u>Selecting an AF to apply to a mesocosm NOEC</u>

According to the REACH guidance, the AF applied to mesocosm studies or (semi-) field data will need to be reviewed on a case-by-case basis (footnote 'f' to Table 3.2), but no guidance is given with respect to the *range* of AFs to be applied. Brock et al. (2008) compared micro/mesocosm experiments for several chemicals in which long-term exposure was simulated. They estimated a geographical extrapolation factor based on the ratio of the upper and lower limit of the 95% confidence interval of NOECs for toxic effects. These factors ranged between 1.4 and 5.4. This suggests that, where there is (a) only a single model ecosystem study, and (b) sensitive taxa are included in the study of a compound with a specific mode of action, an assessment factor of 5 would account for variation in the NOECs. When additional, confirmative mesocosm studies are available, the AF may be lowered. Further discussion around the selection of AFs on mesocosm studies is to be found in Giddings et al (2002).

In determining the size of AF to be applied, the following should be considered:

- What is the overall quality of the micro- or mesocosm study/studies from which the NOEC has been derived?
- What is the relationship between the mode of action of the investigated substance and the species represented in the available micro- or mesocosm studies? Are sensitive species represented?
- Do the available micro- or mesocosm studies include vulnerable species or representatives of taxonomic groups (e.g. families, orders) of vulnerable species that are part of the aquatic ecosystems to be protected?
- Do the available micro- or mesocosm studies represent the range of flow regimes that should be protected by the EQS? Consider specific populations of species inhabiting the lotic and lentic water types to be protected.
- How representative are the mesocosm studies: do they represent the range of trophic statuses of waterbodies that should be protected by the EQS?

3.3.2 Derivation of a QS for the saltwater pelagic community ($QS_{sw,\ eco}$)

The $QS_{sw,\ eco}$ protects the saltwater ecosystem from potential chronic toxic effects. For the derivation of the $QS_{sw,\ eco}$ combined toxicity data sets (with one toxicity value per species) of marine and freshwater species may be used when the provisions for pooling data are met (see Section 3.2.3). As with estimation of the $QS_{FW,\ ECO}$, the $QS_{SW,\ ECO}$ may be derived by several different approaches:

- a deterministic approach using assessment factors applied to a critical datum,
- a probabilistic approach using SSD modelling, and

- using mesocosm data (although field and mesocosm studies are rarely available for saltwater)

3.3.2.1 Extrapolation using the AF method

The procedures for the marine effects assessment as described in the REACH guidance (ECHA, 2008) are adopted here, i.e. specific AFs for marine effects assessment (Table 3.3) are applied to the lowest credible data (critical data) to derive the $QS_{sw,\ eco}$. The AFs (Table 3.3) for deriving the $QS_{sw,\ eco}$ are higher than those used for freshwater. This is justified by the need to account for the additional uncertainties associated with extrapolation for the marine ecosystem, especially the general under-representation in the experimental dataset of specific marine key taxa and possibly a greater species diversity. As a result, the $QS_{,\ eco}$ is often more stringent than the corresponding standard derived for the freshwater environment.

Even when based on the same set of data, the $QS_{sw,\ eco}$ may differ therefore from the $QS_{fw,\ eco}$. Where data are available for additional marine taxonomic groups, the uncertainties are reduced and so the magnitude of the AF applied to a data set can be lowered (Table 3.3).

Data from studies with marine test organisms other than algae, crustaceans and fish, and/or having a life form or feeding strategy differing from that of algae, crustaceans or fish can be accepted as additional marine taxonomic groups and will allow a reduction in the AF applied (provided that the toxicity data are reliable and relevant). Marine species from taxa other than algae, crustaceans and fish include:

- Macrophyta. e.g. Sea grass (Zosteraceae)
- Mollusca. e.g. *Mytilus edulis*, *Mytulis galloprovincialis*.
- Rotifers. e.g. *Brachyonus plicatilis*.
- Hydroids (e.g. hydroids: *Cordylophora caspia*, *Eirene viridula*);
- Annelida. e.g. *Neanthes arenaceodentata*.
- Echinoderms (e.g. sea urchins: *Arbacia punctulata*, *Strongylocentrotus purpuratus*, *Strongylocentrotus droebachiensis*, *Echinocardium cordatum*, *Paracentrotus lividus, Psammechinus miliaris*, or asteroids: *Asterias rubens*).

In addition, marine organisms that belong to the taxa algae, crustaceans or fish but have a different life form or feeding strategy than the representatives in the freshwater toxicity dataset can be considered additional marine taxonomic groups and may also allow a reduction in the size of the AF:

- Macro-algae. e.g. *Enteromorpha* sp., *Fucus* sp and *Champia* sp.
- Crustaceans (including crabs) are found in both freshwater and marine water. However, crabs, for example, have a life form and feeding strategy very much different from *Daphnia* sp., which is the test organism which is nearly always present in the freshwater toxicity data set, or other common freshwater crustaceans. Thus, such species can be used to reduce the AF where other crustaceans may not. Examples of crabs used in toxicity tests include *Cancer magister*, *Cancer pagurus*, *Carcinus maenas* and *Cancer anthonyi*.

Table 3.3 Assessment factors to be applied to aquatic toxicity data for deriving a $QS_{sw, eco}$

Data set	Assessment factor
Lowest short-term L(E)C50 from freshwater or saltwater representatives of three taxonomic groups (algae, crustaceans and fish i.e. base set) of three trophic levels	10,000 [a)]
Lowest short-term L(E)C50 from freshwater or saltwater representatives of three taxonomic groups (algae, crustaceans and fish) of three trophic levels, plus two additional marine taxonomic groups (e.g. echinoderms, molluscs)	1000 [b)]
One long-term result (e.g. EC10 or NOEC) (from freshwater or saltwater crustacean reproduction or fish growth studies)	1000 [b)]
Two long-term results (e.g. EC10 or NOEC) from freshwater or saltwater species representing two trophic levels (algae and/or crustaceans and/or fish)	500 [c)]
Lowest long-term results (e.g. EC10 or NOEC) from three freshwater or saltwater species (normally algae and/or crustaceans and/or fish) representing three trophic levels	100 [d)]
Two long-term results (e.g. EC10 or NOEC) from freshwater or saltwater species representing two trophic levels (algae and/or crustaceans and/or fish) plus one long-term result from an additional marine taxonomic group (e.g. echinoderms, molluscs)	50
Lowest long-term results (e.g. EC10 or NOEC) from three freshwater or saltwater species (normally algae and/or crustaceans and/or fish) representing three trophic levels + two long-term results from additional marine taxonomic groups (e.g. echinoderms, molluscs)	10 [e)]

Notes:

General note:

Evidence for varying the assessment factor should in general include a consideration of the availability of data from a wider selection of species covering additional feeding strategies/ life forms/ taxonomic groups other than those represented by the algal, crustacean and fish species (such as echinoderms or molluscs). This is especially the case, where data are available for additional taxonomic groups representative of marine species. More specific recommendations with regard to issues to consider in relation to the data available and the size and variation of the assessment factor are indicated below.

When there are indications that a substance may cause adverse effects via disruption of the endocrine system of mammals, birds, aquatic or other wildlife species, it should be considered whether the assessment factor would also be sufficient to protect against effects caused by such a mode of action, or whether an increase of the factor would be appropriate.

a) The use of a factor of 10,000 on short-term toxicity data is a conservative and protective factor and is designed to ensure that substances with the potential to cause adverse effects are identified. It assumes that uncertainties identified above make a significant contribution to the overall uncertainty. For any given substance there may be evidence that this is not so, or that one particular component of the uncertainty is more important than any other. In these circumstances it may be necessary to vary this factor. This variation may lead to a raised or lowered assessment factor depending on the evidence available. Except for substances with intermittent release, as defined in ECHA (2008), under no circumstances should a factor lower than 1000 be used in deriving a $QS_{sw, eco}$ from short-term toxicity data.

Evidence for varying the assessment factor could include one or more of the following:

- evidence from structurally similar compounds which may demonstrate that a higher or lower factor may be appropriate.
- knowledge of the mode of action as some substances by virtue of their structure may be known to act in a non-specific manner. A lower factor may therefore be considered. Equally a known specific mode of action may lead to a higher factor.
- the availability of data from a variety of species covering the taxonomic groups of species across at least three trophic levels. In such a case the assessment factors may only be lowered if multiple data points are

available for the most sensitive taxonomic group (i.e. the group showing acute toxicity more than 10 times lower than for the other groups).
Variation from an assessment factor of 10,000 should be fully reported with accompanying evidence.

b) An assessment factor of 1000 is applied where data from a wider selection of species are available covering additional taxonomic groups (such as echinoderms or molluscs) other than those represented by algal, crustacean and fish species; if data are at least available for two additional taxonomic groups representative of marine species.
An assessment factor of 1000 is applied to a single long-term result (e.g. EC10 or NOEC) (freshwater or saltwater crustacean or fish) if this result was generated for the taxonomic group showing the lowest L(E)C50 in the short-term algal, crustacean or fish tests.
If the only available long-term result (e.g. EC10 or NOEC) is from a species which does not have the lowest L(E)C50 in the short-term tests, applying an assessment factor of 1000 is not regarded as protective of other more sensitive species.. Thus, the hazard assessment is based on the short-term data with an assessment factor of 10,000 applied. However, normally the lowest $QS_{sw,\ eco}$ should prevail.
An assessment factor of 1000 can also be applied to the lowest of the two long-term results (e.g. EC10 or NOEC) covering two trophic levels (freshwater or saltwater algae and/or crustacean and/or fish) when such results (e.g. EC10 or NOEC) have not been generated for the species showing the lowest L(E)C50 of the short-term tests.
This should not apply in cases where the acutely most sensitive species has an L(E)C50-value lower than the lowest long term value. In such cases the $QS_{sw,\ eco}$ might be derived by applying an assessment factor of 1000 to the lowest L(E)C50 of the short-term tests.

c) An assessment factor of 500 applies to the lowest of two long term results (e.g. EC10 or NOEC) covering two trophic levels (freshwater or saltwater algae and/or crustacean and/or fish) when such results have been generated covering those trophic levels showing the lowest L(E)C50 in the short-term tests with these species. Consideration can be given to lowering this factor in the following circumstances:
- It may sometimes be possible to determine with a high probability that the most sensitive species covering fish, crustacea and algae has been examined, that is that a further longer-term result (e.g. EC10 or NOEC) from a third taxonomic group would not be lower than the data already available. In such circumstances an assessment factor of 100 would be justified;
- a reduced assessment factor (to 100 if only one short-term test, to 50 if two short-term tests on marine species are available) applied to the lowest long term result (e.g. EC10 or NOEC) from only two species may be appropriate where:
- short-term tests for additional species representing marine taxonomic groups (for example echinoderms or molluscs) have been carried out and indicate that these are not the most sensitive group, and;
- it has been determined with a high probability that long-term results (e.g. EC10 or NOEC) generated for these marine groups would not be lower than that already obtained. This is particularly important if the substance does not have the potential to bioaccumulate.
An assessment factor of 500 also applies to the lowest of three long term results (e.g. EC10 or NOEC) covering three trophic levels, when such results have not been generated from the taxonomic group showing the lowest L(E)C50 in short-term tests. This should, however, not apply in the case where the acutely most sensitive species has an L(E)C50 value lower than the lowest long term result (e.g. EC10 or NOEC) value. In such cases the $QS_{sw,\ eco}$ might be derived by applying an assessment factor of 1000 to the lowest L(E)C50 in the short-term tests.

d) An assessment factor of 100 will be applied when longer-term toxicity results (e.g. EC10 or NOEC) are available from three freshwater or saltwater species (algae, crustaceans and fish) across three trophic levels. The assessment factor may be reduced to a minimum of 10 in the following situations:
- where short-term tests for additional species representing marine taxonomic groups (for example echinoderms or molluscs) have been carried out and indicate that these are not the most sensitive group, and it has been determined with a high probability that long-term results (e.g. EC10 or NOEC) generated for these species would not be lower than that already obtained;
- where short-term tests for additional taxonomic groups (for example echinoderms or molluscs) have indicated that one of these is the most sensitive group acutely and a long-term test has been carried out for that species. This will only apply when it has been determined with a high probability that additional long term results (e.g. EC10 or NOEC) generated from other taxa will not be lower than the long term results already available.

e) A factor of 10 cannot be decreased on the basis of laboratory studies only. It may be permitted if justified by mesocosm or field data.

3.3.2.2 Extrapolation using the SSD approach for deriving an $QS_{sw,\ eco}$

In principle, for quality standards referring to saltwater, the same approach as described in Section 3.3.1.2 can be used. **Marine and freshwater toxicity data are combined, unless evaluation of the freshwater and saltwater toxicity data shows that the data can not be pooled. In such a case, the combined data set can be used to establish a common SSD that is relevant for both freshwater and saltwater effects assessment (Section 3.2.3).**

If a combined dataset is used, the AF of 1-5 applied to the HC5 estimated from the SSD should only be applied for coastal and territorial waters if the data set used to establish the SSD comprises long-term NOECs or EC10s for at least 2 additional typically marine taxonomic groups, other than fish, crustaceans and algae. When there are no additional marine taxonomic groups in the dataset, an AF of 10 is applied **in addition to** the AF of 1-5 to deal with residual uncertainty. This is analogous to the additional AF of 10 for $QS_{sw,\ eco}$ derivation in the deterministic method. When only one additional marine taxonomic group (as defined above) is present in the dataset, an AF of 5 is used **in addition to** the AF of 1-5. This is consistent with the provisions of REACH for marine effects assessment where a larger AF is recommended to cover the increased uncertainty resulting from the larger diversity of marine ecosystems and the limited availability of effects data for marine life forms.

When freshwater and saltwater datasets cannot legitimately be combined, constructing an SSD with ecotoxicological data for marine organisms has the same requirements regarding the quantity and quality of input data as described in Section 3.3.1.2. However, taxa that are poorly represented in the marine environment, like insects and higher plants, may be replaced by more typical marine taxa such as, e.g., molluscs, echinoderms, annelids, specific marine species of crustaceans or coelenterata. This means that the additional marine species are automatically present in this non-combined dataset, and no additional AF is needed in addition to the AF of 1-5 applied to the HC5.

3.3.2.3 Use of simulated ecosystem studies for deriving an $QS_{sw,\ eco}$.

Saltwater mesocosm or field studies can be used for $QS_{sw,\ eco}$ derivation and the guidance for the freshwater situation (Section 3.3.1.3) also applies here. Marine mesocosm data often apply solely to small pelagic organisms such as calanoid copepods, and such studies will therefore seriously under-represent many taxa e.g. benthic epifauna. Thus, it should be taken into account how representative the marine mesocosm study is, when determining the assessment factor to be applied and which standard will be selected as final $QS_{sw,\ eco}$ (ie AF method, SSD method or mesocosm).

Freshwater ecosystem studies could be used for marine effects assessment. However, in such a case an extra assessment factor of 10 should be applied to derive the $QS_{sw,\ eco}$ in addition to the factor applied for the derivation of the $QS_{fw,\ eco}$. However, preference may be given to the deterministic or SSD approach, if the laboratory studies do contain additional marine taxonomic groups.

3.4 Deriving a MAC-QS

For deriving a MAC-QS, the REACH guidance for effects assessment of substances with intermittent release is adopted. If enough short-term EC50/LC50 data are available to construct an SSD this extrapolation approach should be used as well as the deterministic approach, as detailed in Section 3.4.1. Relevant mesocosm studies may be available (especially for pesticides) and these can be used to derive the final MAC-EQS, as described in Section 3.4.1.3 Field monitoring data are unlikely to have a useful part to play in informing the estimation of a MAC-QS because they typically describe changes in biology arising from long-term exposure, so they are more relevant to AA derivation. Any discrepancies in the results obtained with the different extrapolation approaches need to be discussed and the decision for the preferred MAC-QS derivation justified.

Predicted data using QSAR models or 'read across' approaches can be used as supporting information but not as a basis for the derivation of a QS.

Under some circumstances, a MAC-QS may not be justified, eg for substances that exert only sub-lethal effects after prolonged exposure. Steroid oestrogens would be one example.

3.4.1 Deriving a MAC-QS for the freshwater pelagic community ($MAC\text{-}QS_{fw,\ eco}$)

3.4.1.1 Extrapolation using the AF method

For exposures of short duration, acute toxicity data are relevant and the AFs to use are given in Table 3.4. Combined acute toxicity data sets for freshwater and saltwater species may be used if the data can be pooled (Section 3.2.3). Where there are at least 3 short term tests using species from three trophic levels (base set), an AF of 100 applied to the lowest L(E)C50 is normally used to derive the $MAC\text{-}QS_{fw,\ eco}$. Under some circumstances an AF less than 100 may be justified, e.g.

For substances which do not have a specific mode of action (e.g. acting by narcosis only), if the available data show that interspecies variations are low (standard deviation of the log transformed L(E)C50 values is < 0.5) an AF<100 may be appropriate.

For substances with a specific mode of action, the most sensitive taxa can be predicted with confidence. Where representatives of the most sensitive taxa are present in the acute dataset, an AF <100 may again be justified.

Where there is a good understanding of the relationship between acute and chronic toxicity (e.g. acute: chronic ratios for a range of species), the AF used to estimate the MAC may be selected to reflect this, or at least to ensure the MAC is not lower than the AA.

In no case should an AF lower than 10 be applied to a short-term L(E)C50 value.

Table 3.4 Assessment factors to derive a $MAC\text{-}QS_{fw,\ eco}$.

Toxicity data	Additional information	Assessment factor
Base set not complete	–	– [a)]
At least one short-term L(E)C50 from each of three trophic levels of the base set (fish, crustaceans and algae)		100
At least one short-term L(E)C50 from each of three trophic levels of the base set (fish, crustaceans and algae)	Acute toxicity data for different species do not have a higher standard deviation than a factor of 3 in both directions[b)] OR known mode of toxic action and representative species for most sensitive taxonomic group included in data set	10[c)]

Notes.

a) When the base set is not complete, a $MAC\text{-}QS_{fw,\ eco}$ cannot be derived. It should be considered if the base set could be completed with non-testing data (See Section 2.6.). Non-testing data should not be used as critical data in the derivation of the $MAC\text{-}QS_{fw,\ eco}$.
b) To assess the span of the acute toxicity data, all reliable acute toxicity data collected are used, with a minimum of three LC50 or EC50 values, for species representing each of the base set

trophic levels (algae, *Daphnia*, fish). If the standard deviation of the log transformed L(E)C50 values is < 0.5, an assessment factor of 10 could be applied, otherwise an assessment factor of 100 should be applied.
c) Lowest assessment factor to be applied.

For the specific group of insect growth regulators, acute data do not give information on delayed effects and cannot be used for derivation of the MAC-QS because the test duration is too short to detect long-term effects of a single peak of exposure. In general, for compounds with a (very) high acute to chronic ratio, the possibility of delayed effects resulting from a single peak should be considered and the chronic data should be consulted.

3.4.1.2 Extrapolation using the SSD approach

The same approach as described in Section 3.3.1.2 can be applied. However, instead of long-term NOECs, acute L(E)C50 data are the appropriate input data. Combined acute toxicity data sets for marine and freshwater species may be used, if, after evaluation of the freshwater and saltwater toxicity data, the data can be pooled (Section 3.2.3).

The resulting HC5 refers to a 50% effect concentration for 5% of the species, not a no-effect concentration for 5% of the species, because the input of the SSD are L(EC)50 values. An AF is therefore needed to extrapolate to the MAC-$QS_{fw,\ eco}$.(to account for the effects to no-effects extrapolation. This AF should normally be 10, unless other lines of evidence (e.g. acute EC50:acute EC10 (or NOEC) ratios are narrow, or criteria presented in Section 2.9) suggest that a higher or lower one is appropriate.

3.4.1.3 Use of simulated ecosystem studies in deriving a MAC-$QS_{fw,\ eco}$

General guidance regarding the derivation of a QS from micro/mesocosm studies is given in Section 2.9.2. For determining the MAC-$QS_{fw,\ eco,}$ experiments simulating short-term exposure are most relevant.

For substances that do not dissipate quickly, the MAC-$QS_{fw,\ eco}$ values should be based on measured time weighted average (TWA) concentrations, and biological effects determined over a time span that is representative for most acute toxicity studies (i.e. 48–96 h). Measurement of exposure concentrations should take account of both spatial and temporal changes within the mesocosm. Furthermore it is important to determine which part of the exposure profile is most relevant. For example, if the peak concentration causes the effect, the actual initial concentration in the cosms is relevant, as well as the concentration at various time intervals (hours in the case of rapidly-dissipating compounds). An understanding of the exposure phase that is most relevant to any toxic effects (the Ecologically Relevant Concentration, ERC) is important because it (a) influences how the assessor interprets the mesocosm data and (b) how the resulting MAC-EQS should be expressed (e.g. a 24h or a 1 month peak). Such properties must be drawn to the attention of policy makers because it will affect how compliance is assessed, or indeed whether a MAC-EQS for compliance monitoring can be feasibly implemented at all. Such an EQS may still have value for planning purposes.

3.4.1.4 Application of an assessment factor to the threshold concentration from a mesocosm to derive a MAC-$QS_{fw,\ eco}$

For substances for which the mode of action and/or the most sensitive taxa are known, an assessment factor ranging from 1-5 is applied to the lowest threshold concentrations from the available mesocosms, with the same considerations as given for the derivation of the $QS_{fw,\ eco}$ (Section 3.3.1.3).

Brock et al. (2006, 2008) compared the outcome of 6 mesocosm studies with the insecticides chlorpyrifos and lambda-cyhalothrin that simulated short-term exposure. They looked at the spread

(= ratio of the upper and lower limit of the 95% confidence interval) of the threshold concentrations for toxic effects. The spreads were 2.9 for chlorpyrifos and 2.6 for lambda cyhalothrin. They concluded that for a substance with a specific mode of toxic action, an AF of 3 can be applied, provided that the study is well-performed. This can be lowered depending on the number of available mesocosms.

3.4.2 Derivation of a MAC-QS for the saltwater pelagic community (MAC-QS$_{sw, eco}$)

The MAC-QS for coastal and territorial waters (MAC-QS$_{sw, eco}$) is intended to protect the saltwater ecosystem from potential acute toxic effects exerted by transient exposure to toxic chemicals. These peak concentrations can, for instance, occur at fish farms, in connection with batch effluent releases on the ebb tide, or when a ship is cleaned. For transitional waters, the guidance in Section 2.4.4.1 is relevant.

To derive a MAC-QS for saltwater, the same approach as described for the QS$_{sw, eco}$ can be applied in principle. However, instead of using long-term NOECs, acute L(E)C50 data will serve as input data. Combined acute toxicity data sets for marine and freshwater species may be used, if analysis shows that the data can be pooled (Section 3.2.3.).

3.4.2.1 Extrapolation using the AF method

As in the derivation of the QS$_{sw, eco}$, when additional information on the sensitivity of specific saltwater taxonomic groups is available, the additional assessment factor of 10 can be lowered to 5 (one additional marine taxonomic group) or 1 (two or more additional marine taxonomic groups), see Section 3.2 for explanation of what is meant by 'additional marine taxonomic groups'. The AFs to be used when deriving a MAC-QS$_{sw, eco}$ are given in Table 3.5.

Table 3.5 Assessment factors to derive a MAC-QS$_{sw, eco}$

Toxicity data	Additional information	Assessment factor
Base set not complete	–	– a)
At least one short-term L(E)C50 from each of three trophic levels of the base set (fish, crustaceans and algae)		1000
At least one short-term L(E)C50 from each of three trophic levels of the base set (fish, crustaceans and algae)	Acute toxicity data for different species do not have a higher standard deviation than a factor of 3 in both directions b) OR known mode of toxic action and representative species for most sensitive taxonomic group included in data set	100
At least one short-term L(E)C50 from each of three trophic levels of the base set (fish, crustaceans and algae) + one short-term L(E)C50 from an additional specific saltwater taxonomic group		500
At least one short-term L(E)C50 from each of three trophic levels of the base set (fish, crustaceans and algae) + one short-term L(E)C50 from an additional specific saltwater taxonomic group	Acute toxicity data for different species do not have a higher standard deviation than a factor of 3 in both directions b) OR known mode of toxic action and representative species for most sensitive taxonomic group	50

	included in data set	
At least one short-term L(E)C50 from each of three trophic levels of the base set (fish, crustaceans and algae) + two or more short-term L(E)C50s from additional specific saltwater taxonomic groups		100
At least one short-term L(E)C50 from each of three trophic levels of the base set (fish, crustaceans and algae) + two or more short-term L(E)C50s from additional specific saltwater taxonomic groups	Acute toxicity data for different species do not have a higher standard deviation than a factor of 3 in both directions[b)] OR known mode of toxic action and representative species for most sensitive taxonomic group included in data set	10[c)]

Notes.

a) When the base set is not complete, a MAC-$QS_{sw,\ eco}$ cannot be derived. It should be considered if the base set could be completed with non-testing data(See Section 6). Non-testing data should not be used as critical data in the derivation of MAC-$QS_{sw,\ eco}$.

b) To assess the span of the acute toxicity data, all reliable acute toxicity data collected are used, with a minimum of three LC50 or EC50 values, for species representing each of the base set trophic levels (algae, *Daphnia*, fish). If the standard deviation of the log transformed L(E)C50 values is < 0.5, an assessment factor of 10 should be applied, otherwise an assessment factor of 100 should be applied.

c) Lowest assessment factor to be applied.

3.4.2.2 *Extrapolation using SSD approach*

The same approach as described in Section 3.3.1.2 can be applied. However, instead of long-term NOECs and EC10s, acute L(E)C50 data (one value per species) are the appropriate input data. Combined acute toxicity data sets for marine and freshwater species may be used, if after evaluation of the freshwater and saltwater toxicity data, the data can be pooled (Section 3.2.3). This would result in the same HC5 for freshwater and saltwater assessments but, given the greater uncertainties in extrapolation for the marine environment, a larger AF is required than that used to deal with residual uncertainty in the freshwater MAC-QS.

For the MAC-$QS_{fw,eco}$, the default AF to be used on the HC5 is 10. However when the datasets for fresh- and saltwater are combined, for a MAC-$QS_{sw,\ eco}$ derivation an additional assessment factor of 10 is used to deal with residual uncertainty, resulting in a total AF of 100. In line with the derivation of the $QS_{sw,\ eco}$, when one typically marine taxonomic group is present in the dataset, an additional AF of 5 is used on top of the default AF of 10 and when two typically marine taxonomic groups are present, no additional assessment factor is necessary. When separate datasets are used to calculate an SSD for MAC-QS derivation, it follows that the necessary amount of data for marine taxa are available to calculate an SSD, and an additional AF on top of the default AF of 10 is no longer necessary.

3.4.2.3 *Use of simulated ecosystem studies in deriving a MAC-$QS_{sw,\ eco}$*

For the derivation of the MAC-$QS_{sw,\ eco}$ the highest initial concentration in a simulated ecosystem study that caused no ecologically relevant effects may be used. Further guidance regarding the derivation of the MAC-QS from micro/mesocosm studies is given in Section 2.9.2. Freshwater mesocosms should not be used in the derivation of an MAC-$QS_{sw,\ eco}$.

3.5 Deriving EQSs for metals

Many of the principles outlined below also apply to all naturally occurring substances, including metalloids.

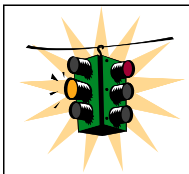
3.5.1 *Metal specific mechanisms of action*

Advances in our understanding of the physiological processes that control the uptake of inorganic metals and toxicity in aquatic systems indicate that for most metals (e.g. Cd, Cu, Zn, Ni, Pb, Ag), the primary target tissues are 'respiratory organs (gills or gill-like structures)' at the interface between the organism and the waterbody. Indeed, *bioavailable* metal species (especially free metal ions) have a high affinity for negative binding sites at gills and gill-like surfaces. Some metals, such as copper and zinc, are taken up and eliminated through the sodium, potassium or calcium channels of the cellular membranes, and are often mediated by specific transport systems (e.g. cation ATPases)[11]. Excessive uptake of metal ions can, thereby, cause impairment of the physiological gill functions; the primary toxicity symptom is often an inhibition of active ion transport (Na^+, K^+, Cl^-) that results in ionic imbalances ultimately leading to toxicity (e.g. ICMM fact sheet No. 7; Pagenkopf, 1983; Playle et al, 1992; Di Toro et al., 2001; Grosell et al., 2002; Landner and Reuther, 2004).

The understanding of the interactions between metal species, water characteristics and ionoregulatory impairment of the respiratory organs, as well as acute and chronic toxicity, has formed the basis for metal bioavailability models. The potential for additional toxicity through dietary intake also has been assessed for a range of metals (Cu, Zn, Ni), and the data from laboratory settings (waterborne versus dietborne toxicity, assessment of potential for secondary posioning), mesocosms contaminated with metals (ECI, 2008) and field exposure assessments (Crane *et al*., 2007; Tipping *et al*., 2007) demonstrated that metal EQSs derived from water-only exposures and the application of metal bioavailability models are, at least for the metals investigated, also protective for dietborne exposures as well as of ecosystem structures and functioning.

Research data on metal speciation, metal bioavailability and metal ecotoxicity have been applied in the EU risk assessments for cadmium, zinc, nickel and copper and in the context of the WFD for cadmium (hardness correction)[12]. The models created through such work have allowed a reduction in the intraspecies variability of several orders of magnitude by the normalisation of acute and chronic toxicity data and they adequately predict metal toxicity within a factor of 2.

3.5.2 *Generic guidance on setting quality standards for metals in water and sediments*



Look Out!

In case of use of bioavailability correction in deriving a QS, the following consideration should be also taken into account:

- Use a QS reference that protects at least 95% of the surface waters instead of 90% in order to follow a precautionary approach.
- Ensure that the use of BLM in upstream parts of a river basin should

[11] Other metals and metalloids may be associated with other uptake mechanisms; for example, arsenic and polonium are often associated with the uptake of phosphorus.

[12] Chronic biotic ligand models (BLMs) have been built and validated in the laboratory and in the field for several metals (Zn, Ni, Cu and to some extent Cd), and the models allow the prediction of chronic metal toxicity in a wide range of waters worldwide. Acute BLMs are available for a much wider range of metals.

	not lead to environmental problems in downstream inland-, transitional- or marine waters, either in the water phase and/or in the sediment and/or in biota due to a changes in bioavailability. • Investigate trend monitoring to evaluate the accumulation of pollutants in sediment. • Ensure that the efforts to reduce emissions (source oriented track) by improving techniques are not diminished. • Reconsider the applicability of bioavailability corrections by evaluating the state of play, for instance every 6 years.

The following generic guidance relates to deriving QSs for metals in water and sediments. For guidance on deriving standards for biota and secondary poisoning, see Section 4.6; for more detailed guidance on sediments, see Section 5.2.2, for an explanation of the specific temporary standards used to derive an EQS see appendix 6

The methods used to incorporate availability/bioavailability corrections will depend on the availability of data and models and metal-specific considerations (e.g. importance of metal–DOC binding in aquatic systems, and availability of a metal-specific biotic ligand model (BLM)).

Figure 3.1 and the text below outline the different steps that allow QSs for metals to be derived for freshwater, marine and benthic compartments in a way that accounts for (bio)availability and background concentrations. The guidance provided is focused on the setting of an AA-EQS, based on chronic ecotoxicity data (NOECs/EC10s) and chronic bioavailability models. A similar approach can nevertheless also be followed when a MAC-EQS is to be derived, based on acute data (EC50s) and acute BLMs.

Because of the differences in iono- and osmoregulatory environments, there may be differences in the toxicity of a substance, and especially of a metal, to freshwater and saltwater species, and it is important to check for such differences. Thus, data should only be pooled if the sensitivity of saltwater species cannot be shown to be significantly different from the sensitivity of freshwater species. Availability corrections for freshwater cannot currently be directly translated to saltwater conditions; therefore, pooling of freshwater and saltwater data should be avoided when availability corrections have been applied.

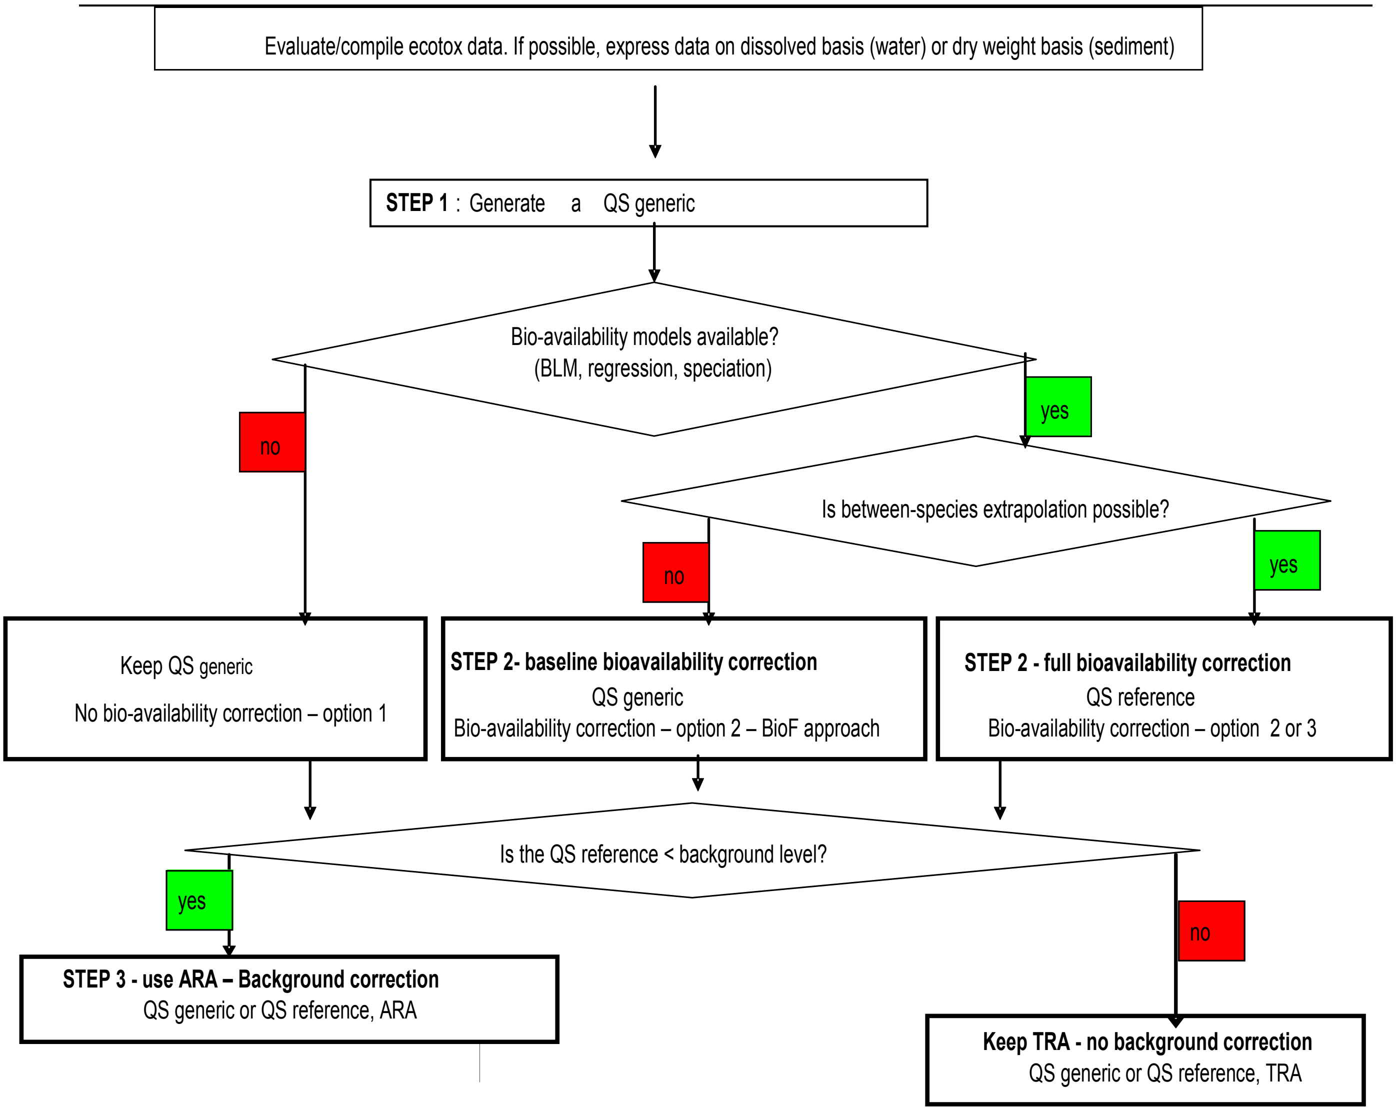


Figure 3.1 Recommended general scheme for deriving QSs and the consideration of bioavailability and background corrections

TRA = total risk approach, ARA = added risk approach (The ARA should not be used in combination with bioavailability correction)

3.5.2.1 Deriving the QS for freshwater

There are three main steps in deriving the QS which are outlined in Figure 3.1. These three steps are the development of a 'generic' QS using ecotoxicity data (Step 1), a QS using bioavailability considerations (Step 2) and a QS accounting for natural backgrounds (Step 3).

The available toxicity data first needs to be compiled and evaluated (See Section 2.6.2.). The quality criteria to be used are the same as those used for organic substances, but some metal-specific issues are to be considered as outlined below.

STEP 1

For the water compartment the first step is simply to express the toxicity data on the basis of the dissolved concentration, after filtration using 0.45-µm filters. Any matrix effects related to the filtration of samples should be assessed[13].

If dissolved concentrations in the test media are not given, the relationship between the total and dissolved metal concentrations in ecotoxicity media should be checked if possible, taking the following into account:

- For some metals and soluble metal salts (e.g. Zn, Cu) tested in artificial media (and especially when tested in semistatic or flow-through systems), no additional conversion into a dissolved fraction has to be applied because there is evidence that all the metal is in solution[14].
- For other less soluble metals, however (e.g. lead), an additional step to convert the total concentration into a dissolved fraction is needed. An analysis of relevant solubility products for the relevant metal salts or the ratio of matched dissolved and total metal monitoring data can inform this estimation of dissolved metal concentrations. Solubility products may be found in, for example, the *Handbook of Chemistry and Physics*, 86th edition, CRC Press.
- If test media are natural waters, total concentrations from individual experiments can be recalculated to dissolved concentrations using partition coefficients (taking binding to DOC into account). It has to be borne in mind, however, that the calculated dissolved concentrations for several metals may be uncertain since the partition coefficient (K_p) has been found to vary by several orders in magnitude.

Once data have been collated derive a $QS_{generic,fw}$ based on extrapolation from ecotoxicity data as described in earlier sections. This should be based on conditions of high bioavailability and on a total risk approach (i.e. backgrounds are not accounted for), thereby adopting a reasonable worst-case approach, as outlined below.

STEP 2 - Bioavailability correction

The influence of the key abiotic factors on metal toxicity needs to be investigated and quantified. The simplest (bio)availability correction is the application of **speciation models**. In cases where speciation models (e.g. WHAM (Tipping *et al*., 1991); MINTEQA2, NICCA (Kinniburgh *et al*., 1999) are available, (bio)availability corrections can be considered[15]. For some metals, models have been developed that go beyond metal speciation and these explain the relationships between abiotic factors and metal bioavailability/toxicity. These are toxicity-based models ranging from

---

[13] The handling of the samples should not affect the dissolved metal fraction in any way; contamination during sampling and filtration should be avoided by using ultra-pure equipment. All laboratory equipment, such as glassware, plastics, etc., must be rinsed with a dilute acid (e.g. 1% HNO_3 solution) and demineralised water before use in order to remove all metals adsorbed. Acidification should be done after filtration. Appropriate quality assurance measures (e.g. procedural blanks, assessment of the matrix effect) are recommended.

[14] In most laboratory test systems, the suspended solids are low and the dissolved to total ratio is very high, typically 95% or greater. Organic particles (e.g. from faeces and food) that appears in the test systems throughout the test, do not significantly affect the dissolved metal concentration in the test when semistatic or flow-through systems are used. Solubility products may be found in, for example, the *Handbook of Chemistry and Physics*, 86th edition, CRC press.

[15] Most often this is the free metal ion, but it should be noted that the free ion is not necessarily the best predictor for all metals, and other metal species, such as neutral species (e.g. AgCl, HgS) and anionic species (e.g. SeO^{2-}, AsO_4^{2-}), may contribute to the observed toxicity (Campbell, 1995).

simple **regression models** (e.g. Cd hardness function) to the more-comprehensive **BLMs**[16] for copper (Santore *et al*., 2001; De Schamphelaere and Janssen, 2002 and 2004; De Schamphelaere *et al*., 2002 and 2003b), nickel (Keithly *et al*., 2004; Hoang *et al*., 2004), silver (Paquin *et al*. 1999) and zinc (Heijerick *et al*., 2002a; Heijerick *et al*., 2002b)) as applied in environmental risk assessments. The use of these models could be considered for deriving QSs under the WFD.

Where toxicity in laboratory experiments is expressed in terms of dissolved metal concentrations and **speciation models**, **chronic regression models** (e.g. Cd hardness correction) or **BLMs** have been developed and validated for the metal/metal compounds of concern, it is recommended that the no observed effect concentrations (NOECs) and/or the effect concentrations for 10% of the tested species (EC10) are expressed on a 'bioavailable' basis (free metal ion concentrations if speciation models are used; normalised dissolved metal concentrations when regression models and BLMs are used).

Bioavailability models should, however, only be applied within their development/validation domains. The ranges applicable to the models, such as those for pH, hardness (H) and DOC, should therefore be specified in the manuals of the models that are used. In other cases, the use of such bioavailability models is allowed on a case-by-case basis only when strong scientific arguments can be formulated to support their application.

For bioavailability to be incorporated into compliance checking, the relevant physicochemical parameters of the investigated site/region (for example pH_{site}, H_{site}, DOC_{site}) affecting metal bioavailability need to be gathered and checked against the applicability domain of the bioavailability model. Site-specific physicochemical parameters are preferred, but if these are not available, information from adjacent sites or similar eco-regions can be used.

The incorporation of (bio)availability into the QS means that compliance monitoring must also be based on (bio)available concentrations. Details are given below.

<u>Implementing a bioavailability based EQS</u>

The following options can be used to correct for availability/bioavailability and for compliance checking (see also Figure 3-1):

Option 1: If there is no relationship between the abiotic factors and toxicity the only viable option is implementing a $QS_{generic,fw}$ as the AA-EQS based, if possible on the lowest species-specific geometric mean EC10s and/or NOECs or SSD approaches as described in Appendix 1. Compliance monitoring is then simply based on dissolved concentrations of metals.

If a bioavailability based approach can be adopted then there are two ways of implementing the QS.

Option 2: The first tier consists of comparing the monitoring results for the dissolved metal from a particular region or site (site-specific C_{TRA}) with the $QS_{reference,fw}$ value.

This $QS_{reference,fw}$ should in principle be protective for all waterbodies that may be monitored. Where possible, the toxicity data should be normalised to a well-defined 'reference' condition that is based on a reasonable worst case (to ensure all waterbodies are protected). Different options are possible to define a reference condition and thus to derive a $QS_{reference,fw}$.

[16] The BLM mathematically integrates the interaction of a trace metal with solution phase ligands to predict its speciation and its subsequent interaction with receptor sites (the biotic ligand) on the organism (ICMM fact sheet No. 7).

Examples of this may be:

- Use the relevant 10th or 90th percentile (depending on parameter) of the bioavailability parameters in Europe, e.g. if DOC is an important parameter, the DOC level used should correspond to the lower 10th percentile of DOC concentrations found across Europe. Unrealistic scenarios induced by combining parameters (e.g. pH, hardness) need to be avoided.
- Use conditions that apply to a sensitive eco-region or river representative of a reasonable worst case of the area to be protected by the $QS_{reference,fw}$.
- Considering that ecotoxicity tests are usually carried out under conditions that maximise bioavailability, an alternative option would be to use the $QS_{generic,\ fw}$, (non-normalised QS), as the $QS_{reference,\ fw}$. This alternative has the disadvantage that the water conditions in ecotoxicity tests are variable and, thus, the actual boundaries of the $QS_{reference,\ fw}$ water conditions are not well defined or would have to be obtained indirectly from model calculations. However, this option allows a common approach to setting $QS_{reference,\ fw}$ for metals, irrespective of whether bioavailability models are available or not (see Option 1).
  To avoid the situation in which some EU countries have waterbodies that are unprotected by the $QS_{reference,\ fw}$, the assessor should also define, when publishing the $QS_{reference,\ fw}$, the boundaries of the water conditions for which the $QS_{reference,\ fw}$ is derived. If the physicochemical conditions of a specific river basin fall outside the $QS_{reference}$ protection zone (e.g. DOC and/or pH values of <10th percentile of Europe or the most-sensitive eco-region), but inside the BLM developed/validated boundaries; then to ensure protection of the ecosystem, for each of these sites, a $QS_{site\text{-}specific,\ fw}$ may be derived and assessed against the monitoring data for compliance. If the physico-chemical conditions of the site fall outside of the BLM boundaries the $QS_{generic,\ fw}$ is applied.

Compliance is achieved when measured concentrations are less than the $QS_{reference,\ fw}$ value. If the $QS_{reference,\ fw}$ value is exceeded (bearing in mind that the EQS derived from this value may be expressed as an annual average, in which case several samples taken over the period defined in the standard contribute to the decision about compliance or failure), then a (bio)availability factor (BioF) will be applied to the monitoring data C_{TRA}. The BioF is based on a comparison between the expected bioavailability at the reference site and that relating to site-specific conditions.

Option 3: This is identical to that described in Option 2 except that bioavailability correction is applied to the QS instead of the monitoring data. The end result is the same but Option 3 results in a site-specific QS, which might be preferable in some cases. If the $QS_{reference}$, fw is exceeded then a site-specific QS is derived relevant to the site-specific conditions ($QS_{site\text{-}specific,\ fw}$), which is assessed against the monitoring data for compliance. Effectively, (bio)availability is accounted for in the QS rather than in the monitoring data – the reverse of Option 2.

Options 2 and 3 only differ in that they apply the bioavailability correction to the exposure and effects side of the assessment respectively.

The preferred choice of Options 1 to 3 and practice for site-specific QS and BioF calculations depends on (1) the availability of suitable models (see Criterion 1 below), (2) the extent to which it is possible to read across between species for which a BLM has been developed and species for which a BLM has not been developed (Criterion 2) and (3) preferences from policy/administrative points of view.

Criterion 1: The availability of models

If the (bio)availability correction relates to chemical availability (e.g. speciation modelling), it is not organism-specific because it applies to the medium in which all organisms are living. In such cases, if a quantitative relationship between the parameter (e.g. [M^{2+}]) and ecotoxicity (NOECs/EC50s) has been developed, the observed quantitative relationship can be applied to all ecotoxicity data selected for EQS derivation, and a $QS_{reference,\ fw}$ corrected for availability can be derived as described under one of Options 2 or 3.

If models are available that involve bioavailability correction (e.g. BLMs), the models may be species-specific and, therefore, bioavailability correction is only possible if the BLM models have been developed and validated for at least three higher taxonomic groups, including an algal, an invertebrate and a fish species. Bioavailability corrections based on the three species only is considered as the baseline correction. **If read-across of the models to other species cannot be demonstrated, bioavailability corrections can only be carried out for the BLM species and the $QS_{generic,\ fw}$ can not be translated to a $QS_{reference,\ fw}$. Therefore the most-conservative BioF is subsequently used on a metal by metal basis**. The most-conservative BioF or baseline BioF is the ratio of $QS_{generic,\ fw}/QS_{site\text{-}specific,\ fw}$, determined as the highest ratio of the $NOEC_{generic}/NOEC_{site\text{-}specific}$ calculated for the three BLM (regression model) species. This approach is expected to provide the most-conservative implementation of bioavailability. In such cases, bioavailability correction of monitoring data is preferred over adjustments to the toxicity data. For compliance assessment, the bioavailable exposure concentration of the monitoring data value is, therefore, calculated as $C_{TRA} \times$ BioF, and this is compared with the $QS_{generic,\ fw}$ (Option 2).

Criterion 2: BLM read-across between species

Full BLM normalisation of the entire NOEC (for chronic data) dataset is justified and full bioavailability correction can be performed only if models are available (Criterion 1) and if additional quantitative evidence is available to confirm the applicability of the three BLMs to at least three additional taxonomic groups (at least at the level of class, but preferably at the level of phylum, eg Cyanophyta, Protozoa, Mollusca, Rotifera, Insecta, higher plants). The accuracy of the BLM predictions for the additional taxonomic groups should be proven by showing that the model actually decreases the variability in the data for the investigated additional species, otherwise the BLM read-across is not applicable for that species. In such cases, chemical (abiotic) normalisation might be considered (more details are available from the background document). Full BLM normalisation consists of applying the bioavailability model across species of similar trophic levels (e.g. applying the *Daphnia magna* BLM for normalisation of the toxicity data from other invertebrates). The bioavailability model normalises the chronic effects concentrations (NOEC or EC10) of the metal for each species' endpoint, and a normalised $QS_{site\text{-}specific,\ fw}$ (i.e. a site-specific QS) is calculated. This $QS_{site\text{-}specific.\ fw}$ is compared to the monitoring data for compliance checking (Options 3). Alternatively, the $QS_{site\text{-}specific,\ fw}$ can be used to calculate the site-specific BioF. In this case, the BioF full bioavailability correction is calculated as $QS_{reference,\ fw}/QS_{site\text{-}specific,\ fw}$ ($QS_{site\text{-}specific,\ fw}$ calculated from full BLM normalisations). The bioavailable exposure concentration is then calculated as $C_{TRA} \times$ BioF, and this is compared with the $QS_{reference,\ fw}$.

STEP 3 – Accounting for backgrounds: total risk versus added risk approach

In a TRA, no explicit account is taken of natural background levels; this approach accounts for the total dissolved amount of a metal in a waterbody. This means that no distinction is made between the fraction of a metal that is present in a waterbody for natural reasons and the fraction added because of anthropogenic activities.

Preferably, metal QSs should be based on the TRA. However, QS values below natural background levels may be generated if:

(1) The QS has been set to an unrealistically low level simply because of a (too) conservative approach adopted in the QS derivation (i.e. a large AF) to compensate for uncertainties arising from a lack of reliable (eco)toxicological data.

(2) The QS was set using ecotoxicity tests with organisms cultured/tested under conditions of low metal concentrations compared with the surface water background levels (i.e. organisms locally

may have adapted to higher natural concentrations). This may occur, especially for metals with a significant background concentration in relation to the estimated QS.

Setting QSs below the natural background level would result in an EQS that serves little regulatory purpose and is scientifically indefensible. Furthermore, many waterbodies would fail the QS even though there is no risk to biota. A pragmatic way to overcome this problem is

- to evaluate the scope for refining the QS by reducing uncertainty (including making a correction for bioavailability) and/or
- to use the added risk approach (ARA).

To assess the need for applying the ARA, the $QS_{reference,\ fw}$ (or $QS_{generic,\ fw}$) and the background metal concentration in the EU, taken as the 90th percentile value from the FOREGS database (http://www.gsf.fi/foregs/geochem), should be compared. If the 90th percentile background value is higher or similar to the QS, the ARA should be used preferentially. The procedure for determining local 'natural' background levels is described in Section 3.6.

The ARA was discussed for the purpose of setting QSs by Lepper (2005). This approach accounts for natural background concentrations and avoids setting regulatory standards below this background level in a simple manner: a maximum permissible addition (MPA) to the background level of a certain metal is calculated. The MPA is the maximum amount of a metal that may be added to the local background concentration of this metal without adversely affecting the assessed ecosystem. Correct determination of the natural background level is key in this approach, and this may not be easy to achieve. As background concentrations are often estimated from relatively small datasets, the calculation of background concentrations should be an iterative process, reviewing the values when new monitoring data become available.

In the ARA, the $QS_{added,\ fw}$ is derived from toxicity data that are based on the added concentration of the metal in the toxicity tests without the background concentration in the test media. In order to use the ARA, the toxicity data should thus be re-evaluated. From each toxicity study, the background concentrations presen tin test medium or test water should be subtracted from the total measured concentrations in the test. The result of the study (NOEC, EC10) should then be calculated on the basis of these 'added' concentrations. The QS should be derived using these 'background-corrected' NOECs or EC10s and is termed $QS_{added,\ fw}$. Where bioavailability correction is possible an ARA approach will not normally be used – only the TRA approach.

To assess compliance, the background concentration (Cb) can either be added to the $QS_{added,\ fw}$ ($QS = QS_{added,\ fw} + Cb$) or the monitoring data can be corrected for background concentration ($C_{ARA} = C_{TRA} - Cb$). If the $C_{TRA} < QS$ or $C_{ARA} < QS_{added}$, then compliance is demonstrated. If, for example, the background is expressed as total dissolved metal, but the QS is expressed as bioavailable metal, then the two options may not be comparable. These approaches require that the monitoring data (including the background) and the QSs are compared on the same basis: dissolved concentration or the bioavailable metal fraction.

Under specific local geological circumstances (e.g. in mineralised areas), the local background concentration can be substantially higher than the regional background concentration. The ARA may still be used to assess the possible risk related to anthropogenic emissions in such areas. However, the variability of the local background levels can be substantial under such conditions and policymakers will need to decide on a case-by-case basis whether the (generic) QS can still be applied at all (the local natural ecosystem may be different from the generic ecosystem used to derive the QS). In this respect, it should also be noted that the principle of the ARA cannot be stressed infinitely: if possible, an upper limit for the value of the QS + background level ($QS_{ARA,dissolved/bioavailable}$) may be derived. In practice, this upper value may be formed by the calculated predicted no-effect concentrations for secondary poisoning or human health in water ($QS_{fw,\ secpois}$ or $QS_{dw,\ hh}$) that have also to be considered when local background values are (very) high. Another reason for setting an upper value is that, in reality, the relationship between toxicity and natural background concentrations is unknown, and that some populations might in fact live close to their tolerance limit. It should be stressed that this upper value is **not** a maximum acceptable concentration (MAC-EQS). The MAC-EQS refers to short-term exposures that occur in peaks and in connection with intermittent releases, while the above-mentioned upper limit refers to long-term exposures and to an average concentration (typically based on a year) for the release period.

With data-poor substances, there will often be no information available on the relationship between total and dissolved concentrations, or between abiotic parameters and the dissolved fraction. Therefore, it will not be possible to take bioavailability into account if only total concentrations are given. However, extra effort should always be made to try to take availability into account in the reference ecotoxicity value to which the assessment factor is applied.

The decision to follow the ARA approach will be made after comparing the QS with the background.

Following the ARA, bioavailability can further be considered as in Step 2, but considering only the added fraction at the exposure side (Step 2, Option 2) or the added fraction at the effects site (Step 2, Option 3). Under no conditions should background levels be considered if a total $QS_{reference,\ fw}$ is used.

3.5.2.2 Bioavailability correction for saltwater

Freshwater and marine organisms face very different iono- and osmoregulatory issues related to living in either a very dilute or concentrated salt environment. Differences in iono- and osmoregulatory physiology may also lead to differences in metal accumulation and metal toxicity (Prosser, 1991; Wright 1995; Rainbow, 2002). Despite these apparent physiological differences, it has been shown that marine fish also suffer from osmoregulatory disturbances under metal exposure and, therefore, similar toxicity mechanisms may apply (ECI, 2008).

As for freshwater, the influence of DOC binding, metal speciation and metal ‘availability’ on metal toxicity to marine organisms has been demonstrated for some metals (e.g. Smolders *et al.*, 2004, Cu RAR, 2008). The data show that metals binding to organic ligands can reduce metal toxicity to marine organisms, so an availability correction may be needed. Therefore, if experimental data allow the assessor to derive a quantitative relationship between DOC and ecotoxicity ($NOEC/EC_{50}$), this equation can be used to normalise all marine ecotoxicity data.

In marine waters (coastal and open sea), hardness, pH and alkalinity do not play a role because coastal/open sea waters are characterised by high pH (typically between 7.8–8.3), high salinity (35‰) and high ionic strength. Unlike the inorganic composition of marine waters, DOC levels may vary considerably between marine waterbodies. The MAMPEC model[17] defines receiving marine environment scenarios. The model includes DOC values for coastal and open ocean waters of 2.0 and 0.2 $mg \cdot l^{-1}$, respectively. The applicability of 2.0 $mg \cdot l^{-1}$ DOC as a reasonable worst case for coastal waters was further confirmed from an extensive literature search (see Cu RAR, 2008). A DOC normalisation of the ecotoxicity data to a standard level of 2.0 $mg \cdot l^{-1}$ DOC is,[18] therefore, to be used for deriving a coastal water $QS_{reference,\ sw}$. Alternatively, and if no bioavailability correction can be carried out, a non-normalised generic QS can be used as $QS_{generic,\ sw}$. This corresponds to the Option 1 or Figure 3-1.

Where the waterbody does not comply with the $QS_{reference,\ sw}$, availability can be accounted for by applying Step 2 (see Figure 3-1). Similar to the procedure described for the freshwater compartment (Section 3.5.2.1), availability can be corrected by several means:

---

[17] Standard model employed for the risk assessment of antifouling paints in marine environments.

[18] If DOC has been added to the test media (e.g. as humic acids), the difference in binding strength of the natural DOC compared with added DOC is to be considered.

Option 2: If the marine $QS_{reference,\ sw}$ is exceeded (Tier 1), then a BioF can be applied to the monitoring data value. The BioF is based on a comparison between the expected availability at the reference site and that relating to site-specific conditions. The bioavailability correction for a site can be performed (Tier 2) as follows:

Calculate the BioF using BioF = $QS_{reference,\ sw}$ (2.0 $mg \cdot l^{-1}$ DOC)/$QS_{site\text{-}specific,\ sw}$ (normalised to the site-specific $mg \cdot l^{-1}$ DOC.

Determine the available dissolved metal concentration at the site, calculated as dissolved metal concentration × BioF.

Compliance then can be checked as available dissolved metal concentration at the site < $QS_{reference,\ sw}$.

Option 3: If the marine $QS_{reference,\ sw}$ is exceeded (Tier 1), then a marine $QS_{site\text{-}specific,\ sw}$ is derived based on the site-specific DOC concentration (using the empirically observed relationship between the NOECs/EC10s and DOC) and this value is assessed against the monitoring data for compliance (Tier 2).

The DOC correction proposed for the marine environment is a simple 'availability' correction, irrespective of the species considered and it is, therefore, not necessary to demonstrate the applicability of the DOC correction for a wide range of species.

For estuarine waters, salinity, alkalinity or total carbonate also should be considered, if possible.

3.5.2.3 Using mesocosm and field data for metals

Similar to deriving a QS for organic substances, high quality mesocosm and field data can be used for QS derivation for metals. The quality criteria to be used are the same as those used for organic substances, but some metal-specific issues are to be considered as outlined in Section 3.6.

If a bioavailability correction can be applied, then QSs normalised to the physicochemistry of the mesocosm/field studies are recommended .

3.6 Estimating background levels of metals

3.6.1 General comments

If the QS is below or close to the natural background level and there is no further scope for reassessing either backgrounds or the derivation of the QS, then the ARA may be applied. The general definition of natural background level is the concentration that is present owing to natural and geological processes only, i.e. the background level with no anthropogenic contribution ('pre industrial' levels). In reality, true pristine areas are rare within Europe, and it must be considered on a case-by-case basis whether a given area represents a pristine condition for a specific metal.

In most areas in Europe, any estimate of a natural background concentration will inevitably include a small contribution from anthropogenic sources because much of Europe's landscape has been altered by man's activities for mineral extraction, agriculture or habitation for millennia and this historical contribution may be obscure. In addition, long-term anthropogenic activities, such as drainage, irrigation and special crops (e.g. conifers creating acid soil conditions), may influence environmental release of metals. This contribution is difficult to quantify and distinguish from what concentrations might have been in the absence of such activities. Finally, contributions from diffuse anthropogenic sources, eg aerial deposition, may be impossible to eliminate entirely.
Therefore, any estimate of a background concentration will more likely be an 'ambient' background concentration rather than a value relating to a purely natural pristine environment.

3.6.2 Estimating backgrounds for freshwater

The natural background concentration is determined by mineral and biological factors. A major contribution to the background concentration will be from weathering of surface geology and any groundwater spring inputs. Therefore, a ‘global’ natural background level will normally not be meaningful because of the great variation between different regions.

In freshwater, the preferred procedure for assigning a ‘natural’ background will usually be to determine the concentrations in springs and/or in waterbodies in ‘pristine’ areas in the given region, e.g. headwaters. Other possibilities are:

- To measure concentrations in deep groundwater. In some cases, however, the concentration of the metal may be higher in the groundwater than in the surface water, e.g. because of the groundwater’s contact with deep lying mineral rocks or soils and subsequent dilution by rain.
- To gather information from national or international databases, such as the FOREGS Geological Baseline Programme (http://www.gsf.fi/foregs/geochem).
- Geological modelling, to estimate the contribution from erosion.
- To estimate the concentration in the water from natural background concentrations found in the sediment by means of equilibrium partitioning models.

Pristine waters are scarce and, in practice, mainly restricted to the immediate vicinity of a source. Further downstream, the water will take up the remnants of decaying organic material in the form of DOC. Plants contain substantial amounts of essential elements extracted from the soil that remain present through binding to DOC, thereby causing a natural increase in metal background concentrations. De Schamphelaere et al. (2003b) have measured the natural zinc and copper content bound to DOC. If such bound DOC concentrations measured in practice are taken into account in many surface waters, this natural contribution appears to exceed the mineral contribution described above (see VROM report VEM july 2004, appendix 3 in Dutch).

In other situations, biological depletion may take place, c.f. the great lakes in the USA, but also European mountain lakes with long residence times. In such cases, the natural background concentration might be below the pristine source concentration. This is due to the uptake of essential elements from the upper water layers by organisms which, after death, fall to the deeper regions of the waterbody, thereby taking with them the essential metal. Natural background concentrations may decline in this biological depletion process by over one order of magnitude (e.g. Nriagu *et al*., 1996).

In practice, the input data needed to determine background concentrations in pristine areas by modelling may be inadequate to estimate a reliable value. An alternative pragmatic approach in these cases is to take the 10th percentile dissolved metal concentration of all the monitoring data available for the waterbody or region (after removing sample results with elevated concentrations from known point source discharges or pollution events). If this technique is used, some interpolation of the distribution of values is needed from the laboratory’s reporting limit (the ‘less than’ value) and zero. Using this approach, an example from the Mersey hydrometric area (UK) produces 5th and 10th percentile values of 3.0 and 3.7 $\mu g \cdot l^{-1}$, respectively for dissolved zinc (Figure 3-2).

Further, ‘hot spots’ may also be located using geological information.

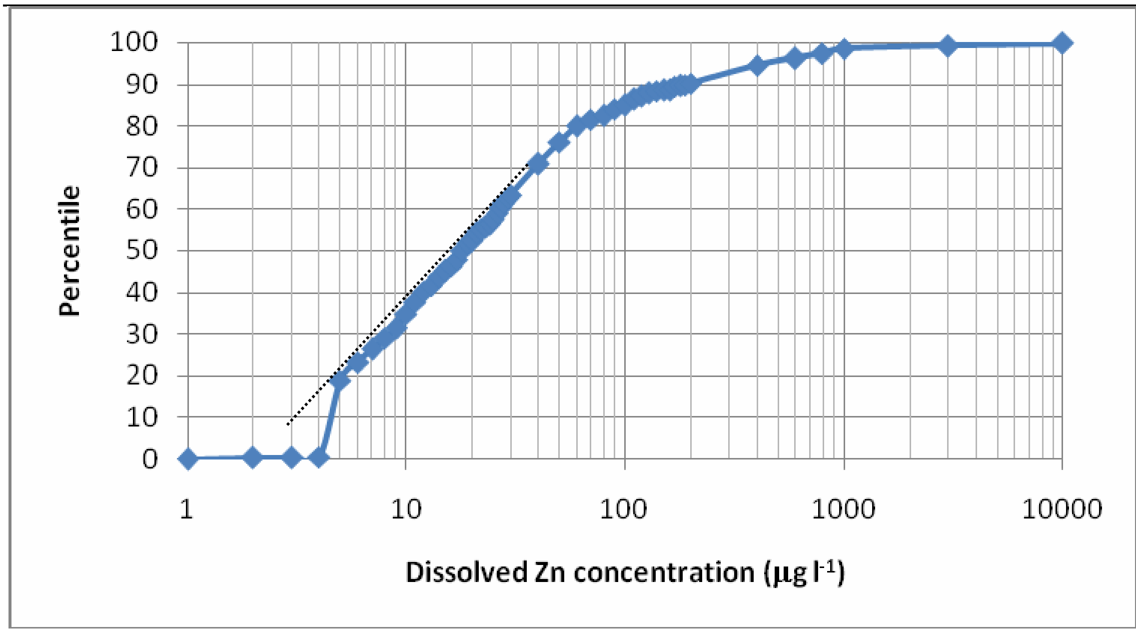

Figure 3.2 Distribution of dissolved zinc concentrations in the Mersey hydrometric area (UK)

A comparison of freshwater background concentrations based on a wider river basin level or more-local hydrometric area is given in Table 3.6. The British Geological Survey (BGS) Geochemical Baseline Survey of the Environment (G-BASE) project data of single measurements taken at small, relatively unimpacted streams are also shown.

Table 3.6 Example freshwater background concentrations based on river basin and hydrometric area levels obtained from different sources

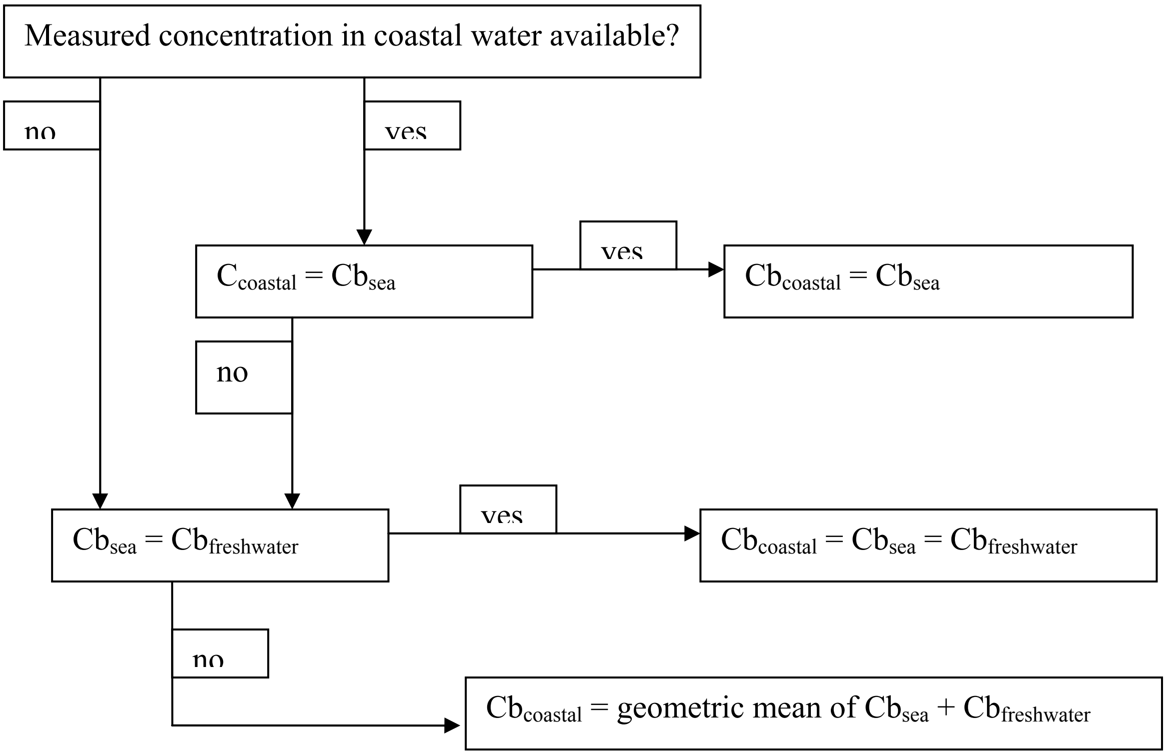
Metal (Dissolved)	FOREGS Ranges (µg·l^{-1})	BGS G-BASE (Median) (µg·l^{-1})	10th Percentile of Monitoring Data (µg·l^{-1})
Cu UK South West England river basin district default	1.45–1.97	1.6	1.8
Tamar hydrometric area specific	<1.97	1.0	0.5
Zn UK South West England river basin district default	2.68–4.00	3.4	3.2
Tamar hydrometric area specific	<2.86	2.0	2.5

3.6.3 Estimating background concentrations for saltwaters

In saltwater, the concentrations of metals (dissolved) far at sea will normally suffice as natural background levels. Natural background concentrations (Cb) may be higher in coastal waters because of the natural input from rivers and the settling of particles. The determination of the $Cb_{coastal}$ in such waters may, however, be very difficult because rivers are likely to drain pristine areas as well as areas influenced by anthropogenic inputs, and thus a pragmatic approach is needed. As a starting point (see Figure 3-3), the dissolved metal concentration in the coastal water is compared with the Cb at sea (Cb_{sea}). If these values are equal, then the $Cb_{coastal}$ for the coastal water is set equal to the Cb_{sea}. If there are no measurements in the coastal water or if the concentration is greater than Cb_{sea} then the Cb in freshwater and at sea are compared. If they are the same, it will be reasonable to set the Cb in estuaries and coastal waters equal to those in freshwater and at sea. If the $Cb_{freshwater}$ is different from $Cb_{sea,}$ the geometric mean of the two values may be used for coastal waters. In cases where the concentration in coastal water is between $Cb_{freshwater}$ and Cb_{sea}, the $Cb_{coastal}$ is set equal to the measured value. If the $Cb_{coastal}$ values derived as above create no problems in relation to measured concentrations and compliance, then no further refinement will be necessary. Alternatively, the $Cb_{coastal}$ can be derived as the 10th percentile of concentrations measured in coastal waters draining only relatively uncontaminated areas.

Guidance is given in OSPAR (2004) on ambient metal concentrations measured in the waters of the Convention area. However, these data should be interpreted with care when deriving coastal background values. Indeed, the ranges presented for the different metals refer to open ocean ranges which are usually lower in value than those for near and on the shelf (e.g. for Cd and Cu).

It is important to note that preference should be given to values reflecting natural background concentrations for coastal zones, and that some might be found in the literature (e.g. see Laane et al., 1992 for the North Sea; Landing et al., 1995 for the Atlantic Ocean, the UK National Marine Monitoring Programme 2004 http://www.jncc.gov.uk/pdf/nmmp2ndreport.pdf; and ICME, 1996).



Alternatively, $Cb_{coastal}$ = the 10th percentile of concentrations measured in coastal waters draining only relatively uncontaminated areas. If the concentration in coastal waters is between Cb_{sea} and $Cb_{freshwater}$ then $Cb_{coastal} = C_{coastal}$

Figure 3.3 Determining the natural background concentration of a metal in coastal waters;
$C_{coastal}$ = concentration measured in coastal water, $Cb_{coastal}$ = natural background concentration in coastal water, Cb_{sea} = natural background concentration at sea, $Cb_{freshwater}$ = natural background concentration in freshwater; concentrations refer to the dissolved metal

3.7 Data requirements for deriving QSs for metals

As for organic substances, aquatic toxicity data to be used for the setting of water (sediment/biota) quality criteria for metals are evaluated as described in Appendix 1. However, the following metal-specific aspects need to be considered:

1. *Measured versus nominal test concentrations*: Because it is important to understand the true exposure concentrations (including the background concentration in the culture medium), **any ecotoxicity study not supported by analytical data (i.e. endpoint concentrations reported as nominal values) would automatically be excluded from the most reliable studies**. Nominal concentrations will usually[19] overestimate the final concentration. Therefore, if the

[19] Except for essential metals (nutrients may be added to the test waters) and if natural waters are used as test waters (the metal concentrations in the natural waters may substantially contribute to the dissolved metal concentration).

lowest effect concentration is a nominal value, then the study should not be discarded unless there are other reasons to invalidate it.

2. *Total versus dissolved metal concentrations in test media*: Measured data on the dissolved fraction (0.45 µm) are required in order to obtain the most reliable toxicity test data. Measurements of dissolved metal concentrations are critical to the assessment of sparingly soluble metals (particles and precipitation may occur) and in the use of natural waters as test media (adsorption to suspended solids may occur). If only total metal measured data are available, it may be possible, in some cases, to estimate the dissolved fraction from published solubility constants for the principal anions present, e.g. sulphate or carbonate, and/or suspended solids/water partitioning coefficients.

3. *Culture conditions*: If the test organisms have been cultured in conditions that are outside the natural background concentration ranges (see Section 3.6), such data should be discarded from the high quality database and, at best, may only be considered as supporting evidence when selecting the assessment factor[20].

4. *Chelators*: Data from studies in which the test media contain artificial chelators (e.g. EDTA) should be excluded from EQS derivation, except in algal tests where small amounts of chelators (EDTA (can be replaced by natural DOC)) are unavoidable.

5. *Test medium characteristics:*

   For water: Considering the strong influence of water physicochemistry on metal toxicity, the physicochemical conditions in a test should be adequately described, especially if corrections for bioavailability are carried out. The aquatic medium used should be characterised by DOC concentration, hardness, pH, alkalinity, presence of complexing agents, such as humic acids and EDTA, and any other specific parameters of importance to the metal in question. Where all the physicochemical data have not been reported for a test and are important for speciation models, it may be possible to estimate the missing data from known physicochemical parameters (e.g. estimate alkalinity from Ca and alkalinity relationships (Adams et al., 2008)) or to use default values derived from other studies using standard test media or from historic monitoring data for natural waters (Santore et al., 2002). The physicochemical parameters should not only be measured at the beginning of the test because the factors may change, e.g. because of food addition.

   Metal–DOC equilibrations: The kinetics of metal–DOC binding in aqueous and sediment test media may require an equilibration period between the metal and test medium prior to exposing the organisms. This is to allow full metal–OC binding in a way that is representative of natural environments (e.g. Ma et al., 1999). Where the kinetics for reaching equilibrium conditions for binding to OC, etc., are known to be slow and may affect the test outcomes, reviewing the details of the test design may provide additional information on the reliability of the data, particularly for any extreme values.

6. *Oxidation state*: Many metals have more than one oxidation number, which poses several complications. Firstly, chemical characteristics, and thus toxicity, can vary markedly between different oxidation states. Consequently, the oxidation number of the trace element(s) in a given substance must be known. This is not necessarily a trivial problem, as mixed oxidation states can occur. Secondly, some oxidation states may be unstable in specific or all environmental compartments, meaning that distinct changes in bioavailability may occur during even a short-term toxicity assay (e.g. Cr(III)/Cr(VI)). In such cases, it may be necessary to derive a separate EQS for each of the relevant oxidation states.

[20] This is especially relevant under the TRA.

7. *Read-across and QSAR*: If ecotoxicity data are lacking for a specific metal or metal compound, read-across of ecotoxicity data from other inorganic compounds of the same metal should be considered. The basic assumption is that the bioavailable metal ion is responsible for toxicity. Ecotoxicity data for simple soluble metal salts, therefore, can be combined on condition that the metal ion alone is responsible for the effects observed for all of the metal salts considered (e.g. $CuSO_4$, $CuCl_2$). Toxicity data measured for all soluble metal salts should, therefore, be used and the effects data (NOECs/EC_{10}s or EC_{50}s) should be expressed as the dissolved (bioavailable) metal ion concentration ($\mu g\ M \cdot l^{-1}$).

   The development of QSAR methods for metals and inorganic metal compounds has not been as actively pursued as for organic substances. However, for some inorganic substances, predicting toxicity from chemical properties may be relevant. In this respect, quantitative ion character–activity relationships (QICARs) and quantitative cationic activity relationships (QCARs) have recently been developed (Ownby and Newman, 2003; Walker et al., 2003).

8. *Combining freshwater and saltwater toxicity data*: As explained in Section 3, **freshwater and saltwater data for metals should generally not be pooled if availability corrections have been applied**.

9. *Interpreting biological effects*: Metals can exhibit physical toxic effects (e.g. smothering by metal precipitates) as well as effects caused by systemic toxicity. Some metals (e.g. Fe, Al) precipitate over short timescales compared with the duration of chronic toxicity tests, making the data difficult to interpret. Chronic data for metals exhibiting this behaviour should be treated with caution. Greater reliance may need to be placed on field data for such metals.

10. *Estimating bioaccumulation (for back-calculating water concentrations from biota standards)*: Section 4.7.2 details how to determine the relevant experimental bioconcentration factor (BCF) or bioaccumulation factor (BAF) data for metals.

3.8 Assessing compliance with a water-column EQS for organic compounds

3.8.1 Option to translate an EQS for dissolved water into an equivalent EQS for total water and/or suspended particulate matter

Standard laboratory toxicity and bioconcentration tests contain low levels of total organic carbon (TOC) in the test system[21]. As a result, the resulting EQSs refer to **dissolved concentrations**. It follows that compliance assessment with a water column EQS should ideally be based on the sampling and analysis of the dissolved fraction. This is similar to the way the PNEC is used according to the TGD (Part 2, Section 2) (EC 2003) and REACH (R.16)(ECHA 2008).

Discrepancies between total and dissolved concentrations may only become evident for very hydrophobic substances, ie K_p values in excess of 10000 $l.kg^{-1}$ or K_{oc} values for linear partitioning into amorphous organic matter in excess of 100000 l kg^{-1}. This will generally only be found for substances with a log K_{ow} above 6. Thus, for compounds with log K_p<4 (or, if this value is not available, log K_{ow} <6), the $EQS_{water,\ total}$ is equivalent to the $EQS_{water,dissolved}$.

[21] OECD guidelines for the acute and chronic daphnid test, the fish early life stage test and short-term fish embryo and sac-fry stage tests, the fish juvenile growth test, the chironomid test and the bioconcentration test with fish all set a maximum level of 2 $mg \cdot l^{-1}$ to the TOC content. In most laboratory studies, however, the TOC content will not reach this level, which means that in practice toxicity results reflect dissolved concentrations.

As explained in Section 2.11 some Member States may have a preference to undertake monitoring using total water samples, incorporating both the dissolved fraction and the chemical that is sorbed onto suspended particulate matter (SPM) or the SPM fraction only. The fraction found on SPM is likely to be particularly important for hydrophobic substances. To allow for this option, guidance is provided here on converting the water column standard as derived for the dissolved concentration (the final EQS value) into an equivalent total concentration in water ($EQS_{water,total}$) that corresponds to the quantity of the substance that is in true solution plus any of the substance sorbed to SPM. In some cases, laboratory tests include significant levels of SPM (OECD test guidelines permit some SPM). For such cases, the dissolved concentration must first be determined (Step 1). Only then can the $EQS_{water,total}$ be estimated (Step 2).

Step 1 – Estimation of $EQS_{water,dissolved}$

If no organic carbon content is present, the concentration is assumed to be fully dissolved and this step can be omitted. The derived quality standard should then be considered to refer to the dissolved concentrations ($EQS_{water,\ dissolved}$). If organic carbon is measured in the critical toxicity studies, the dissolved concentration ($C_{water,\ dissolved}$) can be calculated from the total concentration in critical ecotoxicity experiments ($C_{test\ water,\ total}$) and the total organic carbon content in these experiments ($TOC_{test\ water}$) as follows, , where K_{oc} is in l kg^{-1} and $TOC_{test\ water}$ is in mg l^{-1}.

$$C_{\text{water,dissolved}} = C_{\text{test water, total}} \cdot \frac{1}{1 + K_{\text{oc}} \cdot \text{TOC}_{\text{test result}} \cdot 10^{-6}}$$

In this case, the concentrations are corrected for organic carbon, including DOC, that limits the substance's (bio)availability.

This equation may be used for laboratory toxicity or bioconcentration data, but could also be used to convert data from a mesocosm study or a field bioaccumulation study. Where an EQS has been derived using an SSD approach, it is useful to examine all studies that lie around or below the HC.

Step 2 – Estimation of $EQS_{water,total}$

For highly hydrophobic compounds the final derived EQS (which is an $EQS_{water,\ dissolved}$) should be corrected using the default concentration of suspended matter (C_{SPM}) and the partition coefficient to suspended matter (Kp,susp).

$$\text{EQS}_{\text{water,total}} = \text{EQS}_{\text{water, dissolved}} \cdot (1 + K_{\text{p,susp}} \cdot \text{C}_{\text{SPM}} \cdot 10^{-6})$$

where:

- $EQS_{water,total}$ = quality standard for the total concentration in water;
- $EQS_{water,dissolved}$ is the value of dissolved concentration in water, mostly directly derived from the toxicity or bioaccumulation tests;
- $K_{p,susp}$ = partition coefficient to suspended matter (l·kg^{-1}), which might be estimated as the product of the K_{oc} value for the substance (l·kg^{-1}) and the organic carbon content (f_{oc}) of suspended matter (EU default from TGD (EU 2003) 0.1);
- C_{SPM} = concentration of suspended matter (mg·l^{-1}; For several water types like large rivers the SPM content is reasonably constant and a default value has been proposed for this type of river. EU defaults are 15 mg·l^{-1} for freshwaters and 3 mg·l^{-1}/L for marine waters and for example, the annual average TOC content of the Rhine in the Netherlands is about 4mg l^{-1}, however, under deviating 'local' environmental conditions other values need to be applied); and
- 10^{-6} is = a conversion factor to convert mg into kg.

A further refinement is to base compliance monitoring on the analysis of the SPM instead of the unfiltered water samples. This is because hydrophobic substances are more likely to be sorbed to SPM than to be freely dissolved in the water column. For the purpose of comparing the analyses of

SPM to the derived water column EQS, guidance is provided below on how to convert the water column EQS into an EQS based on SPM (EQS_{SPM}).

When the EQS for an organic chemical is expressed as dissolved concentration in water (referred to as $EQS_{water,dissolved}$ in this section) , a corresponding concentration in SPM may be calculated and used as a surrogate standard. This should be done for hydrophobic organic substances whose partition coefficient triggers exceed those given above.

The algorithms to calculate the concentration in SPM from the dissolved concentration in water and vice versa are as follows:

$$EQS_{SPM} = EQS_{water,\, dissolved} \cdot K_{p,\, susp}$$

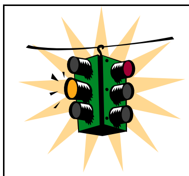
where:

– EQS_{SPM} = quality standard for water referring to the substance concentration in SPM (EU TGD (EU 2003) default has an organic carbon content of 10%);

– $EQS_{water,\, dissolved}$ = quality standard for water referring to the dissolved concentration;and

– $K_{p,\, susp}$ = substance-specific partition coefficient for SPM–water (e.g. f_{oc} . K_{oc} or any valid experimental value);

3.9 Deriving quality standards for water abstracted for drinking water ($QS_{dw,\, hh}$)



Look Out!

The approach chosen in this guidance in case of the absence of a drinking water standard is based on human toxicity. This implies that the precautionary principle and organoleptic aspects such as smell, taste and colour are overlooked. For the production of drinking water these elements play an important role. This means that for some substances there is need for specific measures to limit the risks because of concerns for the potability of drinking water in respect of taste and odour as a consequence of exposure (Commission Recommendation 2001/838/EC).

3.9.1 Overview

In addition to potential exposure through the consumption of fishery products (see Section 4.5), a second route for human exposure to substances in water is through drinking water. The WFD therefore requires quality standards to protect humans against this route of exposure.

In principle, existing drinking water standards are adopted, e.g. EU drinking water standards from Drinking Water Directive 98/83/EC and the World Health Organization (WHO) drinking water standards. These drinking water standards are used to set the $QS_{dw,\, hh}$ for those water bodies used for the abstraction of drinking water ($QS_{dw,\, hh}$). A treatment factor should be applied to the drinking water standard so that the $QS_{dw,\, hh}$ relates to the ‘raw’ water (i.e. it is an ‘environmental’ standard). Drinking water standards and treatment processes used to achieve them should be taken into account in determiing quality standards for water abstraction resources. This should have regard to Article 7 of the WFD with reference where appropriate to simple treatment.

WFD (Article 7(2) and (3)) and DWD (Article (4) require Member States to prevent any deterioration of the present quality of water intended for human consumption or any increase in the pollution of waters used for the production of drinking water.

If no existing drinking water standards are available (either DWD or WHO standards) a standard for drinking water abstraction from surface water may be derived by the procedure described in Section 3.9.2.

3.9.2 $QS_{dw, hh}$ for drinking-water abstraction

A QS for the abstraction of drinking water ($QS_{dw,hh}$) needs to be derived as follows (see also Figure 3-4)[22]:

1. If an EU drinking water standard (from Directive 98/83/EC) or a WHO drinking water standard is available, follow the procedure described below. If both the WHO and EU have a drinking water standard and the values are different, the WHO drinking water standard is preferred,.because it is health-based.

   - o If the drinking water standard is less stringent than the other QS_{water} values already derived (i.e. $QS_{fw, eco}$, $QS_{sw, eco}$, $QS_{fw, ,secpois}$, $QS_{sw, secpois,}$ $QS_{water, hh food}$), it could be decided that a $QS_{dw, hh}$ need not be derived.

   - o If the drinking water standard is more stringent than the other QS_{water} values already derived (i.e. $QS_{fw, eco}$, $QS_{sw, eco}$, $QS_{fw, ,secpois}$, $QS_{sw, secpois,}$ $QS_{water, hh food}$), the $QS_{dw, hh}$ is derived as follows:
     - Substance-specific removal efficiencies are estimated. This may require consultation with drinking water experts. The removal efficiency is expressed as the *fraction (F) not removable by treatment*.
     - The $QS_{dw, hh}$ is then calculated using equation A.

$$QS_{\mathrm{dw,hh}} = \frac{drinking\ water\ \mathrm{standard}\,(98/83/\mathrm{EC})}{F_{\mathrm{not\ removable\,by\ treatment}}} \qquad \text{(A)}$$

2. If neither an EU or WHO drinking water standard is available,, follow the procedure described below:
   - A provisional drinking water standard is calculated according to equation B.

---

[22] High treatment factors reflect the need for a high removal rate. Even where highly effective treatment is already in place, relying on this to compensate for contamination is not the most sustainable approach. Drawbacks include: (i) higher treatment costs; (ii) higher energy consumption and carbon footprints; (iii) compromise of the multiple barrier principle - i.e. an inadequate margin of safety between pollutant concentrations in raw water and drinking water, such that treatment failure could lead to exceedance of maximum acceptable concentrations in drinking water. For this reason Art. 7(3) WFD requests, that “Member States shall ensure the necessary protection for the bodies of water identified with the aim of avoiding deterioration in their quality in order to reduce the level of purification required in the production of drinking water.”

Therefore, in line with the combined approach laid down in the WFD, when deriving EQS for water abstracted for drinking water using treatment factors, Member States should in parallel strive to reduce pollution in the raw water body (e.g. as part of the Programmes of Measures) to reduce the treatment required to reliably meet the drinking-water standards. At a local level, the process of planning the (combined) control measures for the drinking-water supply system, which determine the treatment factors, calls for cooperation between the drinking-water sector experts and the authorities that manage the raw water bodies

$$QS_{\mathrm{dw,\,hh}} = \frac{0.1 \cdot TL_{\mathrm{hh}} \cdot bw}{uptake_{\mathrm{dw}}} \qquad \text{(B)}$$

Use a human body weight (bw) of 70 kg and a daily uptake of drinking water ($uptake_{drw}$) of 2 litres (ECHA, 2008). By default, a fraction of 0.1 of the human toxicological standard (TL_{hh}) is allocated to intake of the substance via drinking water. This default may be adapted, but this should only be done when sufficiently underpinned data (e.g. total diet studies and total coverage of possible intake routes) are available demonstrating that either a higher or lower value is justified. The value for TL_{hh} should be the acceptable daily intake (ADI) or tolerable daily intake (TDI) if these are available, a reference dose (RfD) or a benchmark dose.
If no ADI or TDI is available, the TL_{hh} could be calculated from the $NOAEL_{min}$ (the lowest no observed adverse effect level value from a review of mammalian toxicology data) using equation C. However, before deriving a TDI or an ADI from a NOAEL, a human toxicologist should be consulted in any case.

$$TL_{\mathrm{hh}} = \frac{NOAEL_{\mathrm{min}}}{100} \qquad \text{(C)}$$

If the compound of interest is potentially carcinogenic[23], the TL_{hh} is equal to the concentration corresponding to an additional risk of cancer for 1×10^{-6} (for 70 years exposure).

- If the (provisional) drinking water standard is less stringent than the other QS_{water} values already derived (i.e. $QS_{fw,\ eco}$, $QS_{sw,\ eco}$, $QS_{fw,\ ,secpois}$, $QS_{sw,\ secpois}$, $QS_{water,\ hh\ food}$), it could be decided that an $QS_{dw,\ hh}$ need not be derived and no further work is required.
- If the $QS_{dw,hh}$ calculated using equation B is more stringent than the other AA-QS_{water} values already derived (i.e. $QS_{fw,\ eco}$, $QS_{sw,\ eco}$, $QS_{fw,\ ,secpois}$, $QS_{sw,\ secpois}$, $QS_{water,\ hh\ food}$), the $QS_{dw,\ hh}$ is derived as follows:
  1. The removal efficiency of the substance is estimated. This may require consultation with drinking water experts. The removal efficiency is expressed as $F_{\text{not removable by treatment}}$.
  2. The $QS_{dw,\ hh}$ is then calculated using equation A.

For metals, the same approach as described here is followed.

[23] No guidance is given on how to establish the potential carcinogenicity of a compound, but the assessor should check the appropriate R phrases. No guidance is available on how to estimate a concentration that corresponds to an excess cancer risk of 10^{-6}. Therefore, a human toxicologist should be consulted.

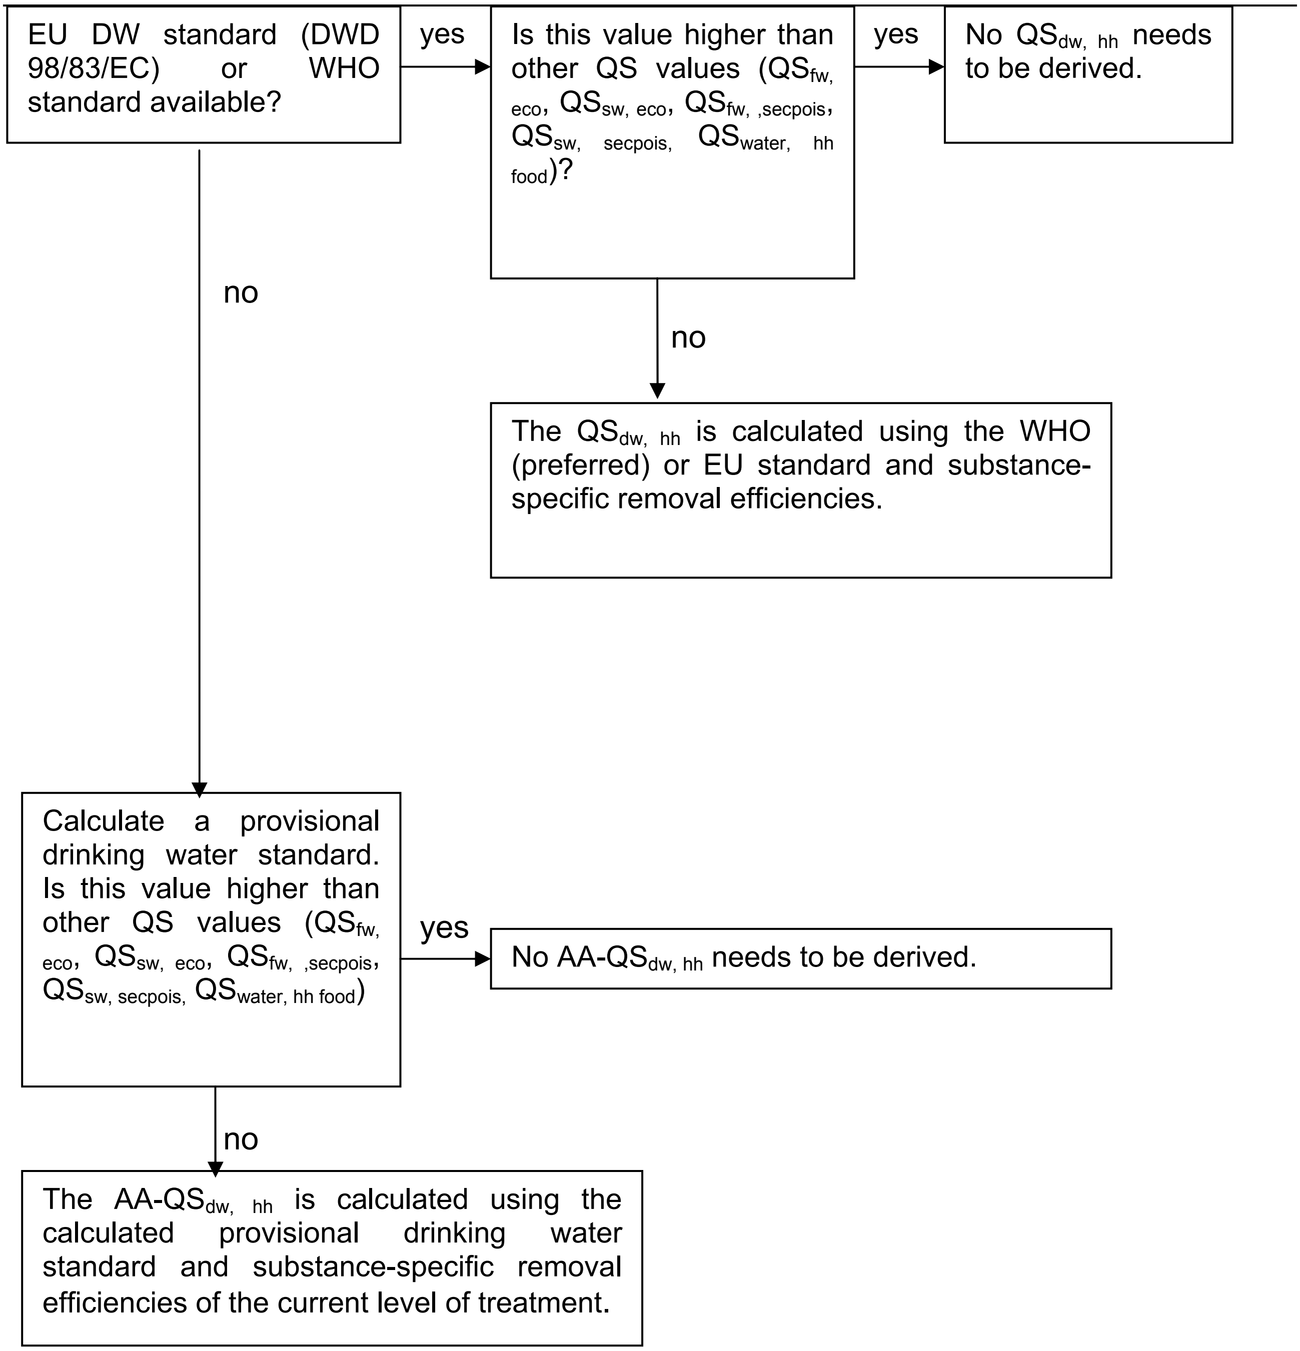


Figure 3.3 Schematic overview of the derivation of the quality standard for drinking water abstraction from surface water ($QS_{dw, hh}$)

4 DERIVATION OF BIOTA STANDARDS

4.1 Introduction

One of the factors leading to unmanageable water column standards is the very low concentrations that may be estimated for some substances, especially those with very low water solubility or a tendency to bioaccumulate through the food web. If these substances pose a significant risk through indirect toxicity (i.e. secondary poisoning resulting from food-chain transfer) and their analysis is more feasible in other environmental matrices, such as biota and/or sediments, then a biota standard may be required alongside, or instead of, the water column EQS. This is typically the case for hydrophobic substances, and biota standards have been proposed for hexachlorobenzene, hexachlorobutadiene and mercury and its compounds in the Daughter Directive to the WFD on EQSs (2008/105/EC), establishing concentration limits in prey tissue (fish, molluscs, crustaceans and other biota). In line with the requirements of the EQS Directive, these biota standards are presented as possible alternatives to a water column standard.

4.2 Protection goals

The WFD requires biota EQSs to protect:

1. Humans from adverse effects resulting from the consumption of chemical-contaminated food (fish, molluscs, crustaceans, etc.).
2. Top predators, such as birds and mammals, from risks of secondary poisoning brought about by consuming toxic chemicals in their prey.
3. Benthic and pelagic predators (e.g. predatory fish) that may also be at risk from secondary poisoning.

This section provides guidance for dealing with the first two protection goals (for which the temporary standards $QS_{biota,hh}$ and $QS_{biota,secpois}$are derived, see Appendix 6). The methodology applies to biota standards for freshwater (inland waters) and marine (transitional, coastal and territorial waters) ecosystems. Currently, technical guidance for benthic and pelagic predators (the third protection goal) is not well-developed. Possible approaches for the future are set out in Appendix 4, but these will need to be developed and tested before they can be adopted as formal guidance. **At present, biota standards developed for birds and mammals are assumed to be sufficiently protective for benthic and pelagic predators**.

The process for deriving and using biota standards to meet these protection goals is illustrated in Figure 4-1. In principle, to derive a biota standard, the assessor must estimate an acceptable level of chemical input when it occurs in the organism's food. Standard toxicity tests are available that estimate a no observed adverse effect level (NOAEL) or a no observed effect concentration ($NOEC_{oral}$) and these values are used to derive a predicted no-effect concentration for the ingestion of food ($PNEC_{oral}$) (taking account of variations between studies, species and test endpoints). Extrapolation from $NOEC_{oral}$ data to a $PNEC_{oral}$ (equivalent to a QS_{biota}) is detailed in Section 4.4.

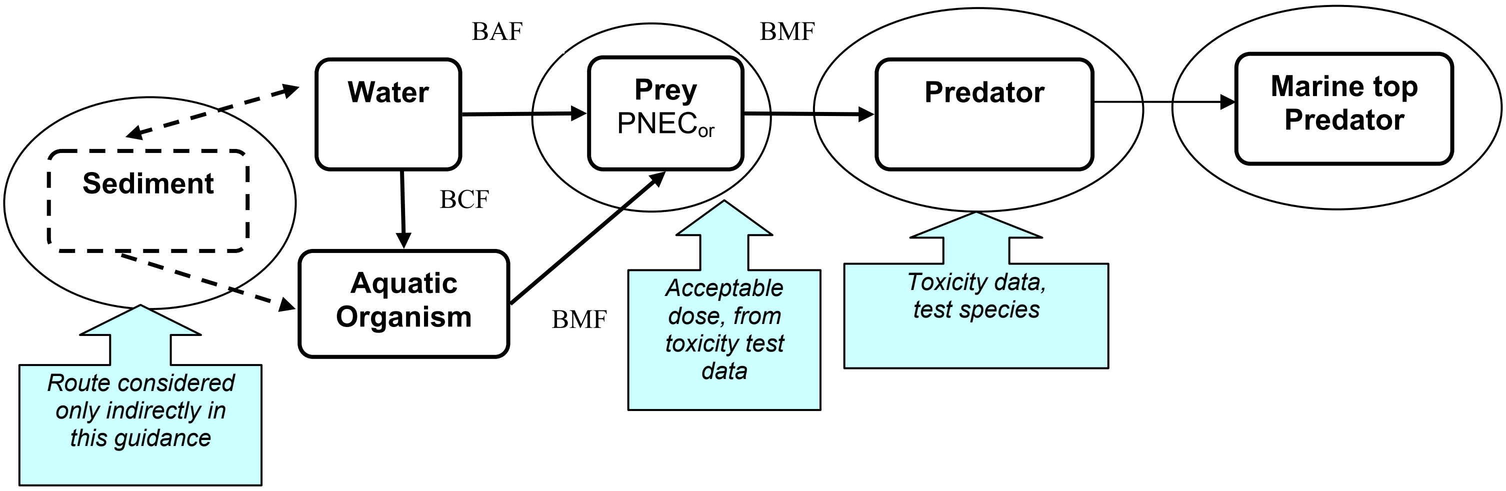

Figure 4.1 Steps involved in deriving a biota standard

Biota standards are preferably expressed as a concentration in an organism – corresponding to the prey items that may form the diet of top predators (including humans). Following the CSTEE (2001, 2004) opinion, biota quality standards are preferably expressed as biota concentrations and assessment is based on direct assessment and monitoring of biota. However, some Member States may wish to retain an option to sample and analyse only water column samples. Translation of the biota standard to a water column threshold is also helpful when selecting an overall EQS (Section 2.5), so that standards can be compared on the same (mass/volume) basis.

Whilst a biota standard could, in principle, be converted into the equivalent water concentration (one that is predicted to give rise to the critical concentration in biota), there are technical disadvantages with this approach for highly hydrophobic substances (those identified as B or vB according to Annex XIII of REACH). The translation to an equivalent water concentration depends on a good understanding of the bioconcentration, bioaccumulation and biomagnification processes from water and through the food web which can be uncertain for such substances.

4.3 Expression of a biota standard

There are several options for expressing a biota standard depending on the methodology used to derive it. A biota standard may refer to:

- A specific species or group of species
- A surrogate matrix for a particular species (e.g. eggs, pellets, etc.)
- A specific group of food (diet products from aquatic ecosystems)

Any of these is acceptable, but prey species are prefereable. The QS should be expressed in terms of g/kg (wet weight) of the whole organism. Since hydrophobic organic chemicals tend to accumulate in body lipids, experimental residue data are sometimes expressed in terms of a lipid-normalised concentration. If lipid normalisation is possible and scientifically justified (i.e. the substance primarily accumulates in lipids), all data should be lipid normalised to a standard lipid content of 5% (ECHA, 2008).

For water column standards, protection against long-term exposure is addressed by expressing the standard as an average over a fixed time (usually a year). Although a biota standard is also intended to protect against prolonged exposure, residues in animals and plants effectively integrate exposure over a period of time and, in any case, sampling of biota is likely to be rather infrequent. Unlike water standards, there is likely to be greater variability in exposure between sites than there is over time. Greater emphasis should be placed on the spatial design of sampling schemes.

4.4 Deriving a biota standard to protect against the secondary poisoning of predators

Secondary poisoning is concerned with toxic effects at higher trophic levels of the food chain which result from the ingestion of contaminated aquatic organisms from lower trophic levels.
In accordance with Romijn *et al*. (1993) and following the paradigm used under TGD (EC, 2003) and REACH (ECHA, 2008), we will define our food chain with its trophic levels as water –BCF→ aquatic organisms –BMF_1→ fish → fish-eating predator for freshwater ecosystems. For marine ecosystems, however, another trophic level may be introduced: water –BCF→ aquatic organisms –BMF_1→ fish –BMF_2→ fish-eating predator → top predator (where BCF is the bioconcentration factor and BMF is the biomagnification factor). This is illustrated in Figure 4.1.

A QS expressed as the concentration found in prey tissue which should protect predators from secondary poisoning ($QS_{biota,secpois}$) is often referred to as the diet-based approach. In terms of deriving the standard, only one extrapolation step, from food to predator (Figure 4.1), is necessary. Extrapolation to take account of possible differences in sensitivity between species is covered in detail in Section 4.4.4.

4.4.1 Identifying the critical data

Few data for an oral route of exposure are available for organisms other than birds and mammals. Whilst scientific and data developments may allow us to assess risks to aquatic predators in the future, in the meantime we must adopt biota standards for birds and mammals, assuming these values provide adequate protection to other taxa that might be at risk from secondary poisoning (e.g. predatory fish). This assumption might only be valid if the secondary poisoning of predators is the most-sensitive route and if the $QS_{biota,\ secpois}$ with the corresponding water concentration is significant lower than a QS for protecting pelagic species.

If relevant ecotoxicological information (e.g. fish feeding studies) can be found in the literature or can be produced for supporting sound QSs, the same approach developed for bird and mammals can be used for pelagic fish species.

The general methodology to derive a $QS_{biota,\ secpois}$ is based on the simple food chain described above and assumes that all species at a certain trophic level contain similar concentrations of pollutants. In addition, it assumes 100% reliance on a particular prey item. This assumption is appropriate where EU-wide standards are required (e.g. for Priority Substances and Priority Hazardous Substances) and to promote consistency in approaches across Member States for Annex VIII substances (Specific Pollutants) of the WFD. However, if a site-specific assessment is required, these assumptions may be refined as described in Appendix 4. The lowest reference concentration is used to derive a $QS_{biota,\ secpois}$ for predators. For substances with a high potential to biomagnify within food chains, it is important that the $QS_{biota,\ secpois}$ be applied to the appropriate aquatic trophic level to protect all predators feeding. Application of the $QS_{biota,\ secpois}$ at that level will also protect wildlife feeding at lower trophic levels. Monitoring should be based on the sampling and analysis of tissues from the prey species.

Although it is not currently practical to develop separate quality standards for the protection of pelagic predators, it is useful to assess whether or not the quality standard for biota is likely to be protective of exposures via food and whether or not the quality standard for water is likely to be protective of exposures via the water. It may be necessary to review this position if information becomes available suggesting that combined exposures (i.e. from both the water and food) lead to greater risks. Under these circumstances, the quality standards may not be protective and a review may be warranted.

4.4.2 Data requirements

Only toxicity studies reporting on dietary and oral exposure are relevant because the pathway for secondary poisoning deals exclusively with uptake through the food chain. Studies that assess effects on developmental or reproductive endpoints are likely to be critical studies because these tend to be more-sensitive endpoints (i.e. give rise to lower $NOEC_{oral}$ values) than survival endpoints.

As secondary poisoning effects rarely become manifest in short-term studies, results from long-term studies establishing long-term NOECs are strongly preferred. A QS derived where no chronic effects data are available is subject to high uncertainty and this must be flagged in the datasheet. The minimum duration for the study requirements is dependent on the characteristics of the chemical and the lifespan and life-stage of the test species. Effects data should ideally relate to tests of 90 days duration or longer (this would result in an AF of 90 or lower according to the TGD and REACH guidance). However, many mammalian toxicity data are generated from 28-day studies. These may be used after correction for daily food intake, as described in Section 4.4.3. The risk of selecting a study with an insufficient length of exposure as the critical datum could underestimate the potency of a compound, and therefore the $QS_{biota,\ secpois}$ may not be protective. On the other hand, by applying a higher assessment factor than needed, the QS may be over protective.

As toxicity data for wildlife species are not normally available, it will be necessary to extrapolate threshold levels from toxicity data of laboratory test species to wildlife species. If studies are available for wildlife species as well as for conventional laboratory test species, both should be included in the assessment.

Further guidance on bird and mammalian toxicity data and their evaluation is provided in the REACH guidance (ECHA, 2008) and in the European Food Safety Authority guidance document (EFSA, 2007).

4.4.3 Expressing toxicological endpoints as a concentration in food

Mammalian or avian toxicity data may be expressed as NOECs relating to concentration in food ($NOEC_{oral}$, expressed in units of $mg \cdot kg^{-1}$ food) or as no observed adverse effect levels relating to dose ($NOAEL_{oral}$, expressed in units of $mg \cdot kg^{-1}\ bw \cdot d^{-1}$). For the standard derivation of EQSs for secondary poisoning, the results need to be expressed as the concentration in food because this is the basis of the adopted risk model. The general rule for the conversion is that the concentration in food is equal to the daily dose multiplied by the body weight (bw) divided by the daily food intake (DFI), or

$$NOEC_{oral} = NOAEL_{oral} \frac{bw}{DFI}$$

where:

– $NOEC_{oral}$ = no observed effect concentration ($mg \cdot kg^{-1}$ food);
– $NOAEL_{oral}$ = no observed adverse effect level [$mg \cdot kg^{-1}\ bw \cdot d^{-1}$];
– DFI = daily food intake ($g\ food \cdot d^{-1}$); and
– bw = body weight (g).

Table 4.1 presents a guide with a standard set of conversion factors that can be used to promote internal consistency when converting concentrations from dose into diet for mammals. The guide should be used only in the absence of more specific data from the study itself or other sources. For example, a chicken (Gallus domesticus) typically consumes around one eighth of its body weight per day, and so the conversion factor in this case would be 8 kg bw·d·kg–1 food. It should be noted that the conversion factors for young birds and mammals might differ from those for adults. For avian reproduction studies, a default factor of 10 can be used as a conversion factor (i.e. bw/DFI = 10) (see Appendix 6 of EFSA, 2008). For this conversion to be valid, no food avoidance should have occurred in the study. Recommendations from EFSA (2008) should be considered as indicative. REACH guidance (ECHA, 2008) should be followed rather than EFSA (2008).

Table 4.1 Conversion factors for converting NOAELs (dose) from mammalian toxicity studies into NOECs (concentration)

Species	Age/study	**Conversion Factor** (bw/DFI) (ECHA, 2008; EC, 2003)	**Conversion Factor** (bw/DFI) (EFSA, 2008)
Rat (Rattus norvegicus	>6 weeks	20	
Rat (Rattus norvegicus)	<6 weeks	10	
Rat	28 and 90days		10
Rat	Two generation study first mating[a]		12.5
Rat	Two generation study overall (females)[a]		8.33
Mouse (Mus musculus)	28 and 90days	8.3	5.0
Vole (Microtus spp)		8.3	
Rabbit (Oryctolagus cuniculus)		33.3	
Dog (Canis domesticus)	Adult/all	40	40
Monkey (Macaca spp)		20	
Chicken (Gallus domesticus)		8	

[a] The first mating value for a two-generation study should be used for assessment when effects (general or on reproduction) are seen to relate to the pre-mating phase of the first mating, or effects are seen only in male F0 parents at any time. For all other aspects of a two-generation study, the overall conversion figure should be used.

NOECs derived from NOAELs in this way are assumed to be equivalent to directly measured NOECs.

4.4.4 Extrapolation to derive a $QS_{biota,\ secpois}$

Two approaches can be followed to determine this quality standard for biota. These approaches are briefly described here with further detail provided in the following sections.

The first is the standard approach from the TGD (EC, 2003; ECHA, 2008). In this methodology, the concentration in the diet of the toxicity test is the basis for the quality standard in biota. The extrapolation from diet to biota comprises the interspecies variation, differences in exposure duration, as well as the difference in caloric content of the diet of laboratory animals and the diet of fish-eating birds or mammals (EC, 2003).

In the second approach, the dose rather than the diet concentration, is used as a starting point (EFSA, 2008), which helps to minimise bias relating to different food intake rates between laboratory and field situations. A group of key species should represent all the organisms at risk from secondary poisoning. Information on body weight, dietary composition and feeding rate by predators are necessary to select those species most likely to experience the highest exposures to contaminants through the aquatic food web. By definition, if these are protected (and the assumptions are correct) other species will also be protected.

4.4.4.1 Derivation of QSbiota, secpois according to the standard approach in REACH

The quality standard that describes the threshold concentration of a substance in the food of a predator, $QS_{biota,\ secpois}$ (≈ $PNEC_{oral}$, in $mg{\cdot}kg^{-1}$ food), is derived by applying appropriate assessment factors (AF_{oral}; see Table 4.3) to the selected NOEC oral for each species. There may be more than one chronic study for the same species. Under these circumstances, the assessor should select the more sensitive study. Data from two different toxicological studies should only be merged if they have been conducted according to a similar guideline, use the same species and test conditions and report the same key endpoints. It may be that a test with a shorter exposure duration reports a more sensitive endpoint than the test with longest exposure duration. In such a case, the assessment factor corresponding to the longest exposure time may be applied to the most sensitive endpoint.

Table 4.2 Assessment factors for the extrapolation of mammalian and bird toxicity data into $QS_{biota,\ secpois}$ (EC, 2003)

TOX_{oral}	Duration of test	AF_{oral}
$NOEC_{oral,birds}$	chronic	30
$NOEC_{oral,mammals}$	28 days 90 days[a] chronic	300 90 30

[A] for consideration of reproduction studies

Since monitoring in biota in the marine compartment is preferably performed at the level of fish rather than e.g. seals, the $QS_{biota,\ secpois}$ for the marine compartment should include BMF_2 (cf. figure 4-1 in section 4.3. Therefore:

$$QS_{biota,secpois,\ fw} = \frac{TOX_{oral}}{AF_{oral}}$$

$$QS_{biota,secpois,sw} = \frac{TOX_{oral}}{AF_{oral} \cdot BMF_2}$$

The final value for the $QS_{biota,\ secpois}$ is selected by comparison of the different values for the tested species and choosing the lowest resulting values (EC, 2003; Lepper, 2005). If sufficient data are available, there is no reason why a probabilistic approach to extrapolation (ie an SSD approach) should not be used. However it should be noted that in the applied assessment factor the factor of 10 to extrapolate from the lowest chronic NOEC values to the $QS_{biota,\ secpois}$ is already included and that when applying a statistical extrapolation, the NOECs need ony to be converted from subacute

(28d; factor 10) and subchronic (90d; factor 3) to chronic and from laboratory diet to fish or mussels (all data; factor 3). For the application of a species sensitivity distribution (SSD), data should be available for a minimum of 10 species. The dataset should include both birds and mammals and should also include wildlife-relevant predatory species of both birds and mammals. For further considerations, the assessor is referred to Section 3.2.4.2.

If chronic NOECs for both birds and mammals are available, the lower of the toxicity values is used in the secondary poisoning assessment. In many cases, only acute toxicity data for birds will be available. Although there is no predictable link between and acute and long term toxicity (ie a substance that is of low acute toxicity will not necessarily be of low long-term reproductive toxicity), a pragmatic approach in the absence of a chronic study is to derive an 'indicative' $QS_{biota,\ birds}$ by applying a large (precautionary) AF of 3000 to the lowest reliable lethal concentration for 50% of the individuals (LC50) value (ECHA, 2008, section R.10.8.2). If the resulting 'tentative' $QS_{biota,\ birds}$, is lower than the $QS_{biota,\ mammals}$ then, given the lack of information on relative sensitivities between birds and mammals, the uncertainties should be highlighted in the datasheet.

4.4.4.2 Derivation of QSbiota, secpois according to the refined approach using key species

If it is possible to identify the key indicator wildlife species in the ecosystem the following approach can be used to derive the $QS_{biota,\ secpois}$. The key species is defined as the most susceptible species on the basis of its ratio of body and daily food intake and its position in the trophic chain (the latter only of the substance is subject to significant biomagnification). The NOEC for the key indicator wildlife species can then be calculated from the lowest reliable NOAEL from laboratory studies using information on body weight (bw) and daily food intake (DFI) for these species as indicated below:

$$NOEC_{wildlife} = NOAEL_{laboratory} * (bw_{wildlife}/DFI_{wildlife})$$

Only the mammals NOAEL is used to extrapolate to mammalian wildlife species. Similarly, only the avian NOAEL is used to extrapolate to avian wildlife species. Then the $QS_{biota,\ secpois}$ is derived from the $NOEC_{wildlife}$ in this case using the assessment factors from Table 4.4. In this table the extra factor of three for the difference in caloric content between laboratory food and a diet based on fish and/or mussels is omitted.

Table 4.3 Assessment factors for the extrapolation of mammalian and bird toxicity data into $QS_{biota,secpois}$ in a refined assessment

TOX_{oral}	Duration of test	AF_{oral}
$NOEC_{oral,\ birds}$	Chronic	10
$NOEC_{oral,\ mammals}$	28days [a]	100
	90days	30
	Chronic	10

[a] Note: The AF of 3 accounting for extrapolation from laboratory to field is omitted because the method already takes the dietrary intake differences between laboratory and field into account

The resulting AF should allow for interspecies variation in sensitivity to account for differences in toxicity. A factor of 10 accounting for interspecies variation is appropriate for this purpose. An additional AF of 3 to 10 is applied when exposure periods are not truly chronic (ie subchronic to chronic extrapolation).

The same considerations as in the standard approach may be applied with regard to the use of acute avian data and data treatment for the same species. For application of the SSD method the same considerations as in the standard approach are valid with the exception that in this case the input data should be based on dose and not diet concentrations.

4.5 Protection of humans against adverse health effects from consuming contaminated fisheries products

The QSbiota, hh food is intended to protect all humans against adverse health effects from consuming contaminated fishery products. Dealing with risks to human health from substances in drinking water is covered in Section 3.9. Like the biota standards for protecting predators, the standards described here are expressed in terms of body residues in food items.
No internationally recognised approach exists for determining the uptake of contaminants from fishery products by humans. However, several EU Directives (Council Directives 91/414/EEC and 97/57/EC) specifically deal with the risks to humans from several classes of organic contaminants, such as dioxins, dioxin-like polychlorinated biphenyls (PCBs) – PCB congeners that exhibit toxicological properties similar to dioxins – and polyaromatic hydrocarbons (PAHs) (Council Regulation (EC) No 1881/2006 of 19 December 2006), and metals, such as lead, cadmium and mercury (Council Regulation (EC) No 78/2005, amending Regulation 466/2001), via edible aquatic species, such as fish, molluscs, crustaceans and cephalopods. Therefore, when legislation has already led to the derivation of standards, the $QS_{biota,\ hh\ food}$ should refer to the maximum allowable concentration in $\mu g \cdot kg^{-1}$ wet weight in the specific tissue or sampling material.

Where no established $QS_{biota,\ hh\ food}$ value exists, the procedure described in Lepper (2005) is recommended. It assumes that the uptake of a substance from fishery products does not exceed 10% of the relevant threshold level (TL), estimated from experimental data and expressed in $\mu g \cdot kg^{-1}\ bw \cdot d^{-1}$ for humans. For practical purposes, the acceptable daily intake (ADI), tolerable daily intake (TDI) or $NOAEL_{oral}$ (the latter divided by an assessment factor) provides such an estimate. The $QS_{biota,\ hh,\ food}$ (expressed as $\mu g \cdot kg^{-1}$) is calculated using defaults for human bw (70 kg) and for the consumption of fishery products ($0.115\ kg \cdot d^{-1}$) as follows:

$$QS_{biota,\,hh\ food} = \frac{0.1 \cdot TL \cdot 70}{0.115}$$

This approach does not specifically consider possible sensitive groups, such as the developing foetus or subpopulations that consume more fishery products than the European average. However, the assumption that fishery products make up no more than 10% of the threshold level value (0.1·TL) at the European average level of compound uptake provides a margin of safety.

4.6 Metals

The approach described above for secondary poisoning and human consumption of fishery products, whereby NOEL, NOAELs for secondary poisoning and ADI, TDI or a comparable human threshold values for fishery products are used, is also applicable to metals. After the quality standard in biota has been derived, it should be compared to the background levels of metals in biota. The definition of the natural background level for metals in biota is as for in water, and the same types of difficulties exist when determining the level. In general, the considerations concerning natural background levels in biota are as for water (see Section 3.5).
Preferably, measurements of metals in biota should be taken from species living close to springs or far at sea. It should be recognized that biota may take up metals from the water as well as from particulate matter in water, including plankton, or from the sediment. In general, measurements in biota living in water where metal levels are elevated in either the sediment or the water should not be used for the determination of the natural background level of the substance in biota. The background concentration in biota is species specific and is further influenced by organisms age/size and the local food habits. Therefore background concentrations for biota should always be reported with species age or size and origin.

4.7 Monitoring compliance with biota standards

4.7.1 Biota monitoring

Procedures for species monitored through international conventions for inland, transitional, coastal and marine waters already exist, e.g. Helsinki Commission (HELCOM), OSPAR, International Commission for the Protection of the Rhine (ICPR). A separate background document summarises current monitoring programmes in Europe, and detailed guidance on the sampling and analysis of chemical residues in biota and sediments is the objective of another guidance document that is being prepared by the Chemical Monitoring Activities Working Group (EC, 2010).

4.7.1.1 Selection of species for monitoring

The primary aim of existing biota monitoring programmes is to assess environmental concentrations through long-term surveillance monitoring but, in principle, species that are already used in existing national or international monitoring programmes should be used for biota monitoring. The choice of particular species is not specified here, but certain criteria should ideally be met:

- The choice of species monitored should depend on the identified protection goal (e.g. humans, top predators).
- The standard in biota refers to a trophic level that is defined by the simple food chain (Section 4.4).
- The sampled organisms need to be potential food for predatory organisms or humans.

To provide an unbiased sample, the use of bulk samples of many individuals is recommended. Furthermore, those life-cycle stages that are most likely to be consumed by predators should be preferred and/or the organisms need to be of a size that is relevant to predator species. Large animals have fewer predators and analysis of these individuals may not provide any useful additional information about predator exposure. However, if the species selected is not high enough in the food chain, the outcome from monitoring could be underprotective for biomagnifying substances (if the concentration of a biomagnifying substance is close to the biota standard at lower trophic level, the concentration would exceed the biota standard at higher trophic levels for such substances). If selection of such a representative species is not possible from the point of view of standard organisms to be monitored in routine monitoring programmes, the biota standard should be adjusted to the appropriate trophic level of the monitored species .

4.7.1.2 Biota monitoring to infer water concentrations

Some Member States may prefer to monitor compliance with EQSs expressed as water concentrations from residues in biota, i.e. to use biota for inferring concentrations in water. This might apply when an EQS is lower than three times the LOQ[25] (limit of quantification). In this case, it is not always possible to quantify some substances in water. In addition, because of dilution effects and a decrease in the solubility of hydrophobic pollutants and metals in transitional, coastal and marine waters, it is expected that low concentrations might occur in these systems. Biota and sediments are able to integrate the pollutant concentrations over a period of time (usually months/years), while water is more variable and, in the case of sea water, levels can be related to the tide period as well as the main current or predominant wind during the sampling. If biota sampling is used in this way, there must be a good correlation between levels of the contaminants in the organism and in the surrounding water so that the biota concentration can be used to estimate the water concentration with confidence. For example, mussels (*Mytilus edulis*, *Mytilus galloprovincialis*) are likely to be a favoured genus in the marine environment because of the existence of historical datasets.

4.7.1.3 Sampling

The sampling frequency, sampling methods, sample preservation and cleanup should follow the guidelines already defined in the WFD monitoring guidance (EC, 2010). Although there are greater unit costs associated with collecting samples and performing the analysis for biota than for water, the sampling frequency is lower than for water.

4.7.2 Converting QSs expressed as biota concentrations into equivalent water concentrations

4.7.2.1 Organics

Normally, the $EQS_{biota}$is expressed as a body residue. It follows that monitoring is also performed in biota. The biota standard ($\mu g \cdot kg^{-1}{}_{diet}$) could, however, be converted into a water column concentration standard ($QS_{fw,secpois}$ or $QS_{sw, secpois}$ in $\mu g \cdot l^{-1}$), e.g. for comparison with other water column standards (see Section 2.5) to select an overall EQS, or to fit in with national monitoring regimes that use only water sampling. This conversion uses the threshold in prey (QS_{biota}) and bioaccumulation data (BCF, BMF and/or trophic magnification data) of the substance concerned. Effectively, the back calculation to a water concentration is equivalent to estimating the PEC_{oral} in chemical risk assessment. As explained below, it is necessary to account for the longer food chains in the marine environment where it concerns the secondary poisoning route, by incorporating not only biomagnification in the prey of predators (BMF_1, as for freshwater), but also in the prey of top predators (BMF_2). This does not apply to the EQS derivation for human fish consumption as here, fish is the species consumed by the 'top predator' (humans). However, the BMF_2 is also needed to set the EQS_{biota} for the marine environment because it is unacceptable to monitor at the trophic level of the marine predators, such as seals, that serve as food for the top predators, such as killer whales and polar bears. This leads to a different value for QS_{biota} for freshwater and QS_{biota} for saltwater where it concerns secondary poisoning, which is explained in the next section.

There are important issues involved in expressing the biota standard as a concentration in prey or as as a concentration in water and these are summarised in Table 4-5.

Table 4.4 Considerations in expressing a biota standard as a concentration in prey or in the water column

	Conversion into a water-column QS	Expression of the standard as body residue
Selection of a suitable 'matrix' for monitoring	• Easy (Daughter Directive text currently requires whole water for organics) • Analytical sensitivity issues likely (see below)	• Need to decide on appropriate trophic level, and species and tissue for monitoring (whole body or specific organ?)
Uncertainty in deriving EQS	• Uncertainty in BCF/BMF or BAF used in converting into water-column standard	• Uncertainty concerning AFs applied to TOX_{oral} and TDI and BMF_2 (only for the marine environment) • Uncertainty in converting into water-column standard eliminated
Comparison with other water-column EQSs	• Direct comparison possible	• Different matrix so cannot compare directly
Availability of data	• Requires toxicity data from feeding studies and BCF and BMF, or BAF	• Requires only toxicity data from feeding studies and BMF_2 (only for the marine environment)
Analysis	• Consistent with existing practice • $QS_{fw, secpois}$ or $QS_{sw. secpois}$ or $QS_{water, hh food}$ often < LOQ • Individual sample costs < biota sample costs, but method development required to achieve required sensitivity • Several samples needed per year	• Method development (e.g. cleanup) may be required to deal with biological matrix • Individual sample costs > water sample costs, but only infrequent sampling needed (requested actually 1/year, but 3 to 4 times/year seems more reasonable)
Relevance to water quality classification	• Need high quality data on food webs and the identification of the correct trophic level • Existing classification rules can apply, e.g. QA/QC Directive, but with high uncertainties and, therefore, low confidence that failure has actually occurred, in part because of sampling uncertainties that come with spot samples	• High – biota residue effectively integrates exposure over long time periods • Need high quality data on food webs and the identification of the correct trophic level for sampling the correct species

Where a QS_{biota} (in general) is to be converted into QS_{water}, experimental BCF and BMF data, or a field derived BAF, are required. The water concentration value is calculated as follows:

$$QS_{water} = \frac{QS_{biota}}{BAF}$$

The term bioaccumulation refers to transfer mechanisms of hydrophobic contaminants by both bioconcentration (accumulation via media) and biomagnifications (accumulation via food). Normally, the combined effects of each step are combined in a multiplicative approach. Therefore, the BAF may be calculated as:

$$BAF = BCF \cdot \prod_{i=1}^{n} BMF_i$$

where the number of BMFs depends on the trophic level or position of the organism in the food web. According to REACH Guidance (ECHA, 2008), a simple food web is assumed that consists of water –BCF→ aquatic organisms –BMF_1→ fish → fish-eating predator. As indicated above, for marine top predators, an additional BMF in prey of top predators (BMF_2) should be applied. Therefore:

$$QS_{fw,\sec pois}(\mu g / l) = \frac{QS_{biota,\sec pois,\ fw}(\mu g / kg)}{BCF(l / kg) \cdot BMF_1}$$

$$QS_{sw,\sec pois}(\mu g / l) = \frac{QS_{biota,\sec pois,\ sw}(\mu g / kg)}{BCF(l / kg) \cdot BMF_1}$$

There are ways in which uncertainty in the calculation can be reduced:

1. The field BAF value for the correct trophic level should be used.
2. The laboratory BCF value is multiplied by the field BMF.

Ideally, the BMFs should be based on measured data. In general, the most reliable data on biomagnification originate from trophic magnification studies. In such studies, the levels of contaminants in several species in an ecosystem are measured and expressed as a function of the trophic level. The trophic level is mostly derived from stable nitrogen isotope ratios and a regression is made between contaminant concentration and trophic level. The contaminant values should preferably be normalised to the fraction in the organisms that contains the substance, e.g. lipids.

The advantage of this method is that it takes into account magnification along the whole food chain and it is not subject to the rather arbitrary choice of two species for which a BMF is calculated. The BMF_1 may be deduced from the increase in (lipid-normalised) concentration of the contaminant over one trophic level in a simple pelagic food chain. Food web magnification factors (FWMFs) or trophic magnification factors (TMFs) are based on the slope of the regression of the logarithm of the concentration versus trophic level. The trophic level is calculated assuming an enrichment of 2 to 5‰ (usually 3.4 or 3.8‰) for $\delta^{15}N$ (based on stable nitrogen isotope ratios) per trophic level. The value of the FWMF or TMF can be taken as the BMF over one trophic level, equivalent to BMF_1 in a pelagic food chain. Care must be taken that the regression is based on trophic level rather than $\delta^{15}N$. If this is not the case, a correction for the increase of $\delta^{15}N$ per trophic level has to be applied.

For the marine environment, an extra BMF is included. In this case, poikilotherms (invertebrates and fish) and homeotherms (seabirds and mammals) should be distinguished. As the first group is related to the first BMF for fish, the second group is representative for the biomagnification in predating birds and mammals. Thus, BMF_2 should preferably be extracted from a study that describes such a food chain. In general, the biomagnification in homeotherms is larger than that in poikilotherms and, thus, BMF_2 is generally larger than BMF_1.

If it appears that the FWMF or TMF is not significantly greater than one, it is reasonable to conclude that there is no significant biomagnification, and both values for BMF may be set to one. If the value for FWMF or TMF is significantly below one, trophic dilution is indicated. For the pelagic food chain, BMF_1 then equals one, as the BMF value represents biomagnification from small fish to predatory fish, while the metabolic capacity in fish is assumed to be uniform and the BCF will mostly refer to fish. For the marine environment, not only the top predators, but also the predators that feed on fish should be protected. Therefore, even if trophic dilution occurs from predator to top predator, this step in the food chain is then superfluous as both refer to toxicity of mammals and birds. In this case, BMF_2 has to be set equal to one as well.

Other sources of information are BMFs from field or laboratory studies. Care should be taken in interpreting these values because they only represent one link in the food chain and may not represent the overall biomagnification potential of a substance. A BMF is restricted to the ratio between the concentrations in the predator and in its prey or food in the case of a laboratory study.

The availability of biomagnification data is limited; therefore, the default BMF values given in Table 4-6 (EC, 2003) may be necessary. However, a reliable experimental BCF value is always preferred above the log K_{ow} to estimate the BMF value because it takes the metabolism of the substance into account, which is an important parameter in food web accumulation.

Table 4-5 Default BMF values for organic substances

log K_{ow} of substance	BCF (fish)	BMF_1	BMF_2
<4.5	<2000	1	1
4.5–<5	2000–5000	2	2
5–8	>5000	10	10
>8–9	2000–5000	3	3
>9	<2000	1	1

The conversion from a biota standard into an equivalent water concentration can introduce uncertainty, especially for highly lipophilic substance (i.e. BCF >2000). Generally, substances with a BCF of 500 or less can be converted into an equivalent water concentration with reasonable confidence. Where it is necessary to convert a biota QS into an equivalent water-column concentration, the uncertainties involved in making the extrapolation may be taken into account by performing the conversion for extreme BAF values as well as using the typical BAF value. If the QS for water lies within the range of possible extrapolated values of the QS for biota, when considering the uncertainties of the extrapolation, it is not possible to determine with high confidence which is the ‘critical’ QS. The worked examples for hexachlorobenzene (HCB) and lindane below show that for HCB the biota QS is likely to be the critical QS regardless of the uncertainties of the extrapolation, whereas in the case of lindane there is uncertainty as to whether the biota QS or the water QS is the critical QS.

HCB example

QS_{water}	13 ng·l^{-1} (EQS Substance data sheet, 2005)
$PNEC_{oral}$	16.7 g·kg^{-1}(EQS Substance data sheet, 2005)
BAF	52,300 L·kg^{-1} (mean value; 26 experimental fish BAF values, min 8130, max 550,000, median 51,900) (Arnot and Gobas, 2006)

$$EQS_{water} = \frac{EQS_{biota}}{BAF}$$

Extrapolated QS_{water}

Calculated with median BAF	0.3 ng·l^{-1}
Calculated with minimum BAF	2 ng·l^{-1}
Calculated with maximum BAF	0.03 ng·l^{-1}

Lindane example

QS_{water}	20 ng·l^{-1} (EQS Substance data sheet, 2005)
$PNEC_{oral}$	33 g·kg^{-1}
BCF	1300 (selected in the EQS datasheet, min 220, max 2200) (EQS Substance datasheet, 2005)[24]
BMF	A BMF of 1 was assumed according to the TGD (EC, 2003)

$$EQS_{water} = \frac{EQS_{biota}}{BCF.BMF}$$

Extrapolated QS_{water}

Calculated with selected BCF	25 ng·l^{-1}
Calculated with minimum BCF	150 ng·l^{-1}
Calculated with maximum BCF	15 ng·l^{-1}

4.7.2.2. Metals

If a secondary poisoning risk (to birds and mammals) from metals is identified (Section 2.4.3.1), or a risk for human fish consumption then the methodology described in Section 4.4 for the derivation of the $QS_{biota,secpois}$ or Section 4.5 for the derivation of the $QS_{biota,\ hh\ food}$ should be followed.

Where toxicological information on critical body (or organ/tissue) levels is lacking, BCFs or BAFs may be used to estimate metal accumulation in animals relative to the concentration in water.

There are added complexities when selecting an overall EQS because BCFs used to back-calculate to a water concentrationmay depend on water concentration. For naturally occurring substances, such as metals, many species regulate their internal concentrations through (1) active regulation (2) storage or (3) a combination of active regulation and storage over a wide range of environmental exposure conditions. Although these homeostatic control mechanisms have evolved largely for essential metals, they are not entirely metal specific and will, to some extent, apply to non-essential metals. A list of metals and metalloids classified by their essentiality to organisms is given in Table 4-7 (ICME, 2001)

[24] Note that the example for lindane used here follows the EQS datasheet (2005), but does not use a BAF value, or apply a BMF value. Use of a BAF value (e.g from Arnot and Gobas, 2006) results in the biota QS being the critical QS.

Table 4-6 Metals and metalloids classified by essentiality to living organisms

Essential	Non-essential
Cr, Co, Cu, Fe, Mn, Mo, Ni, Se, Zn	As, Sb, Cd, Pb, Hg, Tl, Ag, Sn

At low metal concentrations organisms accumulate essential metals (and often non-essential metals via the same uptake mechanisms) more actively in order to meet their metabolic requirements. At higher concentrations organisms with active regulation mechanisms even limit their uptake by the extraction of excess metals (ECHA, 2008). As a consequence metal concentrations in tissue based on a range of exposure concentrations may be quite similar yet the BCFs/bioaccumulation factors (BAFs) are variable, even showing an inverse relationship with external metal concentrations (ie higher BCFs at lower exposure concentrations and lower BCFs at higher exposure concentrations). This means that the use of BCF values for metals must be performed with care.

The text below sets out the steps to be used to select an overall EQS for metals:

1. **Derive standards in biota**
- Derive the $QS_{biota,\ secpois\ fw}$ or the $QS_{biota,\ secpois\ sw}$ following guidance in Sections 4.4 and 4.5.
- Compare the derived value to background levels of the substance for biota and ensure that the QS_{biota} > background concentration in biota (Section 4.6).

2. **Estimate biomagnification (BMF) and bioconcentration (BCF, BAF)**
- Collect (preferably) field-determined BAF data, e.g. of fish and molluscs, in which both internal and external metal concentrations have been reported.
- Determine the relationship between internal and external concentrations for the metal for several species (e.g. fish, molluscs). The $QS_{fw,\ secpois}$ or $QS_{sw,\ secpois}$ and $QS_{wataer,\ hh\ food}$ should be included in the range of internal concentrations (biota concentrations) or, alternatively, the $QS_{fw,\ eco}$ or $QS_{sw,\ eco}$ should be included in the range of external concentrations (water concentrations).
- Collect any relevant data that can be used to assess the bioavailability/bioaccessibility of tissue-associated metal.
- Determine the BMF relevant to the food chain considered.

3. Compare tissue concentration or water concentrations for the routes of direct ecotoxicity and secondary poisoning
- Compare the QS_{biota}/BAF or QS_{biota}/(BCF·BMF) with $QS_{water,eco}$ using a BAF or BCF and BMF that is determined at an internal (biota) concentration equal to the QS_{biota} or, alternatively, compare the $QS_{water,eco}$·BAF or $QS_{water,eco}$·BCF·BMF with the QS_{biota} using a BAF or BCF and BMF that is determined at an external (water) concentration equal to the $EQS_{water,eco}$. A prequisite is that the relationship between internal and external concentrations should be well determined, otherwise this approach cannot be followed.
- If a specific BAF or BCF is not available, a worst case approximation can be made using a BAF or BCF determined at a concentration in water *lower* than the $QS_{water,eco}$.

Does secondary poisoning lead to lower levels than direct ecotoxicity?

$QS_{water,secpois}$ is protective for these effects – no further work

Adopt EQS_{biota} as the overall EQS

For metals, BCF values may be obtained in a variety of ways:

- In cases where there is evidence of concentration dependency of BCFs (i.e. the BCF is higher at lower environmental levels), regression models based on the observed inverse relationship should be used to derive the most-appropriate BCF value for the prey organisms considered (Brix et al., 2001; Efroysmen et al., 2001, McGeer et al., 2003, DeForest et al., 2007).

- Where regression lines cannot be calculated, BCFs may be obtained either by calculating species-specific arithmetic means from BCF studies using environmentally relevant metal concentrations in the test media or by using BAFs observed in the field (Lepper, 2005).

Where there is a choice of BCF or BAF values, the use of BAF is preferred because it considers not only uptake via water, but also exposure via food or sediments, and is therefore considered to be ecologically more relevant than BCF values.

5. STANDARDS TO PROTECT BENTHIC (SEDIMENT DWELLING) SPECIES

5.1 Introduction

Sediments can act as a sink for chemicals through sorption of contaminants to particulate matter, and may act as a source of contaminants to particle feeders through resuspension (eg by dredging or natural events) or back to the water phase by desorption. The derivation of sediment EQSs is particularly relevant for hydrophobic substances and some metals (see 2.4.2). EQSs for sediments are used instead of alongside or, instead of, EQSs for other compartments to assess the status of water bodies. EQSs for sediments are required to protect benthic (sediment-dwelling) species.

Sediments are a major sink for historic pollutants and changes in bioavailability of such contaminants makes compliance assessment more complex than in other compartments. As with other standards, major sources of uncertainty in standard derivation should be highlighted in the technical datasheet dealing with sediment EQSs, along with suggestions on how they might be ameliorated. Section 5.3 provides further suggestions to policy makers on how sediment quality can be assessed and how to identify where management measures may be warranted.

5.2 Derivation of sediment standards

The derivation process is based on that used for effects assessment under REACH (ECHA, 2008) but with an additional consideration of field or mesocosm data. This enables different lines of evidence (sediment toxicity tests, aquatic toxicity tests in conjunction with equilibrium partitioning (EqP) and field/mesocosm studies) to be used to generate the final standard (Figure 5-1). Further detail on each of these steps, eg the use of Equilibrium Partitioning, is provided in the following sections. The temporary standards used in the derivation of sediment standards are explained in Appendix 6.

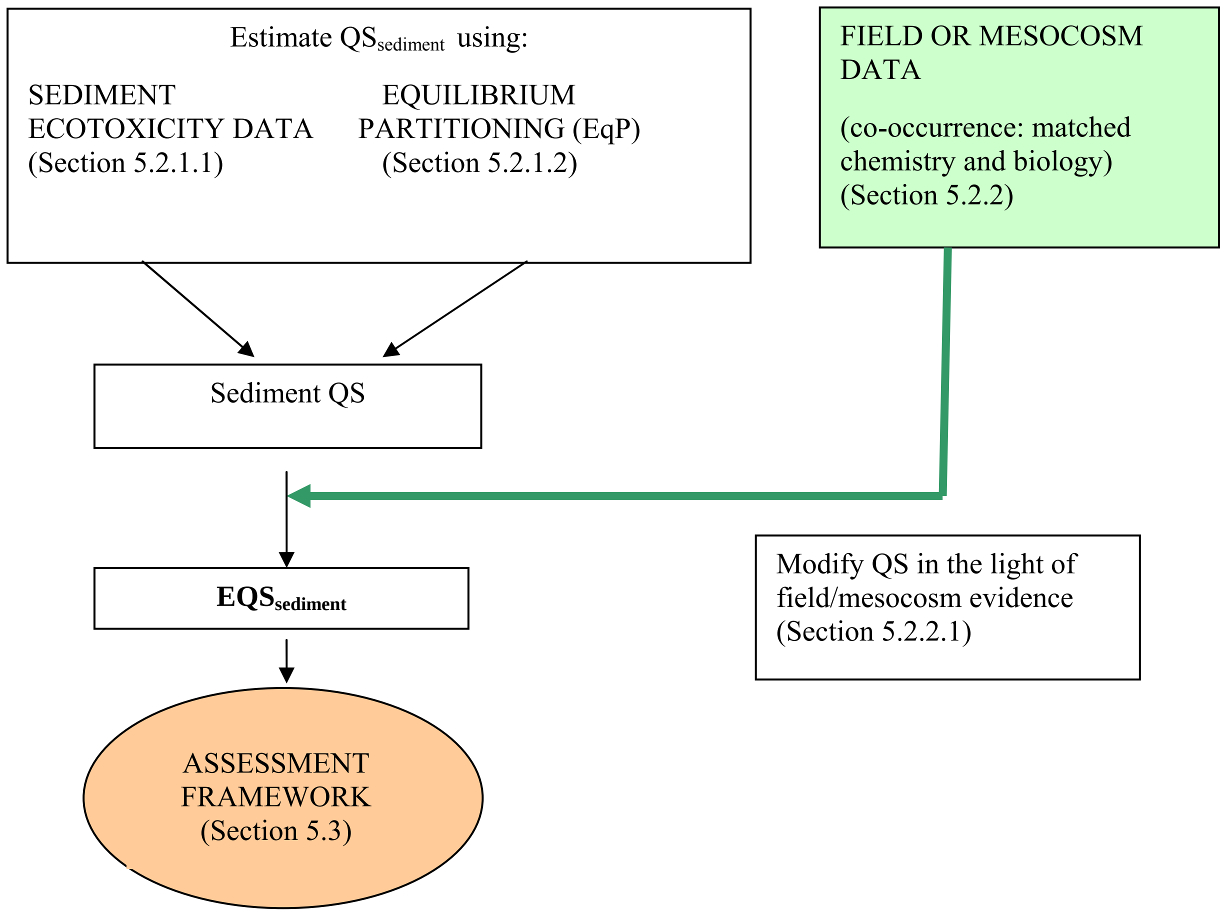

Figure 5.1 Overview of process for deriving a sediment standard

5.2.1 Derivation of $EQS_{sediment}$ for the protection of freshwater benthic organisms

Data used for the derivation of EQS for sediment can include:

(i) ecotoxicity data from experiments with benthic organisms (Section 5.2.1.1)
(ii) water column ecotoxicity data used in conjunction with equilibrium partitioning (Section 5.2.1.2)
(iii) empirical field or mesocosm data (e.g. co-ocurrence of benthos and chemical contamination in the field (Section 5.2.1.3)

Where sediment ecotoxicity data are available, option (i) is preferred over option (ii) because of the assumptions and uncertainties inherent in the equilibrium partitioning approach (detailed in Section 5.2.1.2).

5.2.1.1 Use of sediment toxicity data to derive quality standards

Most sediment laboratory toxicity data are based on the use of spiked sediments in which clean sediment has been deliberately contaminated in the laboratory and test organisms introduced to this spiked sediment. Most tests have been performed according to OECD, ASTM or USEPA guidelines using benthic invertebrates (e.g. *Chironomus riparius* OECD 218 - chironomid test/spiked sediment / growth and emergence). Other test species may be used but details on the test conditions must be reported and the data should be assessed for reliability and relevance as described in Section 2.6.2. Further guidance, specific to sediment toxicity tests, is to be found in Appendix 1.

Test data in which availability of the contaminant is maximised are preferred. Maximising exposure should lead to the derivation of more protective values and decrease the uncertainty associated with EQS (ie reflect a 'worst case' scenario). In the EU, a 'standard sediment' has a default organic carbon (OC) content of 5% and for organic chemicals a normalisation of toxicity data to this standard sediment is preferred for the derivation of the $EQS_{sediment}$.

For substances for which the bioavailability is dependent on the organic carbon content of the sediment, the variability introduced by the presence of toxicity values generated at different organic carbon concentrations can be accounted for by normalizing each (valid) toxicity test result (LC50, EC50, EC10, NOEC) to organic carbon and then express all results in sediment with a standard organic carbon content. The resulting sediment standard can be recalculated to any organic carbon content measured in the field. The organic carbon content of the EU standard sediment is 5%, equal to that used in the TGD, REACH and EUSES.

$$\text{TEST RESULT}_{\text{EU standard sed}} = \frac{\text{TEST RESULT}_{\text{test sed}} \text{ x } F_{\text{oc, EU standard sed}}}{F_{\text{oc, test sed}}}$$

Parameter	**Description**	**Unit**	**Default Value**
TEST RESULT	Outcome of toxicity experiment with benthic organism, expressed as EC50, LC50, EC10, LC10, NOEC etc	mg kg_{dw}^{-1}	
TEST RESULT EU standard test	Test result expressed in EU standard sediment	mg kg_{dw}^{-1}	
TEST $RESULT_{test\ sed}$	Test result expressed in EU standard sediment		
$F_{oc,\ EU\ standard\ sed}$	Organic carbon content (w/w) of EU standard sediment	kg kg^{-1}	0.05
$F_{oc,\ test\ sed}$	Organic carbon content (w/w) of the experimental sediment	kg kg^{-1}	

Results of long-term toxicity tests with sediment organisms are preferred for deriving sediment standards due to the generally long term exposure of benthic organisms to sediment bound substances. If such studies are available, a $QS_{sediment,\ fw\ eco}$ or $QS_{sediment,\ sw\ eco}$ is determined using the assessment factors (AFs) in Table 5-1, applied to the lowest credible datum. The assessment factors are based on those used within the REACH guidance (ECHA, 2008) and applied as follows:

$QS_{sediment}$ [mg/kg] (dry weight) = lowest NOEC or EC10 [mg/kg] /AF (range 100 – 10)

Table 5.1 Assessment factors applied to spiked sediment tests (ECHA, 2008)

Available data	Assessment factor
One long term test (NOEC or EC10)	100
Two long term tests (NOEC or EC10) with species representing different living and feeding conditions	50
Three long term tests (NOEC or EC10) with species representing different living and feeding conditions	10

If only results from short-term tests with sediment-dwelling organisms are available, an assessment factor of 1000 is applied to the lowest reliable value. In situations where only short term test data is available a QS should also be derived using the Equilibrium Partitioning approach (See Section 5.2.1.2). The lowest value would be proposed as the $QS_{sediment}$ in these situations.

In principle, the species sensitivity distribution (SSD) modelling approach (Section 3) can be applied to sediment toxicity data rather than the deterministic (AF) approach. In practice however, the minimum data requirements for an SSD will rarely be met, except perhaps for a few well-studied metals. Guidance on the use of SSD for the derivation of sediment thresholds has not been included within the REACH guidance (ECHA, 2008) however the approach was used within the Voluntary Risk Assessment undertaken on copper (ECI, 2008).

5.2.1.2 Equilibrium Partitioning

If no reliable sediment toxicity data are available, Equilibrium Partitioning (EqP) can be used to estimate the $QS_{sediment, fw EqP}$ or the $QS_{sediment, sw EqP}$

EqP is a mechanistic approach developed by Di Toro *et al*. (1991) for deriving sediment quality guidelines. Assuming the toxicity of a non-ionic organic chemical in sediment is proportional to its concentration in water, then the concentration of this chemical in sediment that will cause toxicity can be estimated if the relationship between the chemical concentration in the pore water and that in sediment is understood.

The partitioning of a chemical between sediment and pore water can be represented by a simple equilibrium equation:

$$C_{SOC} = C_{PW} \times K_{OC}$$

C_{SOC} is the concentration of the chemical in the sediment per unit mass of organic carbon, C_{PW} is the concentration of the chemical in pore water, K_{OC} is the partition coefficient of the chemical to sediment organic carbon). The C_{PW} can be replaced with the chemical concentration in water associated with a biological effect in the water column ($C_{effect\text{-}water}$).

Replacing CPW by the $QS_{fw, eco}$ or the $QS_{sw, eco}$ (Section 3) will yield a $QS_{sediment, fw EqP}$ or the $QS_{sediment, sw EqP}$. For EqP calculations, the equations outlined in the REACH guidance and EUSES will be used.

Calculation of Kcomp-water

In the EqP method outlined in ECHA guidance, the ‘dimensionless’partition co-efficient Ksed-water is used in untis of m3m-3. This parameter is also called a total compartment-water partition coefficient. It is calculated according to the equations given in REACH guidance (ECHA, 2008) R.16, which are presented here for the sediment compartment only. Note that EqP to the bulk-sediment compartment is performed within the current EQS guidance, while REACH guidance uses suspended matter characteristics. This is done for several reasons: the REACH standard organic carbon content of suspended matter is relatively high (viz 10%) for most sediments; compliance checking will be performed with sediemtns rather than suspended matter and sediment standards based on suspended matter characteristics bear more relevance to the water column than do standards based on sediment characteristics. The default values for compartment specific characteristics (Faircomp, RHO solid etc) from the REACH (ECHA, 2008) should be used; their values are listed in the table below the equations.

$$Kp_{sed} = Foc_{sed} \times K_{oc} \qquad 2$$

$$K_{sed-water} = \frac{Ctotal_{sed}}{Cporew_{sed}} \qquad 3$$

$$K_{sed\text{-}water} = Fair_{sed} \times K_{air-water} + Fwater_{sed} + Fsolid_{sed} \times \frac{Kp_{sed}}{1000} \times RHOsolid \qquad 4$$

$$K_{air-water} = \frac{H}{R \times TEMP} \qquad 5$$

Description:

Parameter	Description	Unit	Default value
1000	conversion factor from m^3 to litre	$L\ m^{-3}$	1000
$Cporew_{sed}$	total concentration in pore water of sediment	$mg\ m^{-3}$	
$Ctotal_{sed}$	total concentration in sediment	$mg\ m^{-3}$	
$Fair_{sed}$	fraction air in sediment	$m^3\ m^{-3}$	0
Foc_{sed}	weight fraction of organic carbon in sediment	$kg\ kg^{-1}$	0.05
$Fsolid_{sed}$	fraction solids in sediment	–	0.2
$Fwater_{sed}$	fraction water in sediment	$m^3\ m^{-3}$	0.8
H	Henry's law constant	$Pa\ m^3\ mol^{-1}$	
$K_{air\text{-}water}$	air-water partition coefficient	$m^3\ m^{-3}$	
K_{oc}	partition coefficient between organic carbon and water	$L\ kg^{-1}$	
Kp_{sed}	partition coefficient solid-water in sediment	$L\ kg^{-1}$	
$K_{sed\text{-}water}$	partition coefficient between sediment and water	$m^3\ m^{-3}$	
R	gas constant	$Pa\ m^3\ mol^{-1}\ K^{-1}$	8.314
RHO_{sed}	bulk density of wet sediment	$kg_{ww}\ m^{-3}$	1300
$RHOsolid$	density of the solid phase	$kg_{solid}\ m_{solid}^{-3}$	2500
$TEMP$	environmental temperature	K	285

Calculation of $QS_{sediment,\ fw\ EqP}$ or $QS_{sediment,\ sw\ EqP}$

The calculation of the QS for sediment by equilibrium partitioning according to the REACH guidance (ECHA, 2008) R.10 is given below.

- The $QS_{sediment,fw\ EqP}$ is calculated for freshwater sediments according to EqP from the QS for aquatic organisms, $QS_{fw,\ eco}$ using Eqs 6 and 8 or in the case of marine sediment, from $QS_{sw,\ eco}$
- When the $QS_{sediment}$ has been calculated using EqP and log Kow >5 for the compound of interest, $QS_{sediment}$ is divided by 10. This correction factor is applied because EqP only considers uptake via the water phase. Extra uncertainty due to uptake by ingestion of food should be covered by the applied assessment factor of 10.

$$QS_{\text{sediment, EqP, ww}} = \frac{K_{\text{sed-water}}}{RHO_{\text{sed}}} \times QS_{\text{fw, eco}} \times 1000 \qquad 6$$

$$CONV\text{sed} = \frac{RHO_{\text{sed}}}{F\text{solid}_{\text{sed}} \times RHO\text{solid}} \qquad 7$$

$$QS_{\text{sediment, EqP, dw}} = CONV\text{sed} \times QS_{\text{sediment, EqP, ww}} \qquad 8$$

Description (some of the variables are listed in the previous table):

Parameter	Description	Unit	Default value
1000	conversion factor from m^3 to litre	L m^{-3}	1000
*CONV*sed	conversion factor for sediment concentration wet-dry weight sediment	$kg_{ww} \cdot kg_{dw}^{-1}$	
*F*solid$_{sed}$	fraction solids in sediment	–	0.2
$K_{sed\text{-}water}$	partition coefficient between sediment and water	$m^3\ m^{-3}$	
$QS_{sediment,\ EqP,\ dw}$	dry weight quality standard for sediment based on equilibrium partitioning	mg kg_{dw}^{-1}	
$QS_{sediment,\ EqP,\ ww}$	wet weight quality standard for sediment based on equilibrium partitioning	mg kg_{ww}^{-1}	
$QS_{fw,\ eco}$	quality standard for direct ecotoxicity on freshwater aquatic organisms	mg L^{-1}	
RHO_{sed}	bulk density of wet sediment	$kg_{ww}\ m^{-3}$	1300
*RHO*solid	density of the solid phase	$kg_{solid}\ m_{solid}^{-3}$	2500

Experimentally determined values for K_{OC} are preferable. These K_{OC} values may be derived from standardised tests (e.g. OECD Guideline 106) or from other studies published in scientific literature. Koc values equation (van Vlaardingen and Verbruggen 2007). Examples of QSPRs for defining the relationship between Kow and Koc for different substance groups are provided in Table 5.2.

The EqP approach assumes that phases are at equilibrium, and thus exposure through pore water determined by the HPLC method (OECD guideline 121) should be considered as estimates of the real Koc values and consequently, these values are not used as experimental values. Because K_{OC} values may vary widely and no value for Koc can be considered as the most reliable value, the geometric mean of all valid K_{OC} values is calculated, including one value estimated from K_{OW}. This geometric mean K_{OC} will be used in the above equation. For highly lipophilic substances (Kow > 5), equilibrium may not be achieved, so a correction for exposure through food was introduced in the TGD (EC, 2003). For such substances, an additional AF of 10 is recommended.

Reliance on EqP alone involves several important assumptions such as equilibrium among phases, similar sensitivities among pelagic and benthic species. In a risk assessment scenario, potential sediment risks indicated by EqP would trigger further sediment toxicity testing. This is not always possible in QS derivation so any $QS_{sediment}$ that is based on EqP (or indeed a small toxicity test dataset) carries a high degree of uncertainty that must be highlighted in the datasheet for consideration by policymakers.

Table 5.2 QSPRs for soil and sediment sorption for different classes (Sabljic et al, 1995)

Chemical class	Equation	Statistics
Predominantly hydrophobics	$logK_{OC}$=0.81*$logK_{OW}$+0.10	n=81, r^2=0.89,s.e.=0.45
Non hydrophobics	$logK_{OC}$=0.52*$logK_{OW}$+1.02	n=390, r^2=0.63,s.e.=0.56
Phenols, anilines, benzonitriles, nitrobenzenes	$logK_{OC}$=0.63*$logK_{OW}$+0.90	n=54, r^2=0.75,s.e.=0.40
Acetanilides, carbamates, esters, phenylureas, phosphates, triazines, triazoles, uracils	$logK_{OC}$=0.47*$logK_{OW}$+1.09	n=216, r^2=0.68,s.e.=0.43
Alcohols, organic acids	$logK_{OC}$=0.47*$logK_{OW}$+0.50	n=36, r^2=0.72,s.e.=0.39
Acetanilides, carbamates, esters, phenylureas, phosphates, triazines, triazoles, uracils	$logK_{OC}$=0.40*$logK_{OW}$+1.12	n=21, r^2=0.51,s.e.=0.34
Alcohols, organic acids	$logK_{OC}$=0.39*$logK_{OW}$+0.50	n=13, r^2=0.77,s.e.=0.40
Amides	$logK_{OC}$=0.33*$logK_{OW}$+1.25	n=28, r^2=0.46,s.e.=0.49
Anilines	$logK_{OC}$=0.62*$logK_{OW}$+0.85	n=20, r^2=0.82,s.e.=0.34
Carbamates	$logK_{OC}$=0.37*$logK_{OW}$+1.14	n=43, r^2=0.58,s.e.=0.451
Dinitroanilines	$logK_{OC}$=0.38*$logK_{OW}$+1.92	n=20, r^2=0.83,s.e.=0.24
Esters	$logK_{OC}$=0.49*$logK_{OW}$+1.05	n=25, r^2=0.76,s.e.=0.46
Nitrobenzenes	$logK_{OC}$=0.77*$logK_{OW}$+0.55	n=10, r^2=0.70,s.e.=0.58
Organic acids	$logK_{OC}$=0.60*$logK_{OW}$+0.32	n=23, r^2=0.75,s.e.=0.34
Phenols, benzonitriles	$logK_{OC}$=0.47*$logK_{OW}$+1.08	n=24, r^2=0.75,s.e.=0.37
Phenylureas	$logK_{OC}$=0.49*$logK_{OW}$+1.05	n=52, r^2=0.60,s.e.=0.34
Phosphates	$logK_{OC}$=0.49*$logK_{OW}$+1.17	n=41, r^2=0.73,s.e.=0.45
Triazines	$logK_{OC}$=0.30*$logK_{OW}$+1.50	n=16, r^2=0.32,s.e.=0.38

The process for using laboratory toxicity data and the EqP approach in deriving a $QS_{sediment}$ is summarised in Figure 5.2.

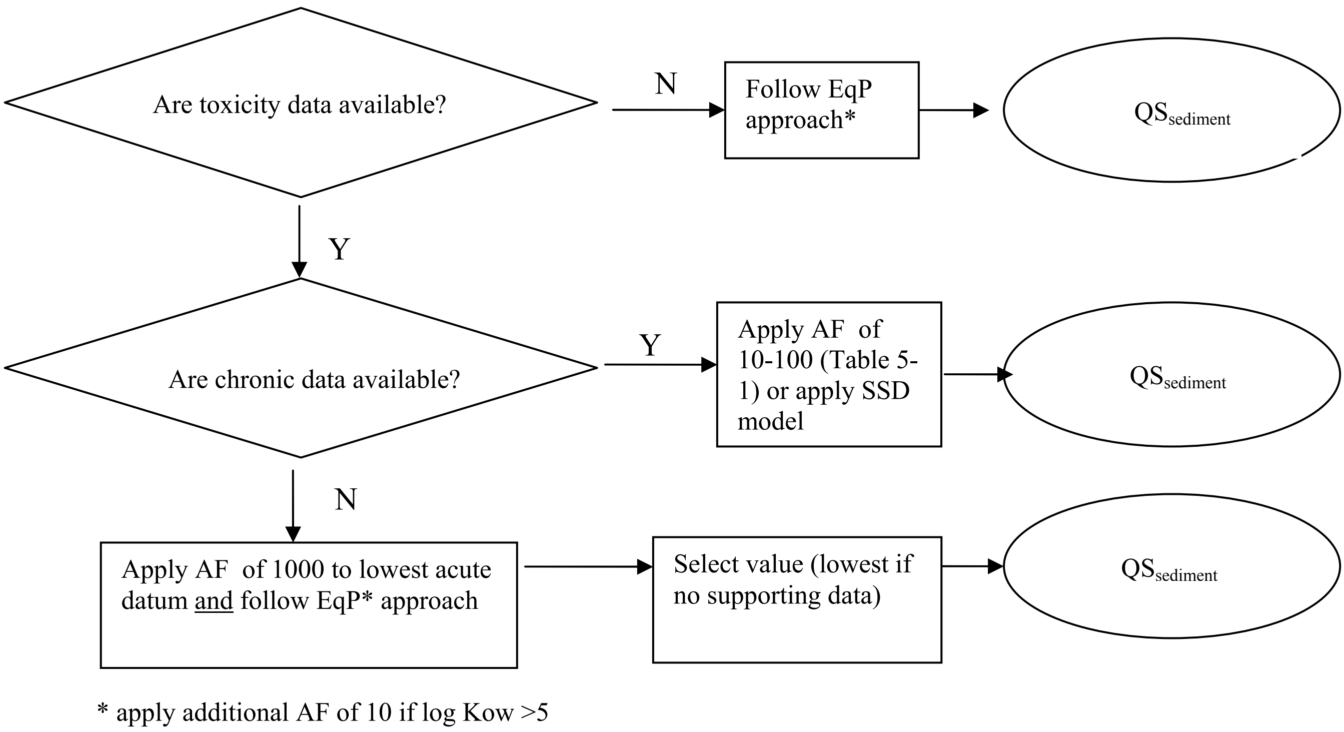

Figure 5.2 Process for the derivation of a $QS_{sediment}$

5.2.1.3 Use of field or mesocosm data

Role of field and mesocosm data

Field and/or mesocosm data should be considered, where available, in the derivation of the $QS_{sediment}$. This approach is consistent with the guidance for water column QSs (Section 2.8.2) and with Annex V of the WFD where it states that *"… the standard thus derived should be compared with any evidence from field studies. Where anomolies appear, the derivation shall be reviewed to allow a more precise safety factor to be calculated …"*

It should be borne in mind that laboratory experiments are likely to result in high levels of chemical availability because spiked sediments are rarely aged. This is in contrast with field or mesocosm data where chemical exposures are more likely to be closer to equilibrium. For these reasons, we would expect a bias in laboratory data toward higher toxicity (and more stringent standards). Lower toxicity under field conditions could reflect the real effect of ageing that should be accounted for, if possible, in standard setting.

In the absence of useful corroborating evidence from the field or mesocosms the QS derived from chronic toxicity data is retained. If this is not possible, the lowest of the QSs derived based on the EqP approach or short term toxicity data is taken as an interim standard (Figure 5-1).

Types of field and mesocosm data

Mesocosm studies may be available which have generated NOEC/EC10 data. Effect concentrations may also be available from field studies. If such tests are considered reliable the results can be used in the derivation of the $QS_{sediment}$ (Section 5.2.1.3.3).
A number of empirical approaches that link biological responses of benthos to chemical contamination in the field have been described (Batley *et al.*, 2005). They are based primarily on field data, in which matched sediment chemistry and biological effects data are analysed using

various statistical approaches to relate chemical concentrations to the frequency of biological effects. Further details on these analyses are to be found in the following sources:

- Threshold effect level (TEL) / probable effect level (PEL)(Smith, Mc Donald et al. 1996), effect range low (ERL) – effect range medium (ERM) (Long, Mc Donald et al. 1995)
- Screening level concentration (SLC) (E.C. 1992; Persaud, Jaagamugi et al. 1993)
- Logistic regression modelling (LRM) (Field, Mc Donald et al. 1999; Field, MacDonald et al. 2002). The LRM approach focuses on establishing the probability of adverse effect as a function of sediment chemical concentration. As this relationship is continuous, this approach can be used to define sediment standards associated with any desired probability of impact. For practical purposes the 10th percentile is the preferred cut-off; this also corresponds to the ERL (see below)
- Field-based species sensitivity distribution (Kwok *et al*. 2008)

For the purposes of QS derivation, field thresholds referring to concentrations where biological effects are unlikely to occur (sometimes referred to as 'threshold effect levels' (TEL), 'effect range low' (ERL) or 'no-effect level' (NEL, in the SLC approach)) are preferred over thresholds associated with a significant biological impact (e.g. 'probable effects level', PEL). The definition of ERL or TEL specify that not more than 20-25% of samples should display a toxic effect..
If a field threshold has not been calculated, one of the approaches referred to above can be applied to matching chemistry and biological data, e.g:

- ERL is the 10^{th} percentile of the distribution of concentrations (dry weight) associated with an effect in a database matching chemistry and ecotoxicological tests applied to sediments collected from the field.
- TEL is the geometric mean of the 50^{th} percentile of concentrations (dry weight) associated with a biological effect and the 15^{th} percentile of the no-effects set.

None of these approaches should be used without a thorough assessment of the reliability of the data and their relevance. Entries associated with an effect for a given chemical are relevant if the concentration for this chemical is at least 2-fold above the background (McDonald *et al.* 1996).

Application of the field/mesocosm data within $QS_{sediment}$ derivation

Reliable data arising from field/mesocosm studies can be used to influence the derivation of the $QS_{sediment}$ as follows:-

1. If the TEL or ERL, or mesocosm NOEC/EC10, is higher than, or equal to the $QS_{sediment, eco}$, derived based on available ecotoxicity data, either the latter is used as the $EQS_{sediment}$ or there may be a case for reducing the size of the AF applied to the laboratory data, but only if the field or mesocosm data are reliable and relevant to a wide range of European (or national, in the case of Specific Pollutants) conditions.

2. If the TEL or ERL is lower than the $QS_{sediment}$ derived based on ecotoxicity tests, there might be a case for increasing the size of the AF if the field or mesocosm data are reliable.

3. If the TEL or ERL is higher than, or equal to, the value calculated by applying the equilibrium partitioning, the latter is used for the derivation of the $EQS_{sediment}$.

4. If the TEL or ERL is lower than the value calculated by applying equilibrium partitioning, the former value is used with an assessment factor (AF) to derive a sediment QS. The AF value would be set at 5.

5.2.2 Metals and the need to cope with bioavailability issues

Where possible, consideration should be given to those factors that affect the availability (and hence toxicity) of contaminants in sediment. Natural sediments used in ecotoxicological tests contain different binding ligands which restrict the mobility of metals. As a consequence, this may also influence the availability and the toxicity of metals to sediment dwelling organisms. Major binding ligands for cations in the aerobic layer of sediments are iron and manganese oxyhydroxides (FeOOH and MnOOH), carbonates and organic carbon (OC). In anoxic sediments, bioavailability of metals can also be controlled by the formation of stable complexes with sulphide. The environmental fate of metals present in anionic forms is dominated by different sorption properties . For metals that have a high affinity to bind to these ligands, it is worthwhile exploring whether a relationship can be established between the observed toxicity levels and the presence of one or more of the ligands. If so, the toxicity of a metal in sediments can then be normalised towards a standard or a specific local condition.

5.2.2.1 Use of data from direct (spiked) toxicity tests

The approach previously described in section 5.2.1.1 will be applied to the set of data constituted on the basis of the following requirements. See also list of general requirements in section 2

- *Sediment:* For deriving sediment QSs from direct sediment toxicity data, information on the sediment chemistry is needed for data interpretation, especially if bioavailability corrections are carried out. In the latter case artificial sediments used in studies should be characterised (e.g. particle size, pH of pore water, organic matter (OM), cation exchange capacity (CEC)/anion exchange capacity (AEC), as well as iron and manganese oxides). If natural sediment is used, SEM (Simultaneously Extracted Metals) and AVS (Acid Volatile Sulphides) concentrations should be measured.
- *Metal-OC equilibrations*: The kinetics of metal-DOC binding in aqueous and sediment test media may require an equilibration period between the metal and test medium prior to exposing the organisms. This is to allow full Me-OC binding in a way that is representative of natural environments (e.g. Ma *et al*., 1999). Where the kinetics for reaching equilibrium conditions for binding to OC etc are known to be slow and may affect the test outcomes, reviewing the details of the test design may provide additional information on the reliability of the data, particularly for any extreme values.
- *Metal-sediment equilibration*: After spiking the water-sediment system with the test substance, an equilibrium period is crucial to ensure partitioning of the substance between the water-phase and solid-phase. For metals and inorganic metal compounds, the concentration of the test substances should be measured in the overlying water of semistatic and static sediment toxicity tests, and testing preferably initiated only when the overlying water concentration reaches stable concentrations (this can be more than 2 months for metals). If these criteria are not met, the tests cannot be assigned Q1.

If a relationship with OC can be discerned, the same normalisation as above (section 5.2.1.1) will also be applicable to metals. In addition for metals, toxicity values are preferred, originating from tests carried out under aerobic conditions, with low acid-volatile sulphide (AVS) levels (e.g. < 1.0 µmol AVS/g dry wt or tests with artificial sediments). These sediments could be considered as realistic "worst cases" for aerobic sediments, since ferric- and sulfide binding to metals is not present.

5.2.2.2 Accounting for background concentrations in sediments

The methodology described for considering metals in the pelagic- water compartment - using an added risk approach where needed (Section 3.5.2.1) - can also be applied to the sediment compartment.

The definition of the natural background levels for metals in metals is similar to that for water. Again, the default procedure will be to search for baseline levels in pristine or close to pristine areas. Unlike the situation for water, the analysis of deeper, undisturbed bed sediments, combined with radio-isotopic techniques, may allow one to estimate historical ambient concentrations, and thus to judge 'pre-industrial' levels.

Other possibilities are to:

- To gather information from national or international databases, for example, FOREGS Geological Baseline Programme (http://www.gsf.fi/foregs/geochem)

- Geological modelling, to estimate the contribution from erosion

5.2.2.3 Equilibrium partitioning

When using the EqP approach for metals, measured Kd values for sediment/suspended solids from freshwater, estuarine and marine waterbodies respectively can be used. Preference is given to Kd values derived from field measurements and not laboratory sorption or toxicity experiments. However, large variations in Kd are often observed even among different field-based measurements and therefore, for freshwater sediments, the QS derived from EqP may be refined by using Kds, modeled from WHAM speciation models (Tipping 1994). It should be noted however that the only solid phase that can be estimated by WHAM is organic carbon. Before using this approach, the validity of organic carbon determined WHAM Kd values should be checked, as other factors may contribute to partitioning.

5.2.3 Dealing with bioaccumulated/biomagnified substances

For some very hydrophobic organic substances such as polychlorobiphenyls (PCBs) polychlorodibenzo-dioxins (PCDDs) or furans (PCDFs), the protection of sediment-dwelling organisms may not be the key objective. Direct toxic effects may arise at concentrations far above the concentrations of concern for predators located at higher levels in food webs, such as predatory fish or mammals. In this case, biota standards should be set. Nevertheless, sediment standards might also be useful, for management or monitoring purposes, as long as they fulfil the trigger criteria set out in Section 2.4.2.

When sediment is the primary source of exposure for target species (fish or mammals), $QS_{sediment}$ for such substances should be derived from the QS_{biota}. Available exposure models range from very simple ones, based on BSAFs (accumulation factors from sediment to biota), to food-web models (Section 4). BSAFs are not recommended, as published values are highly variable. Moreover, studies on uncontaminated areas tend to yield higher BSAFs (Burzynski 2000) than studies on contaminated sites. Food-web modelling would thus be more appropriate but are more appropriately applied at local or regional scales, yielding site-specific or region-specific EQSs. For this reason, this step is not relevant for substances for which a Europe-wide EQS is sought.

5.2.4 Protection of saltwater benthic organisms

The same approach as that described for freshwater sediments are recommended for the derivation of $QS_{sediment}$ for marine waters. Marine and freshwater sediment toxicity data may be pooled unless it can be documented that differences in toxicity exists between freshwater and saltwater sediments. Further refinements of the process for deriving sediment standards for metals are given in Section 5.3

5.2.4.1 Spiked sediment (ecotoxicity) testing

In principle the same approach as that outlined in Section 5.2.1.1 with regard to sediment of inland surface waters is adopted. However, larger assessment factors may apply depending on the quality and quantity of toxicity data available (Table 5-3).

Table 5.3 Assessment factors for derivation of the $QS_{sediment, sw\ eco}$ based on the lowest available NOEC/EC10 from long-term tests (ECHA, 2008)

Available test results	Assessment factor [a)]
One acute freshwater or marine test (L(E)C50)	10000 [b)]
Two acute test including a minimum of one marine test with an organism of a sensitive taxa (lowest L(E)C50)	1000 [b)]
One long term freshwater sediment test	1000
Two long term freshwater sediment tests with species representing different living and feeding conditions	500
One long term freshwater and one saltwater sediment test representing different living and feeding conditions	100
Three long term sediment tests with species representing different living and feeding conditions	50
Three long term tests with species representing different living and feeding conditions including a minimum of two tests with marine species	10

[a)] The general principles of notes (c) and (d) as applied to data on aquatic organisms (Table 3.3) shall also apply to sediment data. Additionally, where there is convincing evidence that the sensitivity of marine organisms is adequately covered by that available from freshwater species, the assessment factors used for freshwater sediment data may be applied. Such evidence may include data from long-term testing of freshwater and marine aquatic organisms, and must include data on specific marine taxa.

[b)] If an indicative $QS_{sediment, sw\ eco}$ is calculated with short-term toxicity data, an alternative EQS must be calculated using the equilibrium partitioning approach (see section 5.2.1.2). The final value is selected by expert judgement, taking all available information into account.

As other combinations of data could occur (van Vlaardingen and Verbruggen 2007), the following additional guidance is offered:

- an assessment factor of 500 is applied if only one long-term marine but no freshwater test is available
- If two long-term tests with marine species representing different living and feeding conditions are available, but there are no freshwater tests, an assessment factor of 100 is applied.
- an assessment factor of 1000 might only be applied to a short-term toxicity test if the lowest value available is for a marine species.

5.2.4.2 Other derivation approaches

The derivation approaches described in Section 5.2.1 also apply to marine and coastal sediments. The standards selected should refer to marine or coastal environments.

5.2.5 Derivation of sediment QS for transitional waters

The same derivation approaches described in Section 5.2.1 and 5.2.4 also apply to sediment in transitional waterbodies.

Specific data for transitional waters will probably be lacking in most cases. To decide whether a freshwater or saltwater sediment QS is most appropriate for a particular location, the most convenient approach would be to assess the diurnal range of salinities, decide whether the considered ecosystem (in a transitional waterbody) is closer to a freshwater system or to a saltwater system, and apply the corresponding QS.

5.3 Using sediment QS that are subject to high uncertainty

5.3.1 Overview

Sediment standards allow the assessment of good status alongside standards for other compartments. The following guidance suggests how we might assess situations where the sediment standard fails. A simple pass/fail approach to assessment is not always appropriate, especially as residual uncertainties in sediment standards can be high making compliance assessment difficult. For this reason, we recommend a tiered assessment framework in which decisions to take remedial measures use sediment standards as only one of a number of lines of evidence. A similar framework has been adopted by OSPAR for monitoring of marine sediments[25]. Member States or Basin Authorities can either implement directly remediation measures or apply either tier.

Detailed advice on monitoring lies outside the scope of this guidance. However, if policymakers deem that formal assessments of compliance using an $EQS_{sediment}$ are necessary, a tiered assessment framework is recommended that uses evidence to corroborate any risks indicated by exceedances of the $EQS_{sediment}$ (Figure 5-3)[26].

In this framework, chemical analysis at Tier 1 provides a ‘face value’ assessment of compliance. This should use an $EQS_{sediment}$ that has been based on data simulating worst-case conditions for availability (Section 5.2.1.1). EQS exceedence would trigger a more detailed assessment (i.e. Tier 2) that accounts for bioavailability or uses biological data to assess whether the benthic community is actually impaired or not. If no risks are expected after accounting for bioavailability, or the biological community was not impaired – even though an EQS exceedance is indicated – any further action might be restricted to further monitoring instead of more costly risk reduction measures. On the other hand, demonstrable impacts coupled with EQS exceedances would be good evidence for a need for risk reduction.

---

[25] Final report of the OSPAR/ICES Workshop on the Evaluation and Update of Background Reference Concentrations (BRCs) and Environmental Assessment Criteria (EACs) and How These Assessment Tools Should Be Used in Assessing Contaminants in Water, Sediment and Biota (February 2004), presented to ASMO as ASMO 04/4/5 Add 1.

[26] Nevertheless, the framework is not mandatory; local authorities may disregard this framework and manage directly to recover a quality matching the standard

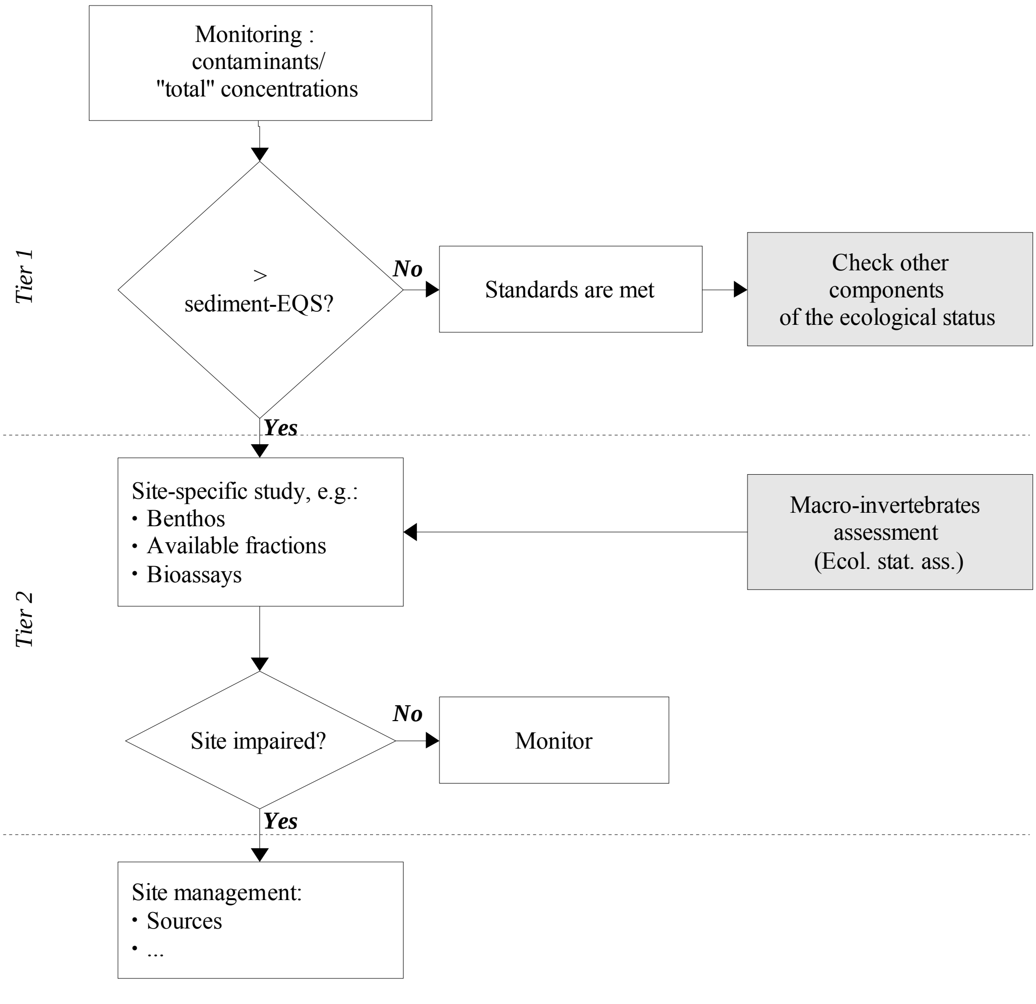

Figure 5.3 Tiered assessment framework for sediments

There are several possible approaches for the second tier, depending on the factors most likely to affect the risks posed by a particular substance. These might include assessment of the bioavailable fraction (Section 5.3.2), benthic community assessment or even bioassays conducted *in situ* or *ex situ*. While benthos assessment and bioassays may provide valuable additional information, they can be difficult to use and should be considered as options, to be selected on a case by case basis.

5.3.2 Assessing the bioavailable fraction

This assessment seeks to refine the exposure concentration to which sediment-dwelling organisms are exposed. One possible way to estimate the bioavailable fraction is to measure the extractable fraction in amorphous organic matter by extraction with a solid sorbent (e.g. Tenax ®) for a set time (e.g. 6h) (Cornelissen, Rigterink *et al*. 2001). This extraction is based on differences in contaminant desorption kinetics between amorphous organic carbon and hard carbon. The concentration in amorphous organic matter is then related to the freely dissolved concentration in pore water (N'Guyen *et al*. 2005; Schüürmann *et al*. 2006). These Tenax ® extractable concentrations are highly related to concentrations in organisms (Landrum, Robinson *et al*. 2007). The concentrations extracted from amorphous organic matter could be compared directly with the sediment quality standards.

Another approach could be to estimate the bioavailable fraction through porewater sampling with SPME (solid phase micro-extraction) or POM (poly-oxy-methylene)[27] or direct measurements in organisms. In this case, measured concentrations should be compared with the $QS_{fw, eco}$ or $QS_{sw, eco}$ (Table 5-4).

Table 5.4 Interpretation of bioavailability measurements

Method	*Exposure concentration compared to*
SPME	Water EQS
POM	Water EQS
Tenax ®	Sediment EQS
Organism	Biota EQS

For metals, several methods for measuring bioavailability are under development such as e.g. “Diffusive Gradients in Thin-films” (DGT) (Cornu &Danaix 2006), “Sediment or Fauna Incubation Experiment” (SOFIE) (Duester, Vink & Hirner 2008), and “Simultaneously Extracted Metals – Acid Volatile Sulphides” (SEM-AVS).

In the EU risk assessments for cadmium, zinc, and nickel, and in the voluntary industry risk assessments for copper and lead, the SEM-AVS concept has been employed.

For metals the anoxic sediment could be of greatest concern as these tend to be depositional, clayey sediments where metals accumulate. In these sediments, bioavailability of metals can be controlled by formation of stable complexes with sulphide. More erosional sediments that are oxic and have larger grain sizes have no or very low AVS, but also rarely have metal contamination (Burton *et al*. 2007).

The binding strength of the metal sulphide (MS) is inversely related to its solubility product and therefore, metals characterised by the lowest MS solubility product (K_{sp}) will have the highest affinity for sulphides. The MS solubility products, described in Table 5-5 illustrates the large difference in MS solubility products. This means that the presence of FeS and MnS indicates that MS, with solubility product lower then the ones of MnS and FeS are formed by preference, may actually displace the less stable FeS and MnS and are less vulnerable to oxidation.

[27] For a detailed review, see ICES (2008). Report of the Working Group on Marine Sediments in Relation to Pollution (WGMS). Copenhagen, International council for the Exploration of the Sea: 64.

Table 5.5 Solubility products of metal sulphides

Metal sulphide	Log K[(a)]	Log K[(b)]
MnS (s)	-19.15	- 13.50
FeS (amorphic)	-21.80	-
FeS (s)	-22.39	-18.10
NiS (s)	-27.98	-
ZnS (s)	-28.39	-24.70
CdS (s)	-32.85	-27.00
PbS (s)	-33.42	-27.50
CuS (s)	-40.94	-36.10
Ag_2S (s)		-50.10
HgS	-57.25	-52.70

a Di Toro et al, 1990
b Stumm and Morgan, 1981

Based on field validation data, it has been demonstrated that the fraction of metals bound to sulphides in the sediment, and thus sequestered in the solid phase of sediments, is not available for exposure to benthic organisms via the pore water route and toxicity to benthic organisms and can be estimated from SEM-AVS (Simultaneously Extracted Metals – Acid Volatile Sulphides) measurements.

The basic concept behind the SEM-AVS approach is that the Acid Volatile Sulphides (AVS) present in the sediment reacts with the Simultaneously Extracted Metals (SEM). SEM and AVS are operationally defined parameters. AVS (Acid Volatile Sulphides) are those sulphides that are extracted by cold extraction (1 M HCl) of sediments. SEM (Simultaneously Extracted Metals), is the term used for those metals that are liberated under the conditions of the AVS analysis (ICMM fact sheet No. 10).

The SEM-AVS concept has been shown to be predictive of the toxicity of those metals having a high affinity for AVS: e.g. Cd, Cu, Pb, Ag, and Zn. For Ni, field data exist that support the SEM-AVS concept, but as laboratory studies did not constitute a test of this theory further research is still ongoing. For metals with lower sulphide solubility products, the applicability of the SEM-AVS approach has still to be demonstrated and may be questionable. Thus, the SEM-AVS approach cannot be used at this time for metals other than those referred to above.

As several factors influence metal availability, the SEM-AVS approach could be used as a line of evidence in the weight of evidence to predict the absence of metal toxicity, i.e. when SEM-AVS ratio is <1.

Metals act in a competitive manner when binding to AVS. Applying the principles of competitive displacement kinetics, the SEM-AVS model can be made metal-specific. The procedure assigns the AVS pool to the metals in order of their solubility products. For example, ranked from the lowest to the highest solubility product the following sequence is observed for these six metals: SEMHg SEMAg, SEMCu, SEMPb, SEMCd, SEMZn and SEMNi. This means that mercury has the highest affinity for AVS, followed by silver, copper, lead, cadmium, zinc and nickel until the AVS is exhausted. The remaining SEM is that amount present in excess of the AVS and potentially available.

For divalent metals, one mole of SEM will react with one mole of AVS. For silver the stoichiometric relationship differs slightly and one mole of SEM silver reacts with two moles of AVS.

When applying the SEM-AVS concept to compliance checking, consideration is to be given to seasonal and vertical variations on AVS measurements. It is therefore recommended to assess the SEM and AVS in the same sample and to sample sediments for SEM and AVS measurements preferably in spring and from the upper 5 to 10 cm (AVS lowest in spring and upper sediment layer) or on a regionale scale to take the 10th percentile of available AVS.

For more background information on the SEM-AVS concept the reader is referred to the risk assessment made under the EU Existing Substance Regulation for Cd, Zn and Ni and the voluntary risk assessments for Cu and Pb that have been discussed by Technical Committee for New and Existing substances.

6. LIMITATIONS IN EXPERIMENTAL DATA – USE OF NON-TESTING APPROACHES

Several databases of physicochemical and biological effects data are available and data have also been published in the literature. However, the number of tested chemicals with reliable test data remains small compared to regulatory inventories of interest [Netzeva et al, 2007]. Data gaps may be filled by commissioning physical, degradation or ecotoxicological studies but this is not always possible.

A lack of data reflects a lack of knowledge about the properties or effects of a substance and this gives rise to uncertainty. The conventional way to respond to this uncertainty is to apply larger AFs, but this can result in very low QSs that cannot be implemented in practice. In some cases, it may not be possible to derive a QS due to the lack of data. If that uncertainty can be reduced, the need for such large AFs may be reduced accordingly. If carefully chosen, the use of a relevant and reliable non-testing method can provide additional information which can lower the overall uncertainty and result in the use of a smaller AF. Non-testing methods will not be useful in all circumstances however.

Three non-testing approaches to filling data gaps are recognised. These are:

- Grouping methods (Section 6.1)
- QSARs (Section 6.2)
- Analogue approach / read-across (Section 6.3)

Non-testing methods may be used under REACH to fill data gaps, provided that:

- The model used is shown to be scientifically valid
- The model used is applicable to the chemical of interest
- The prediction is relevant for the regulatory purpose (in this case, EQS derivation)
- Appropriate documentation on the method and result is given (e.g. by using the QSAR Model Reporting Format recommended by the European Commission)

All assessments using non-testing methods should be reviewed and updated as new information is generated, and as experience in forming and assessing non-testing methods is continually growing. Figure 6.1 illustrates a scheme for deciding how non-testing methods may be deployed for EQS derivation.

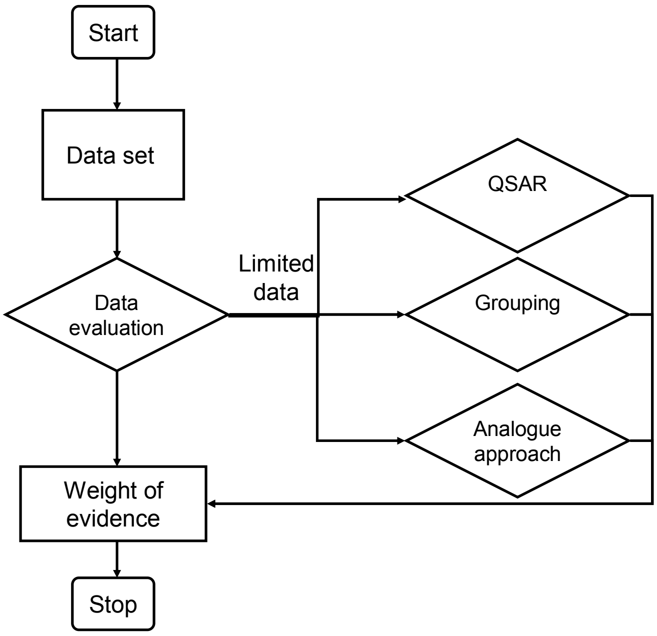

Figure 6.1: Application of non-testing methods

6.1 Grouping of substances / category approach

A chemical category is a group of chemicals whose physicalchemical properties, fate and behaviour and mammalian or environmental toxicological properties, are likely to be similar or follow a regular pattern as a result of structural similarity, e.g. PAHs or another shared characteristic.

The assessment of chemicals using a category approach differs to the assessment of chemicals on an individual basis. The effects of the individual chemicals within a category are assessed on the basis of the evaluation of the category as a whole, rather than being based on measured data for any one particular substance alone. For a substance (a category member) that lacks data for a particular endpoint (e.g. there are no chronic aquatic toxicity data), the data gap can be filled in a number of ways, including read-across from one or more other category members. If the similarity of category members is very high, e.g. for PAHs with the same number of rings, it may only be necessary to use data from one category member using read-across principles to adequately characterise the category member for which data is lacking.

In an ideal situation a category would include all potential members of the category (e.g. all homologues in a series), but this ideal situation will be difficult to achieve in practice. The successful use of a category approach should lead to the identification and characterisation of the hazards for all the members of the category, irrespective of their production volume / exposure.

A chemical category should be described by a matrix consisting of the category members and the relevant endpoints e.g. BCF, log K_{ow}. In some cases, an effect can be present for some but not all members of the category, and then sub-categories should be built (e.g. the 16 hydrocarbon 'blocks' used for hydrocarbons in PETROTOX). Figure 6.2 shows the procedure for category development.

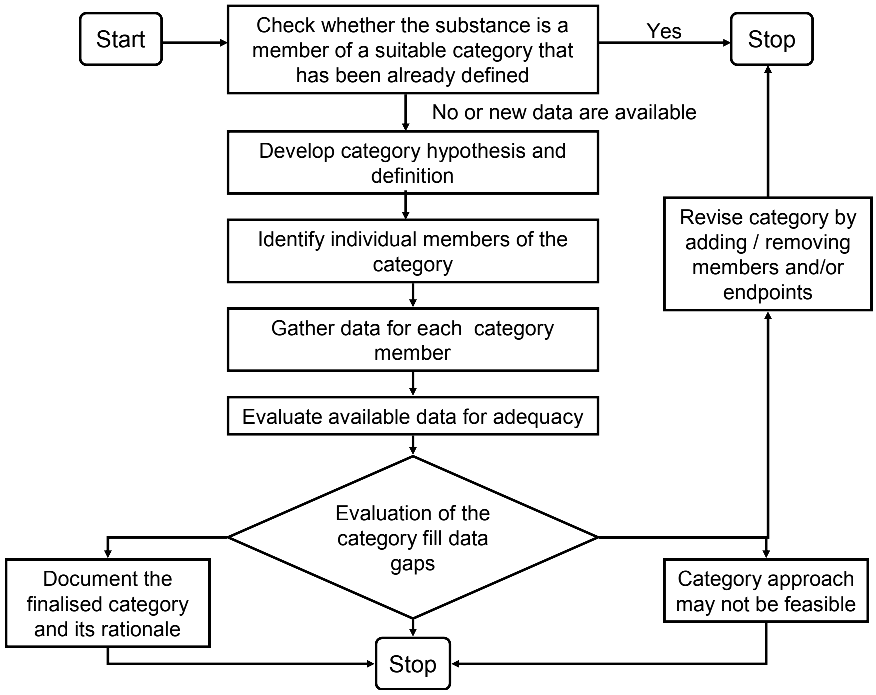

Figure 6.2. Stepwise procedure for category development

Before considering whether to develop a category for a group of substances, the first step should be to determine whether the chemicals of interest are named members of a category that has already been evaluated. The category definition should list all of the substances and endpoints covered. Although the chemical structure is usually the starting point, a category definition could also refer to a group of chemicals related by a mechanism of action (e.g. non-polar narcotics) or a particular property. For each member of the category, relevant data should be gathered and quality assessed as described in Section 2.6.2.

A matrix of data (category endpoints vs. members) should be constructed with the category members arranged in a suitable order (e.g. according to ascending log K_{OW}). The ordering of the members should reflect any trends or progression seen within the category. The cells of the matrix should indicate whether data are available or missing. Categories may be revised by adding or removing member(s) and endpoint(s).

The finalised category should be documented. A category may be revised subsequently in the light of new data or experience.

6.2 QSARs

The chemical category and Quantitative Structure-Activity Relationship (QSAR) concepts are strongly connected. A QSAR is a quantitative (mathematical) relationship between a numerical measure of chemical structure, or a physicochemical property, and an effect/activity e.g. acute toxicity to the waterflea, *Daphnia magna*. QSARs often taken the form of regression equations, and can make predictions of effects/activities that are either on a continuous scale (e.g. reproductive output) or on a categorical scale (e.g. mortality).

For a given category endpoint, the category members are often related by a trend (e.g. increasing, decreasing or constant) in a particular effect, and a trend analysis can be carried out using a model based on the data for the members of the category.

Similarly, a Quantitative Activity-Activity Relationship (QAAR) is a mathematical relationship, but between two biological endpoints, which can be in the same or different species. QAARs are based on the assumption that knowledge about the mechanism or mode of action, obtained for one endpoint, is applicable to the same endpoint in a different species, or to a similar endpoint in the same species, since the main underlying processes are the same (e.g. partitioning, reactivity, enzyme inhibition). QAARs are less widely used than QSARs but also provide a means of performing trend analysis and filling data gaps.

Thus, a chemical category can be seen as a set of internal QSARs (and possibly also internal QAARs) for the different endpoints. Data gaps can also be filled by an external QSAR model, where the category under examination is a subcategory of the wider QSAR (Netzeva *et al* 2008).

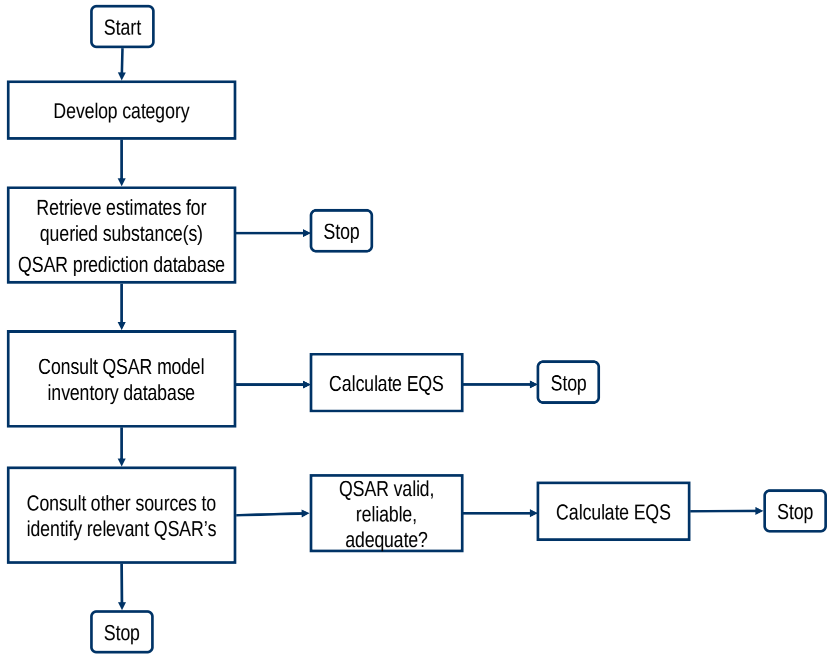

Figure 6.3 Stepwise approach to applying QSARs

There are various publically and commercially available computational tools and databases available to predict data endpoints [Bassan and Worth 2008]. Information regarding QSAR software tools for regulatory purposes is available on

http://ihcp.jrc.ec.europa.eu/our_labs/computational_toxicology/qsar_tools/qsar-tools

If relevant QSAR prediction databases do not include predictions for the particular substance(s) of interest, relevant QSAR models can be searched for in the QSAR database. Failing this, others models can be searched for in the literature, external databases and tools.

Harmonised templates such as the QSAR Model Reporting FormatQMRF and the QSAR Prediction Reporting Format (QPRF) should be used to document the results. The QMRF is a harmonised template for summarising and reporting key information on QSAR models, including the results of any validation studies. The information is structured according to the OECD (Q)SAR validation principles. The QPRF is a harmonised template for summarising and reporting substance-specific predictions generated by QSAR models.

QSARs are suitable for identifying a substance as potentially PBT/vPvB. BIOWIN, BCFWIN and ECOSAR are thought to be reliable models for these assessments. However, mammalian toxicity

QSARs are presently not sufficiently reliable for use in estimating secondary poisoning QS. Although they have a place in supplementing experimental ecotoxicity data, sole reliance on QSARs in ECOSAR for estimating acute or chronic toxicity, and the subsequent use of these results for deriving a QS, is not recommended because of the tendency for ECOSAR to underestimate toxicity for the types of substances prioritised or proposed for QS derivation, sometimes by a substantial amount.

6.3 Analogue approach / read-across

If it is not possible to associate the compound of interest with any existing category, similar compounds may be identified by performing a similarity assessment procedure, as described below. Figure 6.4 describes the application of the analogue approach.

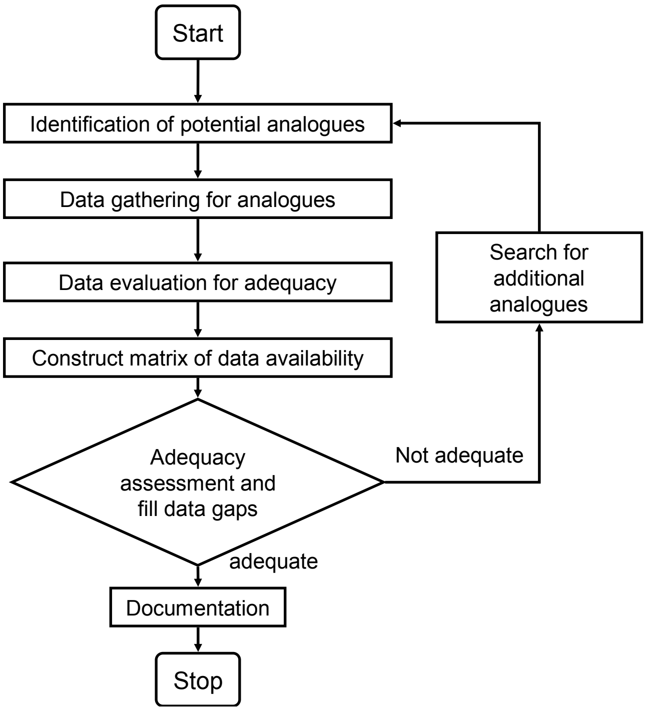

Figure 6.4. Stepwise procedure for the analogue approach

Computational tools, e.g. Toxmatch

http://ihcp.jrc.ec.europa.eu/our_labs/computational_toxicology/qsar_tools/qsar-tools or the OECD Toolbox should be used for analogue selections in combination with electronic substructure searching using molecular similarity indexes (e.g. the Tanimoto similarity index or Hellinger distance [atom environments]) and other molecular descriptors [e.g. log K_{ow}]). For each analogue, relevant data should be gathered and quality assessed as described in Section 2.

The decision about whether data from an analogue can be used to fill a data gap depends largely on expert judgement at present. Wherever possible, the relevance of the read-across should be evaluated in the light of known or suspected mode of action. If the read-across from an analogue is suitable, the approach should be documented according to an appropriate format.

The OECD Toolbox was used to identify suitable analogues for indeno(1,2,3-cd)pyrene by Crane *et al.* (2008). They concluded that read-across using a weight of evidence approach and all relevant measured and estimated values for physical and eco-toxicological properties could be a valuable approach for deriving QSs, if measured data are available for interpolation to the substance and endpoint(s) of interest, or if a reliable trend with low variability exists.

The *de minimis* dataset for reliable read-across consists of:

a) For endpoints that incorporate an assessment of potency (dose-effect): Evidence of a consistent and reliable trend within a category of relevance to the endpoint of interest (e.g. a monotonic increase in log Kow with an increase in measured BCF and toxicity).
b) Consistent and reliable measured values to identify the most sensitive trophic group, if toxicity is the endpoint of interest.
c) Reliable measured data for the endpoint of interest that allow interpolation to a value for the substance of interest.

d) QSAR estimates may be useful in a weight of evidence role for supporting read-across, but should not be used to replace the measured values identified in a – c above.

7. CALCULATION OF QS FOR SUBSTANCES OCCURRING IN MIXTURES

For well-defined mixtures, ie those with a well defined qualitative and quantitative composition, the toxic unit (TU) approach (e.g.Altenburger and Greco 2009) may be used to calculate the EQS. A Toxic Unit (TU) is defined as the ratio of the exposure concentration to the effect concentration for a specific medium (e.g. water). A TU for each constituent$_i$ in a substance / group of substances should be calculated as,

$$TU_i = \frac{C_{w,i}}{QS_i}$$

Cw,i Concentration in water of the constituent i

QSi PNEC for the constituent i

To estimate the toxicity of the mixture, the TU_i for all constituents in the mixture/group of substances are summed.

$$TU_{mixture} = \Sigma TU_i$$

When the $TU_{mixture}$ equals one or is greater than one, the mixture is expected to be above the threshold (ie QS).

EQSs may be defined for grouped substances that exert a similar mode of action and may be expressed according to the concept of Toxic Equivalent [TEQ] concentrations in environmental samples. The Toxic Equivalency Factor [TEF] is the fraction of the PNEC of constituent$_i$ divided by the lowest PNEC measured or calculated for a constituent that belongs to the group of substances being considered (Di Toro, 2000).

$TEQ = \Sigma_n (TEF_i * c_i)$

TEFi Toxic Equivalency factor for constituent i

Ci concentration of constituent i

The TU concept is equivalent to the Toxic Equivalency Factors (TEFs) for PCB's, PCDD's and PCDF's for humans and wildlife which were agreed by the World Health Organization (WHO) in 1997 and have been revised for dioxin-like compounds by the WHO in 2005, including criteria to take substances into the TEQ concept (Van den Berg *et al*. 1998, 2006)

Some substances are of unknown or variable composition, complex reaction products or biological materials (UVCBs). The variability in composition can be large and unpredictable. Methods for assessing UVCBs are still under development but current approaches focus on identified constituents, where assessment can be limited by a lack of data. However some UVCBs, like petroleum substances, can be assessed using the hydrocarbons block method and the use of non-testing methods (eg PETROTOX) to fill data gaps as demonstrated for the case study of gasolines (McGrath, 2005).

PETROTOX (CONCAWE) is a tool to assess aquatic toxicity hazard of complex petroleum and related substances; it:

- includes a library of about 1500 individual hydrocarbons, grouped in 16 hydrocarbon blocks, with details on their physical chemical properties and estimated PNECs

- predicts toxicity of substances to different aquatic organisms (based on the Narcosis Target Lipid Model);

- assesses impact of composition/test design on toxicity results; and

- estimates Predicted No-Effect Concentrations (PNECs) needed as input to environmental risk assessments of petroleum substances using the Hydrocarbon Block Method.

- estimates HC5 of the individual components needed as input to environmental risk assessments of petroleum substances using the Hydrocarbon Block method.

Petrotox estimates the HC5 for the different components and hydrocarbon blocks of the original petroleum product prior to any treatment that occurs prior to discharge. As the shift of the hydrocarbon block composition is not taken into account the estimated HC5 can not be used for EQS setting as it requires the recalculation taking into account the hydrocarbon block composition in the receiving environment. To estimate the toxicity of hydrocarbon mixtures in environmental samples, the HC5 of all the components present in a hydrocarbon block and subsequent calculation of the Toxic Unit (TU) is required. An EQS for hydrocarbon mixtures may be set by grouping them into hydrocarbon blocks.

The PETROTOX model uses QSAR modelling to predict the toxicity of the different fractions. In an alternative approach to derive quality standards for total petroleum hydrocarbons, a fraction based approach was used to calculate the internal concentrations in organisms exposed to spiked sediments. This calculation was based on partitioning of the different fractions between sediment, oil, pore water and the lipids of membranes. The toxicity observed in these spiked sediments for six benthic species was related to the calculated membrane concentrations. HC5 could thus be based on these internal membrane concentrations (Verbruggen et al, 2008). The observed values are lower than the QSAR estimates from the PETROTOX model.

When establishing EQSs for UVCBs such as petroleum products separate values should be defined for different fractions or blocks of the mixture. In compliance checking the concentrations of these individual fraction should be measured and a concentration addition approach should be applied to assess the effect of the total mixture in the environment.

APPENDIX 1: DATA COLLECTION, EVALUATION AND SELECTION

Contents

A1.1. INTRODUCTION

This background document covers the collection of data that may be used to derive Environmental Quality Standards (EQSs), and its evaluation and selection for actual use in EQS derivation.

To promote consistency, it also gives guidance on the presentation and reporting of data. The topics covered are physicochemical data (Section 2), toxicity data (Section 3), bioconcentration and biomagnification data (Section 4) and toxicity data for the protection of humans (Section 5).

This background document is based on that provided in Van Vlaardingen and Verbruggen (2007)

A1.2. PHYSICOCHEMICAL DATA

A1.2.1. Data collection

A1.2.1.1. Identity

The following data on substance identity are collected:

- IUPAC name
- structural formula
- CAS registry number
- EINECS number
- chemical formula
- SMILES code

IUPAC name, CAS registry number, EINECS number and chemical formula are primarily derived from the ESIS database (JRC website http://esis.jrc.ec.europa.eu/). A structural formula can also be obtained here for a great number of compounds. If a structural formula cannot be obtained from the ESIS database, EPI Suite software can be used (US EPA, 2007b) or handbooks can be consulted, e.g. Tomlin (2002) for pesticides or more general handbooks like Mackay *et al*. (2006). The SMILES code is generated by EPI Suite software. If the compound of interest is not available in the EPI Suite database, the SMILES code can be generated using chemical drawing software, e.g. ChemSketch (ACD/Labs, 2006).

A1.2.1.2. Physicochemical properties

Physicochemical parameters should be collected for each compound for which EQSs are being derived. These parameters provide information on the behaviour of the compound in the environment. Data on the following parameters are collected (name, symbol, unit):

- molecular weight: M_w ($g \cdot mol^{-1}$);
- melting point: T_m (°C);
- boiling point: T_b (°C);
- vapour pressure: P_v (Pa), experimental melting point and boiling point can be useful for estimation of the vapour pressure;
- Henry's law constant: H ($Pa \cdot m^3 \cdot mol^{-1}$);
- water solubility: S_w ($mg \cdot L^{-1}$), experimental melting point can be useful for the estimation of the solubility from log K_{ow};
- dissociation constant: pK_a (-);
- *n*-octanol/water partition coefficient: K_{ow} (-);
- sediment/water partition coefficient: K_p ($L \cdot kg^{-1}$). For organic substances, the partition coefficients normalised to organic carbon are preferred: K_{oc} ($L \cdot kg^{-1}$). For metals, field-based partition coefficients (K_p) for suspended matter are searched.

The following steps should be followed to collect physicochemical data:

1. The following databases and estimation methods are used to retrieve or calculate data on physicochemical parameters (Table 1).

Table 1. Sources and estimation methods to be screened for physicochemical parameters.

Parameter	Sources/methods
M_W	Mackay, EPI Suite, SPARC, IUCLID
T_m	Mackay, EPI Suite, IUCLID
T_b	Mackay, EPI Suite, SPARC, IUCLID
P_v	Mackay, EPI Suite, SPARC, IUCLID
H	Mackay, BioLoom, EPI Suite, SPARC, IUCLID
S_w	Mackay, EPI Suite, SPARC, IUCLID
pK_a	Mackay, BioLoom, SPARC, IUCLID
K_{ow}	BioLoom, Mackay, EPI Suite, SPARC, IUCLID
K_{oc}	Mackay, BioLoom, Sabljić, EPI Suite, IUCLID
K_p (metals)	Sauvé, Bockting, scientific literature

SPARC = SPARC online calculator (Karickhoff *et al*., 2007);

IUCLID = International Uniform Chemical Information Database (European Commission (Joint Research Centre), 2007);

Bioloom = BioByte including internet database (BioByte, 2004);

Sabljić = Sabljić and Güsten (1995) cited in European Commission (Joint Research Centre). (2003b) or
Sabljić *et al*. (1995).

Sauvé = Sauvé *et al*. (2000)

Bockting = Bockting *et al*. (1992)

2. Scientific literature. For all of the listed parameters, the open literature may be searched if a reliable estimate is lacking or if the number of reliable or relevant data is very low. This might be most applicable to K_p values for metals (see Annex).

3. Contact people from environment agencies in other countries asking if they have access to specific information on ecotoxicological toxicity data (see Section 0) and/or physicochemical data and are willing to share those data.

4. The industry parties involved in production or use of the compounds under investigation are invited to submit relevant studies, making clear these will be treated as public literature.

A1.2.2. Data evaluation and data tables

All retrieved literature is read and evaluated to assess its relevance and reliability. Important aspects for evaluation are discussed in the annex.

After evaluating a study, the results of the study are summarised by entering these into a data table (Table 2). The structural formula of the compound is also placed in this table.

Table 2. Overview and default table structure for identity and physicochemical parameters listed for each compound.

Properties	Value	Reference
IUPAC Name		
Structural formula		
CAS number		
EINECS number		
Chemical formula		
SMILES code		
Molecular weight ($g \cdot mol^{-1}$)		
Melting point (°C)		
Boiling point (°C)		
Vapour pressure (Pa)		
Henry's law constant ($Pa \cdot m^3 \cdot mol^{-1}$)		
Water solubility ($mg \cdot L^{-1}$)		
pK_a		
n-Octanol/water partition coefficient (log K_{ow})		
Sediment/water sorption coefficient (log K_{oc})		
Sediment/water sorption coefficient (log K_p)		
Suspended matter/water partition coefficient		

A1.2.3. Data selection

A1.2.3.1. K_{ow}

The K_{ow} value that is selected for use in EQS derivation is preferably the experimental value (MlogP) presented by BioLoom (BioByte, 2004). This value is assigned the highest quality in the underlying database (MedChem). Only if this database does not give a value or when careful considerations lead to a different selection, The selected (log) K_{ow} value is the average value of all reliable values determined by the shake flask, slow stirring or generator column method, for which guidance is given in the annex. K_{ow} values estimated using the HPLC method are indirect estimates of octanol/water partitioning and are therefore not regarded as most reliable. They should not be used when more reliable data are available.

When no, or only unreliable, experimental data on K_{ow} are available, the selected data should be calculated with a QSPR programme. The use of the K_{ow} values obtained with the ClogP program (BioByte, 2004) is preferred.

A1.2.3.2. K_{oc}

For the selection of the K_{oc} value, experimentally determined values should be retrieved. These K_{oc} values may be derived from standardised tests (e.g. OECD guideline 106; OECD, 2000) or from other studies published in scientific literature. K_{oc} values determined by the HPLC method (OECD guideline 121; OECD, 2001) should be considered as estimates of the real K_{oc} values and consequently, these values are not used as experimental values. Because K_{oc} values may vary widely and no value for K_{oc} can be considered as the most reliable value, the geometric mean of all valid K_{oc} values is calculated, including one value estimated from K_{ow}. This geometric mean K_{oc} will be used as the selected value in EQS derivations (Otte *et al.*, 2001).

A1.2.3.3. $K_{p,\ susp\text{-}water}$

For organic substances, the value of $K_{p,\ susp\text{-}water}$ is derived from the K_{oc} value and the fraction organic carbon of suspended matter used within the EU ($Foc_{susp,TGD}$), applying Eq. 1. Note that the fraction of organic carbon is equal to 0.1 in this case (the EU standard): the outcome of this equation triggers $EQS_{sediment}$ derivation and should be uniform within Europe.

$$K_{\mathrm{p,\ susp-water}} = K_{\mathrm{oc}} \times F\mathrm{oc}_{\mathrm{susp,\ TGD}} \tag{1}$$

If site-specific data for suspended matter are available these can be used directly as well and might be preferred. The value for $K_{p,\ susp\text{-}water}$ for metals is derived from experimental data. The geometric mean value is calculated from the valid $K_{p,\ susp\text{-}water}$ values summarised in the table containing physicochemical properties (see Annex); this value is used in EQS derivations. If experimental data on K_p for metals are lacking, the data gap is reported and its possible solution suggested.

A1.2.3.4. Water solubility

The selected value for the water solubility may be calculated from the geometric mean of all valid values for the water solubility. Values below 10 $mg{\cdot}L^{-1}$ determined with the shake-flask method should be considered as unreliable. For these poorly soluble compounds, the geometric mean of the generator column and slow-stirring is the value to be used.

A1.2.3.5. Vapour pressure

In general, the guidance in Table 1 of the annex can be used to determine which values for the vapour pressure are reliable. However, if results from different methods deviate significantly from each other, only the methods with a direct analysis of the compound should be used, e.g. the gas saturation method. Complementary to this, the data from GC retention times may be used if there are not enough reliable data. If no experimental data are available, the estimate from EPI Suite can be used (US EPA, 2007b).

A1.2.3.6. Henry coefficient

The validity of values for the Henry coefficient should be considered on a case-by-case basis. When no reliable experimental values are available, the Henry coefficient can be estimated from the quotient of the vapour pressure and the water solubility, provided that reliable values are available for both parameters. If this is not the case, the estimate from EPI Suite can be used (US EPA, 2007b).

A1.3. TOXICITY DATA

A1.3.1. Data collection

To collect toxicity data for a compound the following steps are recommended:

1. Environment agencies in other countries are consulted by sending out an e-mail enquiry, in which they are asked if they have access to specific information on toxicity data and/or physicochemical data (see Section 2.1.2) and are willing to share those data.
2. Industry parties involved in production or use of the compound under investigation are invited to submit relevant studies, which will be treated as public literature.
3. The on-line literature systems Current Contents and TOXLINE are screened.
4. It is important to perform a retrospective literature search. The reference lists of publications or reports obtained should be carefully checked for related studies that have been published at earlier dates. A hard copy of each study that is deemed relevant should be obtained.
5. The ECOTOX database from the US EPA (US EPA, 2007a) is searched for relevant ecotoxicological studies. A copy of all studies retrieved from the search results is requested. Other national or organisational databases may also be searched.
6. The IUCLID database is searched for the compound of interest (European Commission (Joint Research Centre), 2007).
7. The availability of OECD SIDS documents or EU risk assessment reports is checked.
8. The database of the Japanese National Institute of Technology and Evaluation (NITE) is searched.
9. For pesticides, public assessment reports are available online at several locations. The following websites are recommended:
   UK Pesticides Safety Directorate (PSD): http://www.pesticides.gov.uk/psd_evaluation_all.asp
   US EPA: http://www.epa.gov/pesticides/reregistration/
   Health Canada: http://www.pmra-arla.gc.ca/english/pubs/reeval-e.html
   EU Pesticides Database: http://ec.europa.eu/sanco_pesticides/public/index.cfm
10. A further search may be performed in libraries.
11. If no or very few data are found in the steps described above, an additional internet search can be performed on the chemical name and CAS number of the compound using established search engines.

In principle, all ecotoxicological studies are evaluated for usefulness in EQS derivation. Studies from which one of the endpoints LC50, EC50, LC10, EC10 or NOEC can be calculated using data presented by the author(s) are also used. Studies that show results in a graph of good quality that can be used to extract raw data are also relevant.

Ecotoxicity studies conducted in freshwater, seawater, brackish water, groundwater (usually no data) and sediment are relevant. Whether or not data on secondary poisoning should be collected is dependent on whether an assessment is required (see main guidance) some trigger values. In the case that secondary poisoning should be assessed, toxicity data for birds and mammals should be collected, screening the appropriate sources described above. In the case of toxicity to birds, acute 5-day studies generating LD50 values should be collected too.

A1.3.2. Data evaluation and data tables

An outline of the general procedure of the evaluation of the toxicity data is given below.

1. All retrieved literature is read and evaluated with respect to its relevance and reliability.
2. Each study should be assigned a quality code. Section 0 provides more detail.

3. After evaluating a study, the results of the study are summarised by entering it into the data table (see Sections 0 and 0).
   - Toxicity data on freshwater organisms and on marine organisms are placed in separate tables.
   - Data on aquatic and benthic species are separated into acute and chronic data, with a separate table for each category (see Section 0 for more guidance).
   - Toxicity data on birds and mammals are placed in separate tables. If many data are available, a distinction can be made between studies with oral (gavage) and dietary (food) exposure.
4. Each row of the toxicity data table contains a test result for one species, endpoint and summary statistic. The columns of the toxicity data table contain the various study parameters. Columns should be filled as completely as possible. When there is no value for a given parameter, the table cell is filled with 'n/d'.
5. All references of toxicity studies should be included.
6. In the toxicity data tables, all tested species are clustered according to taxonomic groups (see Sections 0 and 0), usually: fish, amphibians, crustaceans, insects, molluscs, annelids, macrophytes, algae, birds, mammals.
7. For benthic toxicity data for organic compounds, recalculate toxicity test results to standard sediment with an organic carbon content of 5% (Section 0). In the toxicity toxicity data table on benthic data, both the test result in the test sediment (expressed as a dry weight concentration) as well as the test result in standard sediment (expressed as a dry weight concentration) are reported. For metals, tests should not be normalised to a standard sediment (Section 0).
8. Finally, a new table of selected toxicity data is created in which toxicity data are aggregated to one toxicity value per species. The table will contain the data that are used for the actual EQS derivation. Guidance to compile this table is given in Section 0.

A1.3.2.1. Study quality: validity codes

Studies are quality assessed according to the scheme developed by Klimisch *et al*. (1997). The quality codes assigned are:

1 = reliable without restrictions: 'studies or data...generated according to generally valid and/or internationally accepted testing guidelines (preferably performed according to GLP) or in which the test parameters documented are based on a specific (national) testing guideline...or in which all parameters described are closely related/comparable to a guideline method.'

2 = reliable with restrictions: 'studies or data...(mostly not performed according to GLP), in which the test parameters documented do not totally comply with the specific testing guideline, but are sufficient to accept the data or in which investigations are described which cannot be subsumed under a testing guideline, but which are nevertheless well documented and scientifically acceptable.'

3 = not reliable: 'studies or data...in which there were interferences between the measuring system and the test substance or in which organisms/test systems were used which are not relevant in relation to the exposure (e.g., unphysiologic pathways of application) or which were carried out or generated according to a method which is not acceptable, the documentation of which is not sufficient for assessment and which is not convincing for an expert judgment.'

4 = not assignable: 'studies or data....which do not give sufficient experimental details and which are only listed in short abstracts or secondary literature (books, reviews, etc.).'

In general, when a test has fundamental shortcomings, it should be classified as not reliable (3). This applies to situations where the test was incubated too long (e.g. for algae), the oxygen content was too low, control mortality was too high, solubility of the test substance was exceeded (see Section 0 for more detail), a co-solvent or emulsifier has been used in high concentrations (see Section 0), pH was out of the appropriate range (see Section 0 for specific guidance), the light used had an unrealistic UV intensity, the identity of the substance is not clear (see Section 0 for more guidance), or the actual concentrations are unknown because of significant but unquantified losses.

If the experiment is carried out in a medium that is not the natural habitat of the tested species, these tests are generally not reported rather than being classified as not reliable (see Section 0 for more guidance).

When a study contains useful toxicity information, but it cannot be used directly for derivation of EQSs, it is still tabulated. Examples are a NOEC value from a short term test, or a value higher than the highest tested concentration or lower than lowest tested concentration (see Section 0 for more detail). The test can then still be classified as reliable or reliable with restrictions.

A1.3.2.2. Acute and chronic studies

A chronic toxicity study is defined as a study in which:

(i) the species is exposed to the toxicant for at least one complete life cycle, or
(ii) the species is exposed to the toxicant during one or more sensitive life stages.

This definition is in line with REACH guidance, which states that NOECs from chronic/long-term studies should preferably be derived from full life-cycle or multi-generation studies (ECHA, 2008). True chronic studies cover all sensitive life stages.

Unfortunately, no clear guidance is provided on individual studies, whether these are to be considered as chronic studies or as acute studies. What is considered chronic or acute is very much dependent on 1) the species considered and 2) the studied endpoint and reported criterion.

For most common species, toxicity studies with fish are considered acute if mortality is determined after 96 hours (standard acute test) or after 14 days (prolonged acute toxicity test). The most common chronic toxicity tests for fish are early life-stage tests (ELS), in which eggs or larvae are exposed and the effects on hatching, malformation and growth are considered. Reproduction studies and most ELS tests for fish, but also for other species such as amphibians (FETAX test) or echinoderms, can be considered as chronic toxicity studies. For daphnids, the standard exposure time for acute toxicity is 48 hours, but with regard to chronic toxicity, there is a factor of three difference between the tests with *Daphnia magna* (21 days) and *Ceriodaphnia dubia* (7 days), the latter having a much shorter reproduction time. For algae, the standard exposure time is 72 hours. In this time, the algae regenerate several times. However, the EC50 of this test is considered as acute, while the NOEC or EC10 of the same test is regarded as a chronic value.

A1.3.2.3. Comparison of toxicity value with water solubility

In principle, toxicity studies that have been conducted at concentrations above the water solubility should not be used. However, depending on the uncertainty in the estimate of the water solubility, test results (L(E)C50, NOEC, EC10) that are ≤2 times the estimated value might be included. The factor of 2 is a rather arbitrary value; when experimental data show that the variation in the estimate of the water solubility is lower, it should be lowered accordingly. When the variation in the estimate of the water solubility is higher than a factor of 2, it may be increased to a factor of 3 (maximum). Toxicity studies showing results above the water solubility receive a footnote stating: 'test result above water solubility'.

A1.3.2.4. Use of co-solvents, emulsifiers and dispersants

Sometimes, the solubility of a compound is so low that a solvent, emulsifier or dispersant is used to prepare suitably concentrated stock solutions of the test substances. Such vehicles may not be used to enhance the solubility of the test substance in the test medium, and in any case the compounds used for this purpose may not be toxic to the tested species. Therefore, a control with the vehicle (solvent control) used should be incorporated in the set-up of the test. According to several OECD test guidelines for aquatic toxicity testing (see Section 0) the concentrations of the solvent, emulsifier or dispersant should not exceed 100 mg/L^{-1} (or 100 µL/L^{-1} or 0.01%).

A1.3.2.5. pH of test water and pK$_a$ and ionisation of test compound

When a test has been performed according to a guideline, the pH should be within the required range and, if not, the test validity should be reviewed, e.g. for effects on organism health or test substance hydrolysis.

In some cases, the compound itself may alter the pH strongly. In such cases, it should always be checked whether any observed toxicity might be caused by this change in pH. If so, the test must not be used because the buffering capacity of the environment will usually prevent such a pH effect in the field. For compounds containing functional groups with acidic or basic properties, the pK_a value(s) should be reported in the table with physicochemical properties (Section 0).

Attention should be paid to possible relationships between pH and toxicity of the tested compound, for example, due to a reduced availability (speciation, precipitation, hydrolysis, etc.) of the test compound. The toxicity of a compound may be influenced by its degree of ionisation[28]. As a rule, hydrophobicity, and consequently bioaccumulation and toxicity, will increase with decreasing ionisation. The degree of ionisation of a compound in a toxicity test is determined by several factors:

- the pK_a (s) of the test compound,
- the concentration of the test compound,
- pH of the test compartment (water, sediment),
- the buffering capacity of the test-matrix.

In practice, a compound's potential to ionise (pK_a in physicochemical table) should be checked. The presence of one or more pK_a value(s), or ionisable group(s), triggers attention for pH effects in toxicity studies. If toxicity test results show that toxicity is dependent on the pH of the test medium, the results are rejected if the pH falls outside the range of what can be expected naturally.

Test results should be rejected when the toxicity in a given study is not caused by the compound alone, but also by a pH change. Hence, results from tests with ionisable compounds performed in buffered media (providing sufficient buffering capacity) are more reliable than those performed without a buffer. Studies that explicitly measure pH after addition of the toxicant are most useful in this respect.

A1.3.2.6. Purity and identity of the test substance

In some tests the identity of the test substance is largely unknown or the purity of the test substance is very low. Depending on the nature of the impurities present, if these have been identified at all, a minimum purity of 80% is required, unless it is known that the impurities do not cause any toxic effects by themselves and do not influence the toxicity of the substance of interest. When the purity of the tested compound is <90%, the test result should be corrected for purity. For pesticides, toxicity should be expressed in terms of the concentration of active ingredient.

[28] 'Degree of ionisation' as used in this section expresses the ratio of the number of charged molecules over the total number of neutral and charged molecules at a given concentration and at a given pH.

A1.3.2.7. Toxicity studies performed in other media

Benthic species are sometimes tested in a water-only system. In such cases the data are still tabulated, but for organisms that normally live in the sediment and not on the surface of the sediment, the test should be assigned the code ‘invalid’.

A1.3.2.8. Dealing with toxicity values higher or lower than range of test concentrations

If the highest concentration in a toxicity test is not high enough to determine the NOEC or L(E)C50, the result of that study should be tabulated as NOEC ≥ or L(E)C50 >, followed by the value of the highest test concentration. The test result should be reported in the toxicity data tables. The result itself cannot be used in calculations of EQSs. However, it is valuable information that a species from this taxon (or trophic level) has been tested and that it was not sensitive to the toxicant at a known concentration. It may therefore have a useful supporting role. For example: when NOEC values for algae, *Daphnia* and fish are found, of which one is a ‘NOEC ≥ ’ value, and this value is not the lowest effect concentration, an assessment factor (AF) of 10 may be applied, whereas the AF would have been 50 if the study had been rejected.

For similar reasons, the data from tests resulting in an effect at the lowest test concentration should be tabulated as NOEC < or L(E)C50 <, followed by the value of the lowest test concentration. Although these values cannot be used directly for the derivation of EQSs, useful information can be obtained from comparing the sensitivity of that species with the EQS. This comparison may permit an adjustment to the AF.

A1.3.2.9. Quality Assurance

Toxicity studies originate from various sources, which are tracked as much as possible to the original source. The two key sources are (i) publications in scientific journals and (ii) original study reports that have not been published elsewhere. The latter category has been in the minority since, for reasons of confidentiality, original study reports are often unpublished and may not be accessible.

Studies do not need to have been performed under a formal quality assurance scheme, such as Good Laboratory Practice (GLP). The reported description of a study and comparison with results from comparable studies and organisms, should provide all information necessary to assess its quality.

A1.3.2.10. Use of toxicity tests performed according to established guidelines

International guidelines exist for performing toxicity studies for many species. If such protocols are followed and the requirements for the study are met, the results from such studies are generally reliable. Quality data do not, however, have to conform to formal test guidelines. The most frequently used guidelines for ecotoxicological studies are summarised in this section, although others may also be reported.

- OECD guideline 201: Alga, Growth Inhibition Test. The EC50 from this 72-h algae test is considered an acute value, the NOEC or EC10 a chronic value. The guideline version from 1984 mentions both biomass (sometimes called growth) and growth rate as endpoints. From studies based on the OECD 201 - 1984 guideline, the value for the growth rate is preferred, because this is the more relevant parameter (European Commission (Joint Research Centre), 2003a). However, if only growth is presented, this value can be used as well. The result for the endpoint biomass (growth) is generally somewhat lower than the growth rate and can therefore be considered as a conservative value.

N.B. This guideline was revised in 2006. Endpoints derived from a study conducted following the revised (2006) are valid.

- OECD guideline 202: *Daphnia* sp., Acute Immobilisation Test. For the derivation of EQSs for water, only the EC50 from this 48-h acute toxicity study is considered. The endpoint is immobility, as indicated by the inability to swim after agitation.
- OECD guideline 203: Fish, Acute Toxicity Test. For the derivation of EQSs for water, only the LC50 from this 96-h acute toxicity study is considered. The recorded endpoint is mortality.
- OECD guideline 204: Fish, Prolonged Toxicity Test: 14-day Study. This study is also considered as an acute toxicity study, and consequently, in most cases, only the LC50 is used for the derivation of EQSs.
- OECD guideline 205: Avian Dietary Toxicity Test. This test can be used as an acute toxicity test with birds for the assessment of secondary poisoning.
- OECD guideline 206: Avian Reproduction Test. This test can be used as a chronic toxicity test with birds for the assessment of secondary poisoning, because the exposure duration is at least 20 weeks.
- OECD guideline 210: Fish, Early-life Stage Toxicity Test. This test with fish is a chronic test which covers the life cycle of fish from eggs to free feeding juvenile fish. The recorded endpoints are mortality at all stages, time to hatch, hatching success, length, weight and any morphological or behavioural abnormalities.
- OECD guideline 211: *Daphnia magna* Reproduction Test. This is a chronic test with water fleas. The most important endpoint is the number of young per female (both young and parent alive). Other endpoints are the survival of the parent animals and time to production of first brood. Additionally, parameters such as growth (e.g. length) of the parent animals, and possibly intrinsic rate of increase are useful endpoints.
- OECD guideline 212: Fish, Short-term Toxicity Test on Embryo and Sac-fry Stages. In the guideline it is stated that this test can be used as a screening test for chronic toxicity. Especially for species that cannot be kept under laboratory circumstances for a period long enough to perform a full early-life stage (ELS) test, this test can be a useful alternative. Because the sensitive life stages from egg to sac-fry are covered in this test, it can be considered a chronic test. However, it is expected to be less sensitive than the full ELS test. The same endpoints are recorded as for the full ELS test.
- OECD guideline 215: Fish, Juvenile Growth Test. Because the recorded endpoint is growth during 28 days and the criterion is the NOEC or EC10, the test can be regarded as chronic.
- OECD guideline 218: Sediment-Water Chironomid Toxicity Test Using Spiked Sediment. This is a chronic toxicity study with a chironomid species. The measured endpoints are the total number of adults emerged and the time to emergence. Additionally, larval survival and growth after a ten-day period are recommended endpoints.
- OECD guideline 219: Sediment-Water Chironomid Toxicity Test Using Spiked Water. This test is similar to OECD guideline 218. However, for reasons of stability of the test concentrations, the OECD 218 is preferred. If a test with spiked water is available this test should always be accompanied by a determination of actual concentrations in the sediment.
- OECD guideline 220: Enchytraeid Reproduction Test. The 14-d range finding test from this guideline in which mortality is recorded is an acute test. The definitive test that lasts for 6 weeks is a chronic test. In this test the number of offspring is recorded as well as the mortality of the parent animals, which are only exposed for three weeks and are thereafter removed from the system.
- OECD Revised Proposal for a New Guideline 221: *Lemna* sp. Growth Inhibition Test. For this 7-d test with duckweed the same considerations can be made as for the algal test (OECD 201): the EC50 from this test is considered an acute value, the NOEC or EC10 a chronic value. Both chronic and acute data should be retrieved from the test. The preferred endpoints are growth rate (based on frond number) or biomass (dry weight, fresh weight or frond area).

- FETAX (Frog Embryo Teratogenesis Assay *Xenopus*): This test is a rather short test of 96 hours duration, possibly extended with a few hours, if the larvae have not reached a certain developmental stage. However, considering the sensitive endpoints (next to mortality also development and malformation) and the sensitive life stage (embryonic stages), this test can be considered as chronic for the derivation of EQSs.
- EPA. Ecological Effects Test Guidelines. OPPTS 850.1735. Whole sediment acute toxicity invertebrates, freshwater. Draft, 1996. This test can be used as a chronic test for species such as *Hyalella azteca*.

In addition to tests on birds (OECD guidelines 205 and 206), the OECD has a series of guidelines of toxicity tests with mammals for use in human health risk assessment. These data might also be used in the derivation of EQSs (secondary poisoning of top predators) provided that the test endpoints relate to the effects at the population level of the species. The following OECD guidelines are most important in this respect:

- OECD guideline 401: Acute Oral Toxicity
- OECD guideline 407: Repeated Dose 28-day Oral Toxicity Study in Rodents
- OECD guideline 408: Repeated Dose 90-Day Oral Toxicity Study in Rodents
- OECD guideline 409: Repeated Dose 90-Day Oral Toxicity Study in Non-Rodents
- OECD guideline 414: Prenatal Development Toxicity Study
- OECD guideline 415: One-Generation Reproduction Toxicity Study
- OECD guideline 416: Two-Generation Reproduction Toxicity

A1.3.3. Aquatic toxicity data tables

The following subsections (Sections 0 to 0) discuss the data to be reported in the aquatic toxicity data tables. The parameters are treated in the same order as they appear in the default toxicity data table. The following subsections have titles identical to the column headings in the data tables.

A1.3.3.1. Species

All available toxicity data for a given compound are ordered by test organism. Species are grouped in taxonomic groups. Species names are reported in Latin. Taxonomic groups are shown in bold font, species names are shown in italic font. Species names within a taxon are listed in alphabetical order. For example:

Bacteria

Pseudomonas putida

Algae

Chlorella vulgaris

Pseudokirchneriella subcapitata

Scenedesmus acuminatus

Crustacea

Daphnia pulex

A1.3.3.2. Test organism information

The most relevant properties of the test organism are mentioned in this column; e.g. age, size, weight, life stage or larval stage. Toxicity data for organisms of different ages, size, life stage, etc., are presented as individual entries (i.e. one entry in each row) in the data table.

A1.3.3.3. Chemical analysis

This column reports whether the test compound is analysed during the experiment. Y (Yes) is entered in this column when the compound has been analysed. When no analysis for the test compound is performed, N (No) is entered in this column.

In some cases the test compound is analysed, but the test results (L(E)C50, EC10, NOEC) are not calculated from the measured concentrations. If the test result is based on nominal concentrations, this is mentioned in a footnote to this study: ‘Test result based on nominal concentrations’. This is valid when measured concentrations are close to initial concentrations (drop in concentration <20% over exposure period) and ‘Test result based on nominal concentrations, measured concentrations were >80% of nominal’ is noted.

If the test compound is analysed, but not used for the test results and there is considerable change in the concentration during the test (>20% loss of test compound), the test result should be recalculated using *actual* concentrations. In such cases, a footnote should mention that test results are recalculated to actual concentrations.

In static or renewal tests, when samples are analysed at different points of time, the mean of the measured values is used. When the initial concentration is not measured and one or more samples during the test are, a mean of the initial nominal and the measured concentration(s) is used. In general, taking the average of start and end concentrations slightly overestimates the average concentration during the whole experiment, while the geometric mean underestimates the concentration. For calculating the mean concentration during the course of a static experiment, the best assumption is an exponential decay of the concentration in time. In continuous flow experiments, the concentrations are usually reported as mean measured values and, here, no further calculations are necessary.

A1.3.3.4. Test type

The following test types are distinguished:

S	static system
Sc	static system in closed bottles or test vessels
R	renewal system (semistatic)
F	flow-through system
CF	continuous flow system
IF	intermittent flow system

A1.3.3.5. Test compound

- This column can be deleted when the compound under consideration has only one structural molecular configuration.
- If the tested compound is a metal, the tested metal salt should be reported here.

- If the tested compound is a stereoisomer[29] or consists of a mixture of isomers, the name of the tested molecule(s) should be reported here. For some stereoisomers it might be appropriate to derive individual EQSs. The stereoisomers dieldrin and endrin are an example of such a case.
- If the tested compound is a structural isomer, the individual compounds, in general, have different physicochemical and toxicological properties and each compound will be the subject of a separate EQS derivation (e.g., anthracene and phenanthrene).
- Formulated products (e.g. biocides, pesticides) should be reported here.

A1.3.3.6. Purity

Unit: %

The purity of the test compound expressed as percentage is reported in this column. Alternatively, the following abbreviations may be entered for the designation of chemical purity.

ag	analytical grade
lg	laboratory grade
rg	reagent grade
tg	technical grade
fp	formulated product

Here, the first four have a relatively high purity, while technical grade is in general somewhat less pure. When the purity of the test compound is expressed only by an abbreviation, this abbreviation is reported. However, a purity expressed as percentage is preferred.

A1.3.3.7. Test water

In this column, the test water or medium is reported using abbreviations. Choose from the following list. A footnote to the test may be added if further description of the test medium is needed.

am	artificial medium, such as media used for bacterial and algal tests, artificial seawater
dw	de-ionised water, dechlorinated water or distilled water
nw	natural water, such as lake water, river water, sea water, well water
rw	reconstituted water: (natural) water with additional salts
rtw	reconstituted tap water: tap water with additional salts
tw	tap water

A1.3.3.8. pH

If possible, measured pH values should be reported. If a pH range is given, this range is reported.

A1.3.3.9. Temperature

Unit: °C

[29] Stereoisomers: geometric isomers (*cis*- and *trans*-isomers or *E*- and *Z*-isomers), optical isomers (+- and –-isomers or *R*- and *S*-isomers) and conformational isomers (e.g. chair and boat structures in cyclohexane ring structures).

In this column the temperature at which the test is performed should be reported, preferably a measured temperature. If a temperature range is given, the range is reported.

A1.3.3.10. Hardness

Unit: mg $CaCO_3 \cdot L^{-1}$

This column is shown in tables showing data from freshwater experiments, not for marine water. The hardness of the test water should be reported here. If the hardness of an artificial medium is not reported, but the composition of the medium is reported, the hardness should be calculated. Recalculation should be performed by summing the molar concentrations of all calcium (Ca) and magnesium (Mg) salts and expressing the result as $CaCO_3$ in units of $mg \cdot L^{-1}$.

A1.3.3.11. Salinity

Unit: ‰

This column is only shown in tables showing data from saltwater experiments, and replaces the column for hardness in the freshwater tables. In practice salinity may be determined by recalculating the measured chloride ion only to total salinity, using the assumption that the total amount of all components in the oceans is constant. The average salinity of seawater is around 35‰ (roughly 35 g of salts per litre of seawater). The unit of salinity might also be found expressed in parts per *thousand* (ppt) as w/w. To derive the salinity expressed in ppt the following conversion can be applied:

- when only chloride ions (Cl^-) have been measured, the salinity can be recalculated to ‰ from the chloride concentration using: S(ppt) = 1.80655 × chloride concentration (ppt), in which S = salinity
- psu = practical salinity units[30]. One psu roughly equals one ppt (‰). Seawater has a salinity of approximately 35 psu ≈ 35 ‰ = 35 $g.kg^{-1}$.

Animals living (and tested) in brackish water environments are not placed in separate tables, but are included in the saltwater tables. The division between freshwater, brackish water and seawater on the basis of salinity is given in Table . The division in these categories is rather arbitrary and depends on the source used. For the division between freshwater and brackish water, the value of 0.5‰ is defined in the Water Framework Directive (European Commission, 2000).

Table 3: Classification of water according to salinity.

Water type	Salinity (‰)
Freshwater	<0.5
brackish water	0.5–30
Seawater	30–40

A1.3.3.12. Exposure time

The duration of exposure to the toxicant in the toxicity experiment is given in this column. The abbreviations listed below in Table 4 can be used. A rule of thumb is to stick to the most common expression of test duration in case of standardised tests (e.g. OECD or ISO tests) where this is

30 However, because of the qualitative nature in which salinity is used in EQS derivation, this definition and its inherent accuracy are not relevant.

possible. For example, for a reproduction study with Oncorhynchus mykiss, 60 days (post-hatch) is noted rather than ‘2 months’.

Table 4: Used abbreviations for exposure times.

Test duration in	Abbreviation	
Minutes	min	
Hours	h	
Days	d	
Weeks	w	
Months	mo	
Years	y	

A1.3.3.13. Summary statistics

The summary statistics commonly encountered in ecotoxicological tests are summarised in Table . Their use in EQS derivation is described in the third and fourth columns of this table.

Table 5. Summary statistics derived from toxicity studies and their use in EQS derivation.

Test type	Criterion	Use in EQS derivation?	Action
acute test	EC10 or LC10	No [a]	▪ Tabulate value; may be valuable as additional information
acute test	EC50 or LC50	Yes	▪ Tabulate value
acute test	ECx or LCx	No	▪ Tabulate value; may be valuable as additional information
acute test	LOEC	No	▪ Omit if NOEC is also available from same experiment ▪ Else: tabulate value; may be valuable as additional information
acute test	MATC[31]	No	▪ Omit if NOEC is also available from same experiment ▪ Else: tabulate value; may be valuable as additional information
acute test	NOEC	No [a]	▪ Tabulate value; may be valuable as additional information
acute test	TLm	Yes	▪ Tabulate as LC50 [b]
Chronic test	EC10 or LC10	Yes	▪ Tabulate value
Chronic test	EC50 or LC50	No [a]	▪ Tabulate value; may be valuable as additional information
Chronic test	ECx (x < 10)	No	▪ Omit if NOEC is also available from same experiment ▪ If more than one ECx value is available, try to establish an EC10 from a reliable dose-response relationship ▪ Else: tabulate value; may be valuable as additional information
Chronic test	ECx (10 < x < 20)	Yes	▪ Omit if NOEC is also available from same experiment ▪ If more than one ECx value is available, try to establish an EC10 from a reliable dose-response relationship ▪ Tabulate value if the ECx is the lowest effect concentration measured. Calculate NOEC = ECx/2 (TGD guidance) and tabulate this NOEC [c]
Chronic test	ECx (x ≥ 20)	No	▪ Tabulate value; may be valuable as additional information ▪ If more than one ECx value is available, try to establish an EC10 from a reliable dose-response relationship
Chronic test	LOEC	No	▪ Omit if NOEC is also available from same experiment ▪ Else: (i) if percentage effect is known, see ECx in this table for further guidance ▪ Else: (ii) if percentage effect is unknown: tabulate value; may be valuable as additional information
Chronic test	MATC - single value, no further information	Yes	▪ Omit if NOEC is also available from same experiment ▪ Else, if no further information is available, calculate NOEC = MATC/√2 (TGD guidance) and tabulate this NOEC [d]
Chronic test	MATC - reported as a range	Yes	▪ Omit if NOEC is also available from same experiment ▪ Else, if no further information is available, tabulate the lowest value of the range as NOEC [e]
Chronic test	MATC – spacing factor is given [f]	Yes	▪ Omit if NOEC is also available from same experiment ▪ Else, if no further information is available, calculate NOEC = MATC/√(spacing factor)[f] and tabulate this NOEC [g]

[31] The MATC is the geometric mean of NOEC and LOEC.

Test type	Criterion	Use in EQS derivation?	Action
Chronic test	NOEC	Yes	▪ Omit LOEC if it is also available from same experiment

Notes to Table 5.

a) For toxicity tests with algae and *Lemna* sp., both the EC50 and the EC10 or NOEC are used in the EQS derivation, if available.

b) A footnote should be added to the toxicity data table stating that the TLm is used as LC50.

c) A footnote should be added to the toxicity data table stating that the NOEC is calculated as ECx/2.

d) A footnote should be added to the toxicity data table stating that the NOEC is calculated as MATC/√2.

e) A footnote should be added to the toxicity data table stating that the lowest value of the MATC range is taken as NOEC.

f) The spacing factor is the factor of difference between two subsequent testing concentrations employed in the toxicity experiment.

g) A footnote should be added to the toxicity data table stating that the NOEC is calculated as MATC/√(spacing factor).

The most common summary statistics are either EC50 or LC50 in the case of acute toxicity tests and EC10 or NOEC in the case of a chronic test. Other examples of summary statistics that are regularly found in the literature are LOEC, MATC (the geometric mean of NOEC and LOEC) and TLm, which is equivalent to the LC50. If a NOEC is reported, the LOEC can be omitted.If the endpoint presented is an ECx or LOEC value with an effect between 10 and 20% (i.e., x = 10-20), then a NOEC can be derived according to the TGD, by dividing the ECx by a factor of 2. In such a case, the NOEC can be presented in the toxicity data table, with a note that this value is estimated from an ECx value.

In a strict sense, calculating NOEC as ECx/2, according to the TGD, is only allowed for ECx values with an effect smaller than 20%. However, EC20 values are often presented in the literature. If there is no other information on the dose-response relationship (e.g. a companion EC50, which enables the calculation of an EC10), the EC20 divided by 2 can be considered as NOEC as well, accompanied by a footnote in the table with selected toxicity data (see Section 0).

The information on dose–response relationship should be used as much as possible. If it is possible to derive EC50 and EC10 values from a range of tabulated or graphically presented ECx values, these derived endpoints can be included in the toxicity data table as well, accompanied by a footnote stating the method of derivation.

A1.3.3.14. Test endpoint

The list below shows some relevant endpoints:

growth (weight, length, growth rate, biomass)

number (cells, population)

mortality

immobilisation

reproduction

hatching (rate, time, percentage)

sex ratio

development (egg, embryo, life stage)

malformations (teratogenicity)

proliferation (cells)

filtration rate

carbon uptake (algae)

reburial (of e.g. certain crustacean species)

This list is not exhaustive. In general only those endpoints that have consequences at the population level of the test species (see main guidance). Toxicity test results based on endpoints of whose relationship to effects at the population level is uncertain are not included in the toxicity data tables. Some examples of endpoints where effects at population level are unclear include:

blood or plasma protein levels

histopathological endpoints

organ weights (e.g. hepatosomatic index, gonadosomatic index)

mRNA induction

endpoints determined *in vitro* tests

behavioural responses (e.g. swimming behaviour, antenna motility, etc.)

coloration

However, it should be noted that these endpoints might be reconsidered when a definite correlation or causal relationship with population sustainability can be established.

A1.3.3.15. Value

Unit: $mg \cdot L^{-1}$, $\mu g \cdot L^{-1}$.

The unit in which the results of toxicity tests are expressed is optional. For reasons of comparison and to avoid errors, the same unit is used throughout all aquatic toxicity data tables in one report. In general, values are expressed in two or three digits. At most, four significant digits are reported. However, further calculation with these data may be necessary: averaging, dividing the values by an AF, use of the results in species sensitivity distributions (SSDs), etc.

Toxicity data for metal compounds are always expressed in quantities of the cation, not the salt. For example, a test performed with $CoSO_4 \cdot 7H_2O$ is expressed as Co^{2+}. Test results are recalculated if necessary. A similar approach is followed for all charged substances with a non-toxic counterion.

A1.3.3.16. Validity

This column contains a number (1, 2, 3 or 4) indicating the quality of the study. Section 0 describes the background of the quality scoring system.

A1.3.3.17. Notes

This column contains references to footnotes that are listed below the toxicity data tables. Numbers are used to refer to footnotes.

A1.3.3.18. Reference

The reference to the study from which data are tabulated has the following format:

1 author	Bringmann, 1956
2 authors	Bringmann and Kühn, 1976
3 or more authors	Bringmann *et al*., 1977

If two or more studies have the same citation, distinguish between the different studies by adding a character to the year, e.g. 1980a. All cited references are listed in a reference list.

A1.3.4. Sediment toxicity data tables

The following subsections (Sections 3.4.1 to 3.4.18) discuss the parameters that are reported in the toxicity data tables on acute and chronic toxicity data for benthic species. The parameters are treated in the same order as they appear in the default toxicity data table. The following subsections have titles identical to the column headings in the data tables.

A1.3.4.1 Species

See Section A1.3.3.1. for guidance on reporting data on species.

A1.3.4.2. Test organism information

See Section A1.3.3.2.

A1.3.4.3. Sediment type

In this column, list the sediment type: e.g. fine sandy or organic rich, muddy.

A1.3.4.4. Chemical analysis

See Section A1.3.3.3.

A1.3.4.5. Test compound

See Section A1.3.3.5.

A1.3.4.6. Purity

See Section A1.3.3.6.

A1.3.4.7. pH

Report the pH or the range of pH values, of the test sediment in this column.

A1.3.4.8. Organic carbon

Unit: %

In this column the weight percentage of organic carbon in the sediment is reported. When the percentage organic matter (om) is given, recalculation to percentage organic carbon (oc) is necessary according to Eq. 2:

$$\%\, om = 1.7 \times \%\, oc \qquad (2)$$

This is the general conversion between organic matter and organic carbon used throughout the whole process of deriving EQSs. The value of 1.7 is derived from the TGD (based on standard soil in the TGD containing 2% oc or 3.4% om).

A1.3.4.9. Temperature

See Section A1.3.3.9.

A1.3.4.10. Exposure time

See Section A1.3.3.12.

A1.3.4.11. Summary statstic

Extensive information on the summary statistics is given in Section A1.3.3.13. ECx data are treated in the same way as ECx data for aquatic species.

A1.3.4.12. Test endpoint

See Section A1.3.3.14.

A1.3.4.13. Result for test sediment

Unit: $mg{\cdot}kg^{-1}$, $\mu g{\cdot}kg^{-1}$

The unit in which the results of toxicity tests are expressed is optional. For reasons of comparison and to avoid errors, the same unit is used for all benthic toxicity data tables. This column shows the result as obtained in the experiment, expressed in weight per kg dry weight of the test sediment (i.e. *not* recalculated to standard sediment). For further guidance, see Section A1.3.3.15.

A1.3.4.14. Result for standard sediment

Unit: $mg{\cdot}kg^{-1}$, $\mu g{\cdot}kg^{-1}$

The unit in which the results of toxicity tests are expressed is optional. For reasons of comparison and to avoid errors, the same unit is used for all benthic toxicity data tables. This column shows the result recalculated into weight per kg of standard sediment (dry weight).

The bioavailability of compounds in sediment is influenced by properties like organic matter content, pH, etc. This hampers direct comparison of toxicity results obtained for the same substance in different sediments. To make results from toxicity tests conducted in different sediments more comparable, results should be normalised using relationships that describe the bioavailability of the compound in sediment. Results are converted into a standard sediment, defined as having an organic carbon content of 5% (w/w, see Section A1.3.4.8).

<u>Organic compounds</u>

For non-ionic organic compounds, it is assumed that bioavailability is determined by organic matter content only.

Recalculation to standard sediment is possible with the software program EUSES (European Union System for the Evaluation of Substances; European Commission, 2004).

Metals

In general, toxicity data for metals should not be normalised to a standard sediment. For EQS derivation, all reliable toxicity results with metals to benthic organisms are grouped in the appropriate data table without normalisation.

A1.3.4.15. Validity

This column contains a number (1, 2, 3 or 4), indicating the quality of the study summarised. Section 0 describes the background of the quality scoring system.

A1.3.4.16. Notes

See Section A1.3.3.17.

A1.3.4.17. Reference

See Section A1.3.3.18.

A1.3.5. Bird and mammal toxicity data tables

When secondary poisoning is assessed, results from toxicity studies with birds and mammals are tabulated in separate tables. Data on bioconcentration and biomagnification should be collected as well. For information on the collection of these parameters, see Section A1.4. An expert on human toxicology should be consulted when interpretation of toxicity tests with mammals is complex, e.g. multiple dosing.

A1.3.5.1. Species

See Section A1.3.3.1.

A1.3.5.2. Test organism information

See Section A1.3.3.2.

A1.3.5.3. Product or substance

Toxicity studies on birds or mammals may also be carried out with formulations or products rather than individual substances. Report the name of the substance, product of formulation that has been used in this column.

A1.3.5.4. Purity or active ingredient content

In the case that a product (or formulation) is tested, report the content of active ingredient (a.i.) present in the product, expressed in %. If the purity of the active ingredient (used in formulation) is also known, report this in a footnote.

If a single substance has been applied in the test, report the purity of the tested compound in this column.

A1.3.5.5. Application route

Relevant are those toxicity tests in which the animals are dosed orally. This might be achieved via a direct method (intubation, gavage) or by dosing via the food or water.

A short list of application routes is given below:

- intubation or gavage

- capsule
- diet
- water or feeding solution

A1.3.5.6. Vehicle

A carrier used to dose the test substance to the test animals is reported here.

A1.3.5.7. Test duration

The value in this column reports the total duration of the test. The abbreviations listed in Table 4 can be used. This column should also be filled in when the test duration is equal to the exposure duration. The test duration might be longer than the exposure time, which is reported in the next column (Exposure time). For example in the acute avian dietary toxicity test, in which the exposure lasts 5 days, but the minimal recommended test duration is 8 days.

A1.3.5.8. Exposure time

The duration of exposure to the toxicant in the toxicity experiment is expressed in this column. The abbreviations listed in Table 4 can be used.

A1.3.5.9. Summary statistics

Short term toxicity tests will either yield an LC50 ($mg{\cdot}kg_{food}^{-1}$) or an LD50 ($mg{\cdot}kg_{bw}^{-1}{\cdot}d^{-1}$ in the case of repetitive dosing). Long-term toxicity tests will generally result in a NOEC (no observed effect concentration in diet; $mg{\cdot}kg_{food}^{-1}$), or a NOEL (no observed effect level in a dosing study; $mg{\cdot}kg_{bw}^{-1}{\cdot}d^{-1}$). Results from long-term toxicity tests may also be reported as a NOAEL (no observed adverse effect level), which is the no observed adverse effect level. However, the effects generally observed for the derivation of the NOEC/NOEL are adverse to the organisms.

A1.3.5.10. Test endpoint

The toxicological parameter for which the test result is obtained is tabulated here. Screening for clinical parameters at haematological, histopathological or biochemical level is common in these types of tests. However, secondary poisoning only aims at taking into account effects at the population level.

The list below shows only some of the relevant endpoints:

body weight

egg production

eggshell thickness

hatchability

hatchling survival

mortality

reproduction (e.g. litter size, teratogenic effect, malformation, gestation duration…)

viability (percentage of viable embryos per total number of eggs)

A1.3.5.11. Value from repetitive oral dosing studies

Unit: $mg{\cdot}kg_{bw}^{-1}{\cdot}d^{-1}$.

See also Section 0 for data handling.

From short term toxicity experiments with repetitive dosing on consecutive days (5 d LD50 for birds) and long-term oral dosing studies, a value expressed in $mg.kg_{bw}^{-1}.d^{-1}$ is obtained. The results from such studies (*viz.* LD50 and NO(A)EL) are reported in this column.

A1.3.5.12. Value from diet studies

Unit: $mg.kg_{food}^{-1}$.

See also Section 0 for data handling.

The results of toxicity tests in which the substance of interest is administered via the food are expressed in $mg.kg_{food}^{-1}$. The results of dietary studies (*viz*. LC50 or NOEC values) are reported in this column.

A1.3.5.13. Validity

This column contains a number (1, 2, 3 or 4), indicating the quality of the study summarised. Section 0 describes the background of the quality scoring system.

A1.3.5.14. Notes

See Section A1.3.3.17.

A1.3.5.15. Reference

See Section A1.3.3.18.

A1.3.6. Data selection

A1.3.6.1. Aquatic compartment

One value per species and endpoint is selected for use in the assessment. Where multiple data are available for the same species/endpoint, individual toxicity data may be aggregated using the same principles as those in Chapter R.10 of the REACH Guidance (ECHA, 2008):

1. Identify particularly sensitive species and/or endpoints that may be lost upon averaging data to single values.
2. Investigate multiple values for the same endpoint on a case-by-case basis and seek to explain differences between results.
3. Where valid data show high variation that can be explained, grouping of data is considered, e.g. by pH ranges. If an effect of test conditions is expected to be the cause of variation in toxicity values (hardness of test water, life stage of the test animal, etc.), averaging of data per species should not be performed.
4. Data used for EQS derivation should be selected on the relevance of test conditions (pH, hardness, etc.) to the field.
5. If the variation in test results of different life stages of a test animal is such that averaging data would cause significant underprotection of sensitive life stages, only the data for the most sensitive life stage should be selected. In other words, it is important that sensitive life stages are protected.
6. Calculate the geometric mean of multiple comparable toxicity values for the same species and the same endpoint. This applies to both acute and chronic data.
7. If multiple toxicity values or geometric means for different endpoints are available for one species, the most-sensitive endpoint is selected as long as it is relevant to population sustainability. If multiple valid toxicity data for one species are left that cannot be averaged, the *lowest* value is selected.

Example: There are values (of NOECs or EC10 values) for three different endpoints, derived from several chronic studies with *Daphnia magna.* The geometric mean of NOECs for reproduction is 0.49 mg·L^{-1}, the geometric mean of NOECs for mortality = 3.1 mg·L^{-1} and there is a single EC10 value for growth of 0.67 mg·L^{-1}. The geometric mean value of 0.49 mg·L^{-1} for reproduction is selected for use in EQS derivation.

8. If differences in the chemical form of the test compound (congeners, stereoisomers, etc.) are the cause of variation in toxicity values for a test species, data should not be averaged. In these cases, the *lowest* reliable toxicity datum is selected and separate EQSs should be derived for each chemical form.
9. Particular steps have been developed for metals to account for variations in the toxicity of different metal species. These are explained in Section 4 of the main guidance.
10. Limitations of toxicity data should be explained, for example, when toxicity results are not valid at low pH. Explanation for these types of limitations should be reported in the datasheet in the section dealing with key assumptions and uncertainties.

A1.3.7. Data treatment

A1.3.7.1. Combining freshwater and marine datasets for EQS derivation

1. To derive EQSs for transitional, coastal and territorial waters, toxicity datasets of marine and freshwater species are normally combined because current marine risk assessment practice suggests a reasonable correlation between ecotoxicological responses of freshwater and saltwater biota (i.e. the same datasets can be used interchangeably for freshwater and saltwater effects assessment). Where this is not justified based on the available evidence (i.e. there is a clear difference in the sensitivity of the freshwater and saltwater biota), EQSs for inland surface waters and transitional, coastal and territorial waters must be derived on the basis of distinct datasets for freshwater and marine organisms.Toxicity data for freshwater organisms and marine organisms are combined *before* EQS derivation for the aquatic compartments. If there are doubts as to whether organisms from both environments show similar sensitivity, differences may be tested in the following way:All freshwater data that are going to be used for EQS derivation are collected (note: this dataset contains one toxicity value per species, see Section 0) and the $\log_{10}$ value of each of these toxicity values is calculated.
2. Repeat the above step for all marine toxicity data.
3. Test whether the two log-transformed datasets have equal or unequal variances using an *F*-test. Perform the test at a significance level (α) of 0.05.
4. A two tailed *t*-test, with or without correction for unequal variances as determined in point 3, is performed to test for differences between the datasets. Perform the test at a significance level (α) of 0.05.
5. When using a statistical test, be aware of some confounders. For example: (i) a specific group of organisms might be more sensitive than other organisms; (ii) over-representation of data from one study or species from a specific taxonomic group in one of the two datasets might cause bias. Results of a *t*-test become increasingly meaningful with increasing sample size.

If the null hypothesis is supported, the datasets may be combined. This procedure must not be applied to metals. For metals, the freshwater and saltwater datasets must always be kept separate.

A1.3.7.2. Conversion of data on birds and mammals

For each of the selected avian or mammalian toxicity studies, the test result is expressed as a $NOEC_{oral}$ in $mg \cdot kg_{food}^{-1}$. No observed adverse effect concentrations (NO(A)ELs, expressed on a basis of $mg \cdot kg_{bw}^{-1} \cdot d^{-1}$), are converted into $NOECs_{oral}$ (in $mg \cdot kg_{food}^{-1}$) using the following equations (Eqs. 3 and 4), with the conversion factors from Table or a suitable factor for the daily food intake for any other species:

$$NOEC_{\text{bird}} = NOAEL_{\text{bird}} \cdot CONV_{\text{bird}} \qquad (3)$$

$$NOEC_{\text{mammal,food\_chr}} = NOAEL_{\text{mammal,oral\_chr}} \cdot CONV_{\text{mammal}} \qquad (4)$$

Table 6. Conversion factors from NOAEL into NOEC for several species.

Species	Common name	Conversion factor ($bw \cdot DFI^{-1}$)
Canis domesticus	Dog	40
Macaca sp.	Macaque species(monkey)	20
Microtus spp.	Vole species	8.3
Mus musculus	House mouse	8.3
Oryctolagus cuniculus	European rabbit	33.3
Rattus norvegicus (>6 weeks)	Brown rat	20
Rattus norvegicus (≤ 6 weeks)	Brown rat	10
Gallus domesticus	Chicken	8

bw = body weight (g); DFI = daily food intake ($g \cdot d^{-1}$).

A1.4. BIOCONCENTRATION AND BIOMAGNIFICATION DATA

A1.4.1. Data collection

The literature should be searched for bioconcentration (BCF) and biomagnification (BMF) studies if a biota EQS is triggered (see Section 2 of the main guidance). Useful data sources for BCF values are the physicochemical properties and environmental fate handbook (Mackay *et al.*, 2006) and ECOTOX (US EPA, 2007a). The BCF and BMF data should be tabulated separately.

A1.4.2. Data evaluation and data tables

In principle, the evaluation of bioaccumulation data follows the evaluation for toxicity. All retrieved literature is read and evaluated with respect to its relevance and reliability. The most relevant BCF studies are those performed with fish, but studies performed with molluscs are important for secondary poisoning as well. The BCF data for other species should be carefully checked because they are prone to experimental errors, e.g. accumulation may not reflect uptake, but adsorption to the outside of the organism. For this reason, BCF values for algae are rarely reliable. A reliable BCF study should be similar in experimental set-up to the updated OECD guideline 305 (OECD, 1996). At least the concentration of the (parent) compound in the aqueous phase, and in fish, has to be measured at several time points. No specific guidance is available for BMF studies, which are mostly derived from field studies. Apart from the analysis, a reliable BMF study requires that the prey and predator species originate from the same area and from the same period in time. After evaluating a study, the results of the study are summarised by entering it into the appropriate data table (Section 0).

A1.4.3. Bioaccumulation data tables

The following subsections (Sections 0 to 0) discuss the parameters that are to be reported in the bioaccumulation data tables. The parameters are treated in the same order as they appear in the default bioaccumulation data table. The following subsections have titles identical to the column headings in the data tables.In the following sections, it is assumed that fish are the test organism most frequently encountered in BCF studies. However, BCF studies with molluscs may also be found. These data are relevant, as the food chain water → mollusc (→ fish) → mollusc/fish-eating bird or mammal is also important.

A1.4.3.1. Species

See Section A1.3.3.1.

A1.4.3.2. Test organism information

See Section A1.3.3.2.

A1.4.3.3. Test substance

Clearly report what compound is used. If a radiolabelled compound is used, it should be reported in this column of the bioaccumulation data table. For organic compounds that have one or more isomers, the specific isomer (or mixture of isomers) used in the test is reported, e.g. diastereomers, *cis*/*trans* conformation, *o*, *m*, *p* substitution, formulations, etc.

A1.4.3.4. Substance purity

See Section A1.3.3.6.

A1.4.3.5. Chemical analysis

A column in the bioaccumulation data table is included that gives information on the analysis of the aqueous phase/biological matrix. However, as the determination of the water and biota concentration is a prerequisite of any good BCF study, this column should give information on how the concentration is determined, e.g. GC-FID or GC-MS (gas chromatography coupled to a flame ionisation detector or a mass spectrometer, respectively) and HPLC-UV (high-performance liquid chromatography). Where a radiotracer is used, the method of detection is important. Liquid scintillation counting (LSC) measures total radioactivity, including the parent compound and metabolites. HPLC used in combination with radiodetection can be used to resolve only the parent compound.

A1.4.3.6. Test type

See Section A1.3.3.4.

A1.4.3.7. Test water

See Section A1.3.3.7.

A1.4.3.8. pH

See Section A1.3.3.8.

A1.4.3.9. Hardness/Salinity

See Sections A1.3.3.10 and A1.3.3.11.

A1.4.3.10. Temperature

See Section A1.3.3.9.

A1.4.3.11. Exposure time

In this column, the times of the uptake phase and, if carried out, the depuration phase are listed. If both phases are determined, the exposure time and depuration time are listed as two separate time spans: e.g. 14 + 14 d.

A1.4.3.12. Exposure concentration

The concentration at which the bioaccumulation study is performed is given in this column table. This is important because guidelines require that the concentration meets some conditions. For example, according to the OECD guideline 305 (OECD, 1996), the highest aqueous concentration should be about one hundredth of the acute LC50 or the acute LC50 divided by an appropriate acute-to-chronic ratio, while the lowest concentration should preferably be a factor of ten below the highest concentration, but at least ten times above the limit of detection in the aqueous phase. As explained in the main guidance (Section 2), the exposure concentration can have a major influence on BCF values. For metals, BCF data are invalid.

A1.4.3.13. Bioaccumulation

Unit: $L \cdot kg^{-1}$.

Here, the value of the BCF or BMF is denoted. The basis for the BCF value is the ratio of the concentration in wet weight (ww) of the organism, mostly fish, divided by the water concentration. The unit of the BCF is $L \cdot kg_{ww}^{-1}$; if the BCF is normalised to dry weight or lipid weight, this should be explicitly indicated with a note describing the origin of the value.

BCF values used for triggering and calculating the routes of secondary poisoning and human consumption of fishery products should be whole body BCFs, expressed in $L \cdot kg^{-1}$. This allows for variation since these BCFs are not normalised to lipid or fat content, which dominates accumulation. The EQS derivation is dependent on the available studies. In most older BCF studies, fat content is often not reported. It is preferable to include such studies because, otherwise, risks to predators and humans may be overlooked.

A1.4.3.14. Biological matrix

In this column in the table, it is reported what part of the organism the BCF has been determined for. Possibilities are, for example, whole fish ww, whole fish dw, edible parts, non-edible parts viscera, etc.

A1.4.3.15. Method

The method used to calculate the bioaccumulation value is reported in this column. Basically, the method can be based on equilibrium concentrations or on kinetics, including the uptake and depuration rate constants (k_1 and k_2). With equilibrium concentrations (noted as equilibrium), the BCF is determined as the quotient of the concentrations in organisms, mostly fish, and water at equilibrium. When the kinetic constants (k_1/k_2) are used to calculate the BCF, the BCF is calculated as the quotient of uptake rate (k_1) and depuration rate (k_2), mostly determined independently during an uptake and a depuration phase (k_1, k_2 independent). However, in some studies, k_2 is first determined from the depuration phase and k_1 estimated from the data of the uptake phase, with this value of k_2 implied to take the non-linearity of the uptake into account (k_1 implied by fitted k_2). A further possibility is that k_1 and k_2 are fitted simultaneously by a non-linear regression model.

If the method cannot be described easily, a footnote to the table can be entered.

A1.4.3.16. Notes

Additional notes may include information on the analysis, the basis of the BCF value (dry weight or lipid weight) or the method used to determine the BCF.

A1.4.3.17. Reference

See Section A1.3.3.18.

A1.4.4. Data selection

A1.4.4.1. BCF – experimental data

Aquatic compartment

From the valid studies summarised in the data table (Section 0) calculate the geometric mean values per species. Of these values per species, the most reliable should be taken unless they are equally reliable, in which case the geometric mean of several BCFs is selected. For metals, BCF values should not be used. Instead, BMF data should be used or an assessment as described in the main guidance.

A1.4.4.2. BCF – calculation method

Aquatic compartment

When a BCF cannot be derived on the basis of experimental data, a BCF may be calculated as described below for substances whose log K_{ow} value is ≥3.

For substances with a log K_{ow} of 2–6, the following linear relationship (Eq. 5), as developed by Veith *et al*. (1979), can be used:

$$\log BCF_{\text{fish}} = 0.85 \times \log K_{\text{ow}} - 0.70 \quad (5)$$

For substances with a log K_{ow} higher than 6, a parabolic equation can be used (Eq. 6):

$$\log BCF_{\text{fish}} = -0.20 \times \log K_{\text{ow}}{}^{2} + 2.74 \times \log K_{\text{ow}} - 4.72 \qquad (6)$$

Because of experimental difficulties in determining BCF values for such substances, this mathematical relationship has a higher degree of uncertainty than the linear one (Eq. 5). Both relationships apply to compounds with a molecular weight of less than 700. Further discussion can be found in REACH guidance, Chapter R.11 (ECHA, 2008).

A1.4.4.3. BMF – experimental data

Experimental BMF values generally originate from field studies. From the valid BMF studies summarised in a BMF data table, the geometric mean value is calculated.

A1.4.4.4. BMF – calculation method

When a BMF cannot be derived on the basis of experimental data, a BMF may be estimated using log K_{ow} data as described in Table 7. In this table, BMF_1 is a value for the biomagnification in the prey of predators for the freshwater environment. For the marine environment, an additional biomagnification step is included, which is reflected in the BMF_2 value. This BMF_2 is a value for biomagnification in the prey of top predators.

The most relevant values for BMF_1 are those for biomagnification from small to larger fish (either fresh or marine water). These larger fish then serve as food for predators such as otters and herons, or seals in the marine environment. Data for biomagnification from other small species such as crustaceans to fish might be useful as well, but care must be taken that in the further assessment of secondary poisoning, BCF and BMF values are consistent. For comparison, the default values from Table can be used. Another group of prey that might be relevant to the route of secondary poisoning are mussels. If mussels are directly consumed by birds or mammals and a BCF value for mussels is available, a biomagnification step would be absent. However, there are also several common fish species that feed on mussels. In such a case BMF data on accumulation from mussels to fish would be relevant.

For the marine environment a further biomagnification step is considered by introducing the BMF_2 value. This step refers to the biomagnification from fish to small mammals and birds. For the marine environment, a good example is the biomagnification from fish to seals. The latter species then serve as prey for top predators such as polar bears and killer whales. However, besides data for the marine environment, other data for biomagnification from fish to fish-eating birds and mammals should be considered as well.

Table 7 Default BMF values for organic substances.

log K_{ow} of substance	BCF (fish)	BMF_1	BMF_2
<4.5	<2000	1	1
4.5–<5	2000–5000	2	2
5–8	>5000	10	10
>8–9	2000–5000	3	3
>9	<2000	1	1

The second column of Table 7 also shows (ranges of) BCF values. However, if one or more experimental BCF data are available, the BCF values from the tables are not needed. If there is no experimental BCF value, the numbers from Table cannot be regarded as guidance, because they represent ranges instead of single values. In such a case, it is better to estimate the BCF from the log K_{ow}. This procedure is described in Section A1.4.4.2. The results are broadly consistent with the ranges presented in Table 7.

A1.5. TOXICOLOGICAL DATA FOR THE PROTECTION OF HUMANS

A1.5.1. Threshold limits

A human toxicological threshold value may be needed for EQS derivation in two cases:

- in the derivation of the $QS_{hh\ food,water}$ (consumption of fishery products)
- in the derivation of the $QS_{dw,water}$ (drinking water)

The human toxicological threshold values that can be used are the ADI (acceptable daily intake) and TDI (tolerable daily intake). The US ATSDR uses the term MRL (minimum risk level) while the US EPA uses the term RfD (reference dose). The basis for the human-toxicological threshold levels is in principle a NO(A)EL from a mammalian toxicity study, which is useful if established threshold levels are unavailable. However, the NOAEL is not a human toxicological threshold limit and an AF (typically 100) must be used. To derive a TDI or ADI from a NOAEL a human toxicologist should be consulted.

Effect data are the relevant NOAEL, ADI, TDI values identified in the human health section of risk assessments according to Council Regulation (EEC) No. 793/93 or Council Directive 91/414/EEC. The ADI or TDI values adopted by international bodies such as the World Health Organization may also be used. Where a threshold level cannot be given, unit risk values corresponding to an additional risk of, for example, cancer over the whole life of 10^{-6} (one additional cancer incident in 10^{6} persons taking up the substance concerned for 70 years) may be used, if available.

A list of organisations or frameworks that have published human toxicological threshold limits is presented in Table (extracted from Hansler *et al*., 2006). In general, it is advised to take the most recent value and consult a human toxicologist on the final choice of the value. If a clear value is reported in a European risk assessment report, this should be used.

Symbol	Description of variable	Unit	Value
AF	assessment factor	–	1–5
bw	human body weight	kg_{bw}	70
$Foc_{standard\ sediment,TGD}$	fraction of organic carbon in standard sediment as defined in the TGD	$kg \cdot kg^{-1}$	0.05
$Foc_{susp,TGD}$	weight fraction of organic carbon in suspended matter as defined in the TGD	$kg \cdot kg^{-1}$	0.1
R	gas constant	$Pa \cdot m^3 \cdot mol^{-1} \cdot K^{-1}$	8.314
TEMP	environmental temperature	K	285

ANNEX TO APPENDIX 1: DATA EVALUATION OF PHYSICOCHEMICAL DATA

1. Evaluation of the vapour pressure for use in EQS derivation

An OECD guideline exists for the experimental determination of the vapour pressure of a compound (OECD guideline 104; OECD, 1995b). In this guideline several methods are discussed, each with its own range of applicability. The following table presents information from the guideline, which specifies what method is suitable for which compound.

Table 9: Domain of applicability of different methods for the determination of vapour pressure

Method	Suitable for liquids	Suitable for solids	Recommended range
Dynamic method	low melting	yes	10^3-10^5 Pa
Static method	Yes	yes	10-10^5 Pa
Isoteniscope	Yes	yes	10^2-10^5 Pa
Effusion method	Yes	yes	10^{-3}-1 Pa
Gas saturation method	Yes	yes	10^{-5}-10^3 Pa
Spinning rotor method	Yes	yes	10^{-4}-0.5 Pa

In the dynamic method (Cottrell's method), the boiling point of a compound is determined at various pressures between about 10^3 and 10^5 Pa. In the static method, the vapour pressure is determined at one specified temperature by means of a manometer (e.g. 25 ºC). The isoteniscope method is based on the same principle as the static method. In the effusion method the weight loss of the compound is measured. This can be done directly by measuring the mass of the remaining substance or by analysing the volatilised amount by gas chromatography (GC). In the proposed update of guideline 104 (OECD, 2002), isothermal gravimetry is added for the effusion method. The weight loss is then determined at different temperatures and an extrapolation to 20 or 25 ºC can be made. The range of vapour pressures that can be determined with this method is 10^{-10} to 1 Pa. The gas saturation method makes use of a column containing a carrier material supporting the substance, through which an inert gas is passed. The concentration of the substance in this carrier gas is then determined, usually by gas chromatography (GC). The last method is the spinning rotor method, where the retardation of a spinning ball due to the friction with the gas phase is measured.

In general, the methods that make use of an analysis of the substance, for example, by gas chromatography, are less prone to errors due to impurities than the other methods. The OECD guideline does not mention this explicitly. However, degassing of more volatile compounds prior to the determination of the vapour pressure also enhances the reliability of the determination.

The retention time in gas chromatography can be used to estimate the vapour pressure of a compound. Although this is not a direct determination of the vapour pressure, it generally gives rather accurate results and is applicable to substances with a very low vapour pressure. In addition to this, the vapour pressure can be estimated by the programme MPBPwin, which is incorporated in EPI Suite (US EPA, 2007b). The programme makes use of three estimation methods, which are the Antoine method, the modified Grain method and the Mackay method. All three methods make use of the boiling point for their estimation of the vapour pressure. Also the melting point of the compound is a necessary parameter for the estimation. Both boiling and melting point can be estimated by the programme, but experimental values can also be entered if known. For solids, the result of the modified Grain method is presented as the preferred value, while for liquids this is the mean of the Antoine method and the modified Grain method. A value for the vapour pressure can also be estimated by SPARC (Karickhoff *et al.*, 2007), which has a mechanistic thermodynamic basis. In the data tables, both estimated values are reported as well.

2. Henry coefficient

No general accepted guideline exists for the determination of the Henry coefficient. However, several methods exist to determine the Henry coefficient experimentally.

In the batch stripping method, gas is bubbled at a known rate through a solution of the compound in water. The Henry coefficient is calculated with a mass balance from the decrease in the aqueous concentration. The concentration in air is generally not measured. This method works well for fairly volatile compounds with Henry coefficients higher than 2.5 and occasionally down to 0.25 $Pa \cdot m^3 \cdot mol^{-1}$ (Mackay *et al.*, 2000).

One common method, very similar to the batch stripping method, is the gas stripping method in which a gas is bubbled through the aqueous solution and both the aqueous concentration and the gas concentration are determined. The technique was applied to chlorobenzenes, PAHs, and PCBs in a range from 0.018 to 276 $Pa \cdot m^3 \cdot mol^{-1}$ (Ten Hulscher *et al.*, 1992).

A method for highly volatile compounds (i.e. higher than 120 $Pa \cdot m^3 \cdot mol^{-1}$) is the equilibrium partitioning in closed systems (EPICS) method. With this method a known volume of solute in water solution is equilibrated with air in sealed vessels. The headspace air concentrations are measured. The method has a high precision (Mackay *et al.*, 2000). A number of other headspace analysis techniques that are used, are slightly different from the EPICS method, in some techniques not only the headspace but both phases are analysed (Mackay *et al.*, 2000).

A method for less volatile compounds is the wetted-wall method. In this method the solute is equilibrated between a thin flowing film of water and a concurrent air flow in a vertical column. Both phases are measured. The method has been applied to pesticides and other less volatile compounds, but no recommended range is given (Mackay *et al.*, 2000). In the handbook (Mackay *et al.*, 2006), values for polychlorinated biphenyls (PCBs), polyaromatic hydrocarbons (PAHs), and two pesticides are tabulated using this method. Values for PCBs and PAHs range from 0.91 to 74.3 $Pa \cdot m^3 \cdot mol^{-1}$. One of the pesticides (alachlor) has a much lower Henry coefficient of $8.43 \cdot 10^{-4}$ $Pa \cdot m^3 \cdot mol^{-1}$. This is in agreement with the method being suitable for less volatile compounds.

Also the Henry coefficient is sometimes related to retention times (Mackay *et al.*, 2000). However, results obtained using this method should be considered as an estimate. Another estimation that is often used for the Henry coefficient is the quotient of vapour pressure and solubility. This method works quite well for substances that have a solubility of less than 1% in water. The Henry coefficient can also be calculated by a bond contribution method as included in EPI Suite (US EPA, 2007b). These estimated values should be included in the data table.

3. Evaluation of the water solubility for use in EQS derivation

For the experimental determination of the water solubility, an OECD guideline is available (OECD guideline 105; OECD, 1995c), in which two methods are discussed. These methods are the flask method (shake-flask) and the column elution method (generator column). The flask method can be used for compounds with a solubility higher than 10 $mg \cdot L^{-1}$. Below that value, colloid formation will overestimate the true aqueous solubility and in that case the column elution method should be used, which prevents this phenomenon.

Apart from the methods proposed in the OECD guideline, the water solubility of poorly soluble liquid compounds can be accurately determined by means of the slow-stirring method. The reliability of the slow-stirring method applied to liquid substances can be considered as equivalent to that of the column elution method. Only few examples are available of the use of this method for the determination of the solubility, mostly for hydrocarbons and phthalate esters (Tolls *et al.*, 2002; Letinski *et al.*, 2002; Ellington, 1999). This method is often used to prepare saturated solutions of hydrocarbon mixtures (oil products) in water (water accommodated fractions or WAF), by which information on the solubility of a mixture is given (Schluep *et al.*, 2002).

Estimates of the water solubility can be made by two different programmes included in EPI Suite (US EPA, 2007b). These programmes are WSKOWwin, which estimates the solubility from log K_{ow}, and WATERnt, which is a fragment method for water solubility independent of log K_{ow}. Experimental values for log K_{ow} and melting point can be entered in WSKOWwin if available. Otherwise WSKOWwin will use the default values (experimental or calculated) from EPI Suite for these parameters. Another estimation method for the water solubility is the calculation performed by SPARC (Karickhoff *et al.*, 2007), which has a mechanistic thermodynamic basis. These estimated values are reported as well in the data tables.

4. Evaluation of K_{ow} values for use in EQS derivation

Several methods are available for the experimental determination of log K_{ow}. In the OECD guidelines, two methods are available and further there is one draft guideline. The first method is the shake-flask method (OECD guideline 107; OECD, 1995a). This method works well for log K_{ow} values in the range between -2 and 4 (occasionally up to 5), but is impossible to use with surface-active materials. For these materials, a calculated value (using BioLoom; BioByte, 2004) or an estimate based on individual *n*-octanol solubility and water solubility should be provided, preferably in mutually saturated *n*-octanol and water (Sijm *et al.*, 1999; Li and Yalkowsky, 1998a; Li and Yalkowsky, 1998b).

The second method is the HPLC method. Values of log K_{ow} in the range between 0 and 6 can be estimated using high performance liquid chromatography (OECD guideline 117; OECD, 2004). The HPLC method is not applicable to strong acids and bases, metal complexes, surface-active materials or substances which react with the eluent. The HPLC method is less sensitive to the presence of impurities in the test compound than is the shake-flask method. Nevertheless, in some cases impurities can make the interpretation of the results difficult because peak assignment becomes uncertain. For mixtures which give an unresolved band, upper and lower limits of log K_{ow} should be stated.

Before deciding on what procedure to use, a preliminary estimate of the log K_{ow} should be obtained from calculation (see the annex to OECD guideline 117), or where appropriate from the ratio of the solubilities of the test substance in the pure solvents. Still, the HPLC method should be regarded as an estimation method of the log K_{ow}, because it does not directly measure the distribution of a compound between octanol and water.

Another method that determines the distribution of a compound between *n*-octanol and water directly, but whose reach extends beyond the range of the shake-flask method, is the slow-stirring method (draft OECD guideline 123; OECD, 2003). With this method, log K_{ow} values up to 8.2 can be accurately determined, making it suitable for highly hydrophobic compounds. This method prevents the formation of micro droplets of *n*-octanol in the aqueous phase, which results in an overestimation of the water concentration and, consequently, an underestimation of the log K_{ow} value. For the same reason, the shake-flask method can only be used up to log K_{ow} values of around 4 and definitely not higher than 5.

Another method that is not mentioned in OECD guidelines is the generator-column technique. Although this technique is most frequently used for the determination of the water solubility, it is occasionally used for the determination of log K_{ow}. Because the supporting material silica, saturated with *n*-octanol containing the compound, is held in a column, the formation of micro droplets is excluded. For this reason, the results from this technique can be considered equivalent to results obtained with the slow-stirring method. In general, good correlation exists between the slow-stirring method and the generator-column technique, within the experimental error of both methods. However, only a limited number of studies is available that makes use of this technique, primarily for chlorinated biphenyls and dibenzodioxins (e.g. Tewari *et al.*, 1982; Miller *et al.*, 1984; Doucette and Andren, 1987; Doucette and Andren, 1988; Hawker and Connell, 1988; Shiu *et al.*, 1988; Li and Doucette, 1993; Yeh and Hong, 2002).

Except from experimental determination, log K_{ow} values can also be calculated with a QSAR programme. The log K_{ow} values calculated with ClogP (BioByte, 2004) and EPI Suite (US EPA, 2007b) are always presented for comparison. Both programmes are based on a fragment contribution method. Besides this, SPARC (Karickhoff *et al.*, 2007) is a third estimation programme for the log K_{ow} that is frequently used. This programme is not based on a fragment contribution but has a mechanistic thermodynamic basis.

5. Evaluation of K_{oc} values for use in EQS derivation

The organic carbon normalised partition coefficient (K_{oc}) is calculated or directly retrieved from literature for all valid adsorption studies collected. The sediment type that underlies these partition coefficients is reported in the table. The organic carbon content is also reported. The method to determine the K_{oc} most accurately is the OECD guideline 106 (OECD, 2000). All K_{oc} values that are determined with a method similar to this guideline can be regarded as reliable. However, the TGD also allows K_{oc} values to be derived from field studies or simulation studies. Therefore, whether or not a sorption study is reliable remains subject to expert judgement.

The K_{oc} may also be calculated. Estimation of K_{oc} from K_{ow} is the preferred route, following the QSAR method described in the TGD (cited in the next section). A short description of the use of the method is given after the citation.

Citation from TGD, part III (European Commission (Joint Research Centre), 2003b):

> 'The models are based on linear regression analysis and log K_{ow} as descriptor variable. It should be noted that all models are developed assuming an equilibrium state. For certain classes of chemicals, e.g. anilines and carbamates, this assumption is not correct, because the sorption to soil is irreversible due to the formation of bonded residues. Improvements of the more specific models is certainly feasible if parameters for more specific interactions are taking into account.
>
> '*Domain*

An extensive description of the domain is given in Table [32]. The description is made in terms of chemical structures as well as in terms of log K_{ow} ranges.

> '*Accuracy*

The standard errors of the estimates (± 2σ range = 95%)[33] range from 0.35 to 1.0 log units for the different models. The standard errors are indicated in Table 3[5] for each model. A cross-validation has not been performed yet. External validation is not possible, because all available data have been used to generate the models (Sabljić *et al.*, 1995 cited in: European Commission (Joint Research Centre), 2003a).'

---

[32] The number of the table refers to that given in this annex and not the table number in the TGD.

[33] For clarification, the standard error is equal to σ.

Table 10. Domain of the sorption models (Sabljić et al., 1995 cited in: European Commission (Joint Research Centre), 2003a).

Model	X-variable domain log K_{ow} in log units	Chemical domain	Substituents or Warnings
Hydrophobics	1–7.5	All chemicals with C, H, F, Cl, Br, and I atoms	
Nonhydrophobics	(–2.0)–8.0	All chemicals that are not classified as hydrophobics	Overestimated *n*-Alkyl Alcohols (0.9 log units) Organic Acids (0.55 log units) Underestimated Amino-PAHs (1–2 log units) Aliphatic Amines (1–2 log units) Alkyl Ureas (1.0–1.5 log units)
Phenols	1.0–5.0	Phenols	Cl, Br, CH_3, OH, NO_2, CH_3O
		Anilines	Cl, Br, CH_3, CF_3, CH_3O, NMe
		Benzonitriles	Chlorinated
		Nitrobenzenes	Cl, Br, NH_2
Agricultural	(–1.0)–8.0	Acetanilides

Phenylureas	0.5–4.2	Phenylureas	CH_3, CH_3O, F, Cl, Br, Cycloalkyls, CF_3, PhO
Phosphates	0.0–6.5	All Phosphates	
Triazines	1.5–4.0	Triazines	Cl, CH_3O, CH_3S, NH_2, N-Alkyl
Triazoles	(–1.0)–5.0	Triazoles	Alkyl, CH_3O, F, Cl, CF_3, NH_2

Table 11. QSARs for sediment sorption for different chemical classes (Sabljić et al., 1995 cited in European Commission (Joint Research Centre), 2003a).

Chemical class	Equation	Statistics
Predominantly hydrophobics	$\log K_{oc} = 0.81 \log K_{ow} + 0.10$	n=81, r^2=0.89, s.e.=0.45
Nonhydrophobics	$\log K_{oc} = 0.52 \log K_{ow} + 1.02$	n=390, r^2=0.63, s.e.=0.56
Phenols, anilines, benzonitriles, nitrobenzenes	$\log K_{oc} = 0.63 \log K_{ow} + 0.90$	n=54, r^2=0.75, s.e.=0.40
Acetanilides, carbamates, esters, phenylureas, phosphates, triazines, triazoles, uracils	$\log K_{oc} = 0.47 \log K_{ow} + 1.09$	n=216, r^2=0.68, s.e.=0.43
Alcohols, organic acids	$\log K_{oc} = 0.47 \log K_{ow} + 0.50$	n=36, r^2=0.72, s.e.=0.39
Acetanilides	$\log K_{oc} = 0.40 \log K_{ow} + 1.12$	n=21, r^2=0.51, s.e.=0.34
Alcohols	$\log K_{oc} = 0.39 \log K_{ow} + 0.50$	n=13, r^2=0.77, s.e.=0.40
Amides	$\log K_{oc} = 0.33 \log K_{ow} + 1.25$	n=28, r^2=0.46, s.e.=0.49
Anilines	$\log K_{oc} = 0.62 \log K_{ow} + 0.85$	n=20, r^2=0.82, s.e.=0.34
Carbamates	$\log K_{oc} = 0.37 \log K_{ow} + 1.14$	n=43, r^2=0.58, s.e.=0.41
Dinitroanilines	$\log K_{oc} = 0.38 \log K_{ow} + 1.92$	n=20, r^2=0.83, s.e.=0.24
Esters	$\log K_{oc} = 0.49 \log K_{ow} + 1.05$	n=25, r^2=0.76, s.e.=0.46
Nitrobenzenes	$\log K_{oc} = 0.77 \log K_{ow} + 0.55$	n=10, r^2=0.70, s.e.=0.58
Organic acids	$\log K_{oc} = 0.60 \log K_{ow} + 0.32$	n=23, r^2=0.75, s.e.=0.34
Phenols, benzonitriles	$\log K_{oc} = 0.57 \log K_{ow} + 1.08$	n=24, r^2=0.75, s.e.=0.37
Phenylureas	$\log K_{oc} = 0.49 \log K_{ow} + 1.05$	n=52, r^2=0.62, s.e.=0.34
Phosphates	$\log K_{oc} = 0.49 \log K_{ow} + 1.17$	n=41, r^2=0.73, s.e.=0.45
Triazines	$\log K_{oc} = 0.30 \log K_{ow} + 1.50$	n=16, r^2=0.32, s.e.=0.38
Triazoles	$\log K_{oc} = 0.47 \log K_{ow} + 1.41$	n=15, r^2=0.66, s.e.=0.48

n is the number of data, r^2 is the correlation coefficient and s.e. the standard error of estimate.

(End of citation)

The QSARs in Table 3 are from a report cited in the TGD, but they can also be found in the public literature (Sabljić *et al*., 1995). In principle, the appropriate QSAR should be chosen on basis of this table. For many compounds with polar groups attached, a separate QSAR is available for that particular chemical class. In general, these QSARs do not deviate very much from the QSARs for larger subsets of chemical classes. However, if there is doubt about which QSAR to use, for example, due to the presence of more than one functional group, it is often most convenient to use the more general QSARs, in particular the QSAR for non-hydrophobic chemicals. This QSAR, together with the QSAR for predominantly hydrophobic compounds provides a reasonable estimate of the K_{oc} for most compounds.

The K_{oc} can also be estimated with an HPLC method (OECD guideline 121; OECD, 2001). As the title of the method indicates, this is no direct determination of the K_{oc} but an estimate based on another property (retention in HPLC). Also the estimation routine PCKOCwin, which employs a calculation method based on molecular connectivity indices (MCI), may be used to estimate the K_{oc}. PCKOCwin is embedded in the EPI Suite software (US EPA, 2007b). Both methods can aid in the decision by means of an independent estimation, in the case that the interpretation of the estimation method based on log K_{ow} according to the TGD is difficult. Both the estimated value from molecular connectivity and values estimated with the HPLC method, if any available, should be reported.

6. Evaluation of K_p values for metals for use in EQS derivation

Adsorption of metals to the solid fraction of sediment or particulate (suspended) matter is dependent on many variables such as cation exchange capacity, organic matter content and clay content, pH, redox potential, etc. In contrast to organic compounds, there is no estimation method to predict metal–solids partitioning in environmental compartments from compound properties. Thus, partition coefficients for metals have to be determined in and retrieved from experimental studies.

The K_p values are collected from all valid studies reporting metal partition coefficients.

Relevant studies are those that report K_p values for sediment or suspended matter (or K_d values) determined in *field* samples. Batch adsorption studies, performed in the laboratory, are a second type of potentially relevant studies. An established data source of metal K_p values for bulk compartments (sediment, suspended matter) does – to our knowledge– not exist. A few references that are of interest are Sauvé *et al*. (2000) and Bockting *et al*. (1992), although values of the latter have been criticised (Koops *et al.*, 1998). Due to the heterogeneity of adsorbents encountered in various compartments, K_p values for metals usually show a high variation. Since normalisation is generally impracticable, selection of the K_p value(s) to be used in equilibrium partitioning (EqP) needs careful consideration.

APPENDIX 3: BIOCONCENTRATION, BIOMAGNIFICATION AND BIOACCUMULATION

Accumulation is a general term for the net result of absorption (uptake), distribution, metabolism and excretion (ADME) of a substance in an organism. Information on accumulation in aquatic organisms is vital for understanding the fate and effects of a substance in aquatic ecosystems. In addition, it is an important factor when considering whether long-term ecotoxicity testing might be necessary. This is because chemical accumulation may result in internal concentrations of a substance in an organism that cause toxic effects over long-term exposures even when external concentrations are very small. Highly bioaccumulative chemicals may also transfer through the food web, which in some cases may lead to biomagnification.

The change in concentration of a chemical in biota (C_b) over time can be described as:

$$\frac{dC_b}{dt} = k_{upt} \cdot C_w + k_{food} \cdot C_{food} - k_{dep} \cdot C_b - k_{exc} \cdot C_b - k_{met} \cdot C_b$$

where C_w and C_{food} represent the concentrations of the chemical in the water column and in the food; and the subscripts *upt*, *dep*, *exc* and *met* refer to uptake, depuration, excretion and metabolism, respectively (Gobas *et al*., 1988).

Bioconcentration refers to the accumulation of a substance, dissolved in water, by an aquatic organism. The bioconcentration factor (BCF) of a compound is defined as the ratio of the concentration of the chemical in the organism and in water at equilibrium.

$$BCF = \frac{C_b}{C_w}$$

The uptake of a chemical from water is a passive diffusion process across the skin or gill membrane, similar to oxygen uptake. Several factors affect this uptake, such as the physicochemical characteristics of the compound, the characteristics of the receptor and the environmental conditions. For example, Boese (1984) demonstrated that decreasing oxygen level in the water accelerated the accumulation of contaminants in the body of clams.

Bioconcentration is normally related to the octanol-water partition coefficient of the compound and the lipid fraction in tissues of the organism (Van der Oost *et al*., 2003). Several log-linear correlations exist between the logarithm of the octanol-water partition coefficient and the BCF (e.g.: Devillers *et al*., 1996; Hawker and Connel, 1985, 1986).

The existence of equilibrium between the concentration of the chemical in the organism and the concentration in the water is not easy to assess. For example, for rainbow trout Vigano *et al*. (1994) measured a time range between 15 and 256 days to reach equilibrium after exposure to different concentrations of PCBs.

Biomagnification refers to the accumulation of substances via the food chain. It may be defined as an increase in the (fat-adjusted) internal concentration of a substance in organisms at successive trophic levels in a food chain. The biomagnification factor is defined as the ratio between the uptake of a contaminant from food and its removal by depuration (*dep*), excretion (*excr*) and metabolism (*meta*)(Sijm *et al*., 1992),

$$BMF = \frac{k_{food}}{k_{dep} + k_{excr} + k_{meta}}$$

The uptake from food can be also defined as:

$$k_{food} = F_F \cdot eff_F$$

where F_F is the quantity of food ingested per unit mass per unit time and eff_F is the efficiency of uptake of the chemical from food.

The BMF can also be expressed as the ratio of the concentration in the predator and the concentration in the prey:

$BMF = C_o/C_d$

where BMF is the biomagnification factor (dimensionless)

C_o is the steady-state chemical concentration in the organism (mg/kg)

C_d is the steady-state chemical concentration in the diet (mg/kg)

Russell *et al*. (1999) demonstrated that significant biomagnification is not observed for values of log K_{ow} lower than 5.5. Moreover, Fisk *et al*. (1998) observed a high potential to accumulate along aquatic food webs for chemicals with log $K_{ow} \approx 7$.

Laboratory experiments demonstrated that digestibility and absorption of food are critical parameters controlling the BCFs in fish (Gobas *et al*. 1999). Furthermore, Opperhuizen (1991) found that biomagnification accounts for a more important fraction of accumulation of chemicals for larger fish than for smaller fish, which is probably due to a decrease in gill ventilation volume while the relative feeding rate is almost the same.

The term **bioaccumulation** refers to uptake from all environmental sources including water, food and sediment. The bioaccumulation factor (BAF) can be expressed for simplicity as the steady-state (equilibrium) ratio of the substance concentration in an organism to the concentration in the surrounding medium (e.g. water). Normally, it is evaluated using a multiplicative approach. Therefore, the Bioaccumulation Factor (BAF) may be calculated as:

$$BAF = BCF \cdot \prod_{i=1}^{n} BMF_i$$

where the number of biomagnifications factors depends on the trophic level or position of the organism in the food web.

In a recent review, which recommends the use of a high quality field derived BAF, Arnot and Gobas (2006) analysed 392 scientific literature and database sources which included 5317 BCFs and 1656 BAFs values measured for 842 organic chemicals in 219 aquatic species. Their results indicate that 45% of BCF values are subject to at least one major source of uncertainty and that measurement errors generally result in an underestimation of actual BCF values; the situation is similar for BAF, however there are much less published values.

APPENDIX 4: INVESTIGATION OF FURTHER METHODOLOGIES TO IMPROVE THE PROTECTION OF PREDATORS AGAINST SECONDARY POISONING RISK

A4.1. Introduction

In Section 4 (Derivation of Biota Standars) only the protection of top predators' birds and mammals species is considered against the secondary poisoning risk. However the CSTEE (2004) expressed their concerns on the fact that the exposure of chemicals through the food chain is not only relevant for secondary poisoning in birds and mammals, but also for aquatic invertebrates and fish.

Few data assessing the oral route toxicity are currently available for organisms other than birds and mammals. However some relevant ecotoxicological information can be found in the literature or can be produced, as strongly recommended by the CSTEE, for the very limited number of chemicals selected as priority substances.

In order to improve the development of quality standards for the protection of predatory organisms some further methodologies to assess secondary poisoning are discussed.

On one hand, if relevant chronic toxicity data, expressed in terms of the concentration of the chemical in food to which the test subjects were exposed, is available for sediment and pelagic predators e.g. aquatic invertebrates and fish, then a secondary poisoning assessment based on the diet approach set for birds and mammals top predators can be followed, see Section 4. On the other hand, if toxicological data, related to tissue residues in the considered organisms, are available, taking into account all exposure routes for different sediment and pelagic predators, the so-called Critical Body Burden (CBB) approach can be applied for organics as well as for metals. The advantages and disadvantages of this approach are discussed below.

In addition, for the very few data rich cases, the Species Sensitivity Distribution (SSD) approach can be used for both the diet approach and critical body burden approach, to derive an EQS.

Finally, the fish predator is presented as a case study to investigate the potential to derive an EQS based on the previous approaches.

A4.2. Diet Approach

A diet based approach, similar to the one adopted to protect Birds and Mammals Top Predators and in which the concentrations of contaminants in the food of the organisms to be protected are compared against acceptable concentrations in the organisms food, derived from feeding studies, may offer considerable potential for the development of quality standards for the protection of other predatory organisms. A key advantage of this approach is that currently many of the available and relevant chronic toxicity data are expressed in terms of the concentration of the chemical in food to which the test subjects were exposed.

Where this approach is taken it is important that the matrix which is analysed for the assessment of compliance against the quality standard is representative of the food of the organisms to be protected. The species receiving the greatest exposure will be the species with the highest food ingestion rate relative to its body weight and feeding at the highest trophic level(s).

The information presented in Figure 1 indicates that the food ingestion rates, when expressed as a percentage of the organism’s body weight consumed per day, are highest for small organisms, and are higher for small birds than for small mammals.

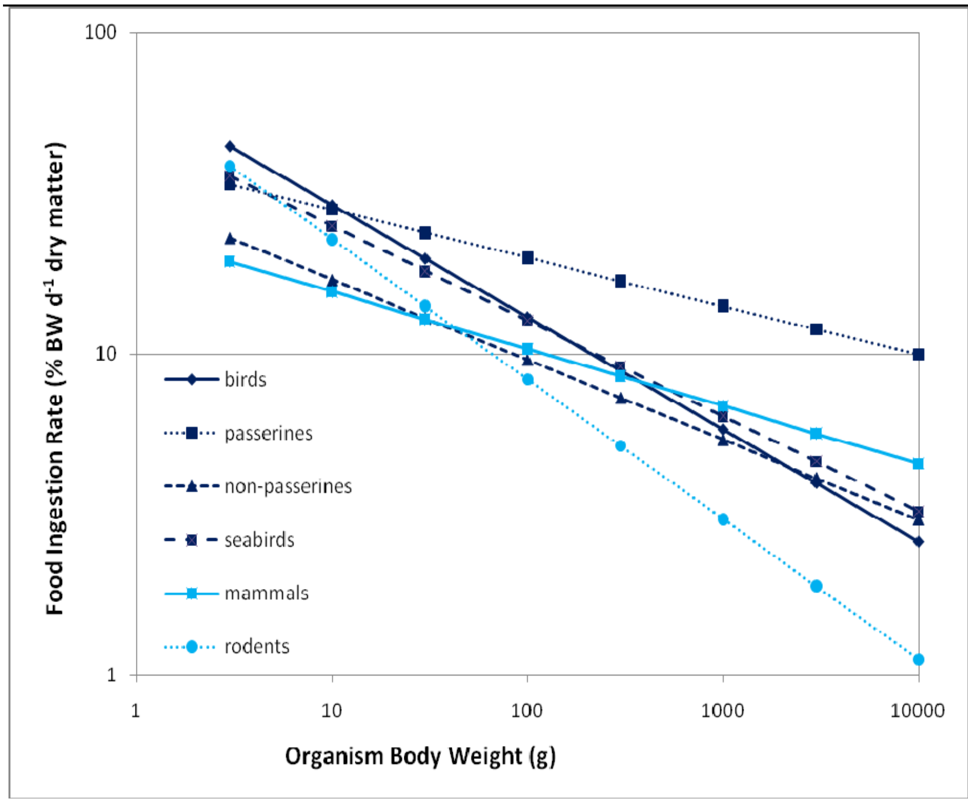

Figure 1 Variation in food ingestion rates, expressed as dry matter and as a percentage of organism body weight per day. Food ingestion relationships from USEPA (1993).

The diet based approach is considered to be a practical option for a relatively large number of substances which may require quality standards deriving for the protection of secondary poisoning.

For the description of the methodology to derive an EQS according to the diet approach please refer to the general and refined approach for birds and mammals top predators in Section 4 of the guidance.

Consideration of mixed diet

If a mixed diet must be considered, the daily food intake rate for food item is not simply achieved by applying the respective fraction as a factor to the respective DFI for a "pure" diet. Instead, the DFI has to be adjusted to reflect the actual contribution of each food item to the daily energy expenditure (DEE) of the indicator species. Starting from a given diet composition in terms of fresh weight, first, the energy content of 1g of the mixed diet (fresh weight) is calculated, taking into account the fractions of individual food items and their respective specific energy contents. Using this figure, DFI_{total}, i.e. the required amount of the mixed diet to reach the DEE of the indicator species can be determined.

$$DFI_{total} = \frac{DEE}{\sum_i PD_i \cdot FE_i \left(1 - \frac{MC_i}{100}\right)\left(\frac{AE_i}{100}\right)}$$

In which:
DFI_{total} = Daily Food Intake rate of total mixed diet (g fresh weight/d)
DEE = daily energy expenditure of the indicator species (kJ/d)
PDi = Fraction (percentage in diet) of food item [i] in mixed diet (related to fresh weight)
FEi = Food energy of food item [i] in mixed diet (kJ/dry g)
MCi = Moisture content of food item [i] in mixed diet (%)

AEi = Assimilation efficiency of food item [i] in mixed diet (%)

The actual DFI_i for one food item [i] in the mixed diet (g fresh weight/d) is then achieved by multiplying DFI_{total} by PDi the fraction for the respective food item.
If the food composition is given in terms of dry weight, the same calculation is applied to achieve DFI_{total}, but the DFIi have to be recalculated to fresh weight to be compliant with the derivation of an $EQS_{biota.TopPredators}$.

Further refinement of the assessment factors

The TGD (2003) highlighted some specific considerations that need to be made in selecting an AF for predators.

- CCME (1998) contains wildlife data on body weight and daily food ingestion rates for 27 bird and 10 mammalian species. In addition, Schudoma *et al*. (1999) derived the mean body weight and daily food intake for the otter. The currently available set on wildlife *bw/DFI* ratios ranges from 1.1 to 9 for birds and from 3.9 to 10 for mammalian species. Comparison of these wildlife conversion factors with the values given in Table 4.4 for laboratory species (8.3 – 40) shows that the wildlife species often have a lower *bw/DFI* ratio than laboratory animals. The difference can be up to a factor 8 for birds and 10 for mammals.
- The interspecies variation, however, should comprise more than just the *bw/DFI* differences between species, e.g. the differences in intrinsic sensitivity. The protective value of the "normal" interspecies variation factor may therefore be questionable in case of predators.
- On top of that, many predator species are characterised by typical metabolic stages in their life-cycle that could make them extra sensitive to contaminants in comparison with laboratory animals (e.g. hibernation or migration). Similar to the *bw/DFI* differences, also this aspect goes beyond the 'normal' interspecies variation.

The Table 4.5 gives AF values corresponding to an AF of 10 for the interspecies variations, (excluding the AF of 3 which take into account differences in ingested dose between the test and wildlife species) and an AF ranging from 3 to 10 for the subchronic to chronic extrapolation.

It should be noticed that in the only study found that examined the use of uncertainty factors for the development of wildlife criteria (U.S. EPA, 1995), a value ranging from 1 to 100 is applied to account for uncertainties when extrapolating toxic effect across species (based on the analysis that 91% of 246 separate interspecies NOAEL ratios for wildlife were less than or equal to a factor of 100) and a value ranging between 1 to 10 is applied to account for the subchronic to chronic extrapolation. In the U.S. EPA (1995) document some guidance is given to select the most appropriate assessment factors on a case-by-case basis. Basically to set the AF for interspecies variation the experts consider the physicochemical, toxicokinetic and toxicodynamic properties of the chemical of concern and the amount and quality of the available data. Selection of the subchronic to chronic assessment factor includes consideration of the amount of time required for the chemical to reach equilibrium in the tissues.

The Canadian Council of Ministers of the Environment adopted the same strategy in their guidelines (CCME, 1998) and proposed an AF ranging from 10 to 100 for the interspecies variations and an AF of 10 for the subchronic to chronic extrapolation.
According to these studies there are still some possibilities to refine the AFs for $EQS_{biota\text{-}TopPredators}$ derivation by increasing the knowledge on the interspecies sensitivity at a site or at EU level and on the toxicokinetic properties of the tested substances.

Finally it should be mentioned that further refinement of the interspecies variation should include more information on the intrinsic and the metabolic stages (e.g. hibernation or migration) sensitivities of the organisms intended to be protected.

Protection of fish predators: Case Study

There are currently a number of standard tests for assessing the potential effects of chemicals on fish, in terms of both their direct toxic effects and their uptake and potential for food-chain transfer.

However, these tests do not usually determine the various effect levels (e.g. NOEC, EC10, etc.) relating to the food exposure so there is currently insufficient information to derive a specific quality standard for pelagic predators. Food ingestion rates for fish assumed within the AQUAWEB model (Arnot and Gobas 2004) range from <0.1, for large fish, up to approximately 15 percent body weight per day, for very small fish (on a wet weight basis). Assuming the food to be 90% moisture the food ingestion rates on a dry weight basis are an order of magnitude lower (i.e. less than 2% body weight per day), the data are shown in Figure 3. These food ingestion rates are much lower than those assumed for birds and mammals, when expressed on a dry weight basis (see Figure 1). This might indicate that quality standards derived for the protection of small piscivorous birds are also likely to provide adequate protection for piscivorous fish when exposed by food ingestion. However differences in species sensitivity and trophic level of the food basket must also be considered.

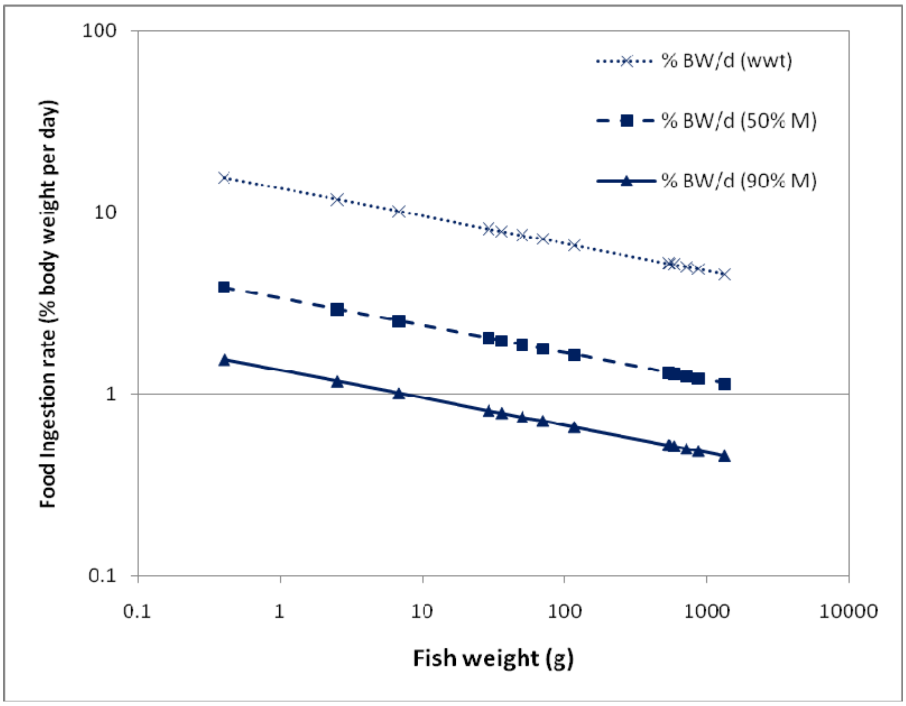

Figure 2 Variation in food ingestion rates for fish, expressed as wet weight (%bw/d (wwt)) and as dry matter assuming 50% (%bw/d (50% M)) and 90% (%bw/d (90% M)) moisture content of the food. All expressed as a percentage of organism body weight per day. (Data from Arnot and Gobas, 2004).

It is not currently considered to be practical to develop separate quality standards for the protection of pelagic predators because of the lack of data. A first approach is to assess if the quality standard for biota is likely to be protective of exposures via the food, and the quality standard for water is likely to be protective of exposures via the water. It may be necessary to review this position should information become available suggesting that where combined exposures occur, from both the water and food, the available quality standards may not be protective and adequate information is available for their derivation and implementation.

A4.3. The critical body burden (CBB) or critical body residues (CBR) approach

The approach of relating ecological toxicity with external concentrations (in this case water values) has some disadvantages for highly hydrophobic substances that do not show toxicity below their solubility values and for substances that tend to bioaccumulate through the food web. For this reason it may be more convenient to change scale of the x-axis when measuring dose and effects and to use concentration in the organisms. In addition measuring concentrations in biota provides indication on the specific bioavailability of a chemical and an integrated estimation of the environmental exposure routes and duration and a strong causality link between acquired dose and biological effect (Meador, 2006). Finally by comparing both metrics in the same experiment it is possible to estimate toxicity and BCF reducing the number of animal tests. Table 4 summarises the main characteristics of this approach when compared with the measurement of water concentrations.

Table 12. Tissue versus water concentration measurements

Tissue concentration	Water concentration
Direct measure of accumulated dose	Indirect measure
Indication of specific bioavailability	Does not consider bioavailable concentration
Integration of exposure routes	Biomagnification not included
Integration of exposure duration	Variable on exposure dynamics (pulse, seasonal, etc.)

The use of Critical Body Burden (CBB) or Critical Body Residue (CBR) - the molal tissue concentration (mmol/kg) of a toxic chemical able to produce a toxic effect, i.e. mortality, reduced growth, reduced reproduction- has been recently promoted by various stakeholders for European risk assessment (see TGD RIP 3.3 and RIP3.2, Chapter R.7B, Appendix 7.8-4), for use in the derivation of environmental quality standards under the Water Framework Directive and in the process of adding substances to the Stockholm Convention on POPs. Under this Convention, CBRs are recommended as a means to compare with environmental concentrations.

This approach was originally proposed after the determination that the tissue concentration of many chemicals with the same mode of toxic action[34] was relatively constant for a defined level of toxicity (McCarty, 1986). McCarty and Mackay (1993) reviewed the CBB approach distinguishing by several model of action, i.e. narcotic, excitatory agents, acetylcholinesterase (AChE) inhibitors, reactives/irritants, central nervous system (CNS) seizure agents, aryl hydrocarbon (Ah) receptor agonists, etc. and between polar and nonpolar compounds. However, even though experimental data supported the application of the CBB approach they cautioned that not all mode of action may support it.

In a recent review, Barron *et al*. (2002) found that experimental data available showed a high variability in tissues residues associated with adverse effects, both within and between chemicals. In addition, dependence on pH, temperature and metabolism showed that the applicability of the CBB approach was not as widely as initially thought. Verhaar *et al*. (1999) showed also that with receptor mediated toxicity the approach did not work. Furthermore, Schuler *et al*. (2004) showed that the CBB approach is not able to deal with substances that form toxic metabolites.

[34] Mode of toxic action is defined as a common set of physiological and behavioural signs that characterize a type of adverse biological response and it can be divided into specific and non-specific. This later is generally referred as the narcosis mode of action (Meador, 2006)

However the inherent advantages of the CBB approach, the great variability range for some substances may exclude the use of one concentration value by model of action and probably a more suitable approach would consists on developing dose-response curves based on tissue concentration like in water and then using the Species Sensitivity Distribution (SSD) approach to arrive at a definition of an EQS. Probably the best approach is to consider case by case. If evidence shows that, for example LR50 (Lethal Residue for 50% mortality), is approximately constant for several species then one value could be used. On the contrary, if the chemical compound shows variable potency between species then the SSD (see below) is the most appropriate method for selecting the tissue residue that will protect the more sensitive species.

Fundamentally, the approach to follow with CBB is the same than using ambient exposure concentrations and both can be combined to produce more results from a single test. In fact, Landrum *et al*. (2004, 2005) provide a methodology for calculating LR50 and MLR50 (mean lethal residues). The main departure from standard toxicity tests (time period ≤96 hours) is that to characterise acute CBR tests should be conducted for a sufficient period of time (7-10 days) to assure that steady-state conditions have been attained. In addition, the same methods to estimate dose-response curves from standard tests (Scholze *et al*., 2001) can also be applied to obtain ER_x (Effective Residues at x proportion) or LR_x (Lethal residue at x proportion). In a similar fashion NOER (No Observed Effect Residue) may be calculated. However, at present stage, we recommend the derivation of a CBB guidance to standardise its application by defining the methodology, the necessary tests as well as the representative species that should be considered. Whereas this already exists for standard toxicity tests an effort is necessary in this case. The coupling with already developed standard toxicity tests is also recommended to reduce animal testing and to obtain already the right conversion values between tissue concentration and water concentration avoiding the high uncertainty of this conversion using the standard approach.

Finally, toxic effects of metabolites should be considered before applying the CBB approach to decide whether to monitor or not the metabolites. In addition, CBB approach does not work for compounds that do not bioaccumulate but cause only a toxic response. These compounds will be eliminated quickly from the organisms and therefore a dose-response curve would not exist or measured concentration will tend to be too low. In this case, probably the food intake would be a more adequate approach. For compounds where exposure and response are separated by long periods of time, i.e. mutagenic chemicals, CBB is not adequate.

Critical Body Residue approach for dietborne metal

As some metals bioaccumulate significantly in metal specific target organs, for example: liver for lead, kidney for cadmium, brain for mercury and eggs for selenium (Beyer *et al*. 1996), it is recommended to identify Critical Organ/Tissue Residues for relevant species instead of the overall CBR proposed for organic compounds. This approach would involve the comparison of measured metal concentrations in the organs of animals with critical established concentrations for the selected organs.

However, in order to apply this approach, relevant indicator species and organs/tissues of these species that are sensitive to the analysed metal would need to be identified and critical concentrations for the organs need to be defined. Afterwards, levels should be monitored. As for the case of organics, it has to be stressed that the interpretation of such data might be hampered by the fact that internal concentrations may result from exposure at different sites. This problem can be overcome by choosing appropriate indicator species foraging and living constantly in a local habitat e.g mussels. The possibility to directly link measured concentrations in organs of indicator organisms to environmental concentrations prevailing in their habitat does increase the relevance of such analyses.

As before, it has to be stressed that due to animal welfare concerns and in order to be in line with the new REACH legislation, the CBB approach should be minimised in vertebrates organisms and should be avoided in top predators.

A4.4. The species sensitivity distribution (SSD) approach

In data rich cases a species sensitivity distribution (SSD) approach using chronic toxicity data for a range of predators might be used in order to estimate an HC5 (Hazardous Concentration for 5% of species). The data requirements for such an approach (i.e. a sufficient number of species will have been tested in long-term tests) are currently unlikely to be fulfilled for many, if not all, substances. This should consider issues such as the applicability of different species, minimum data sets for the use of a species sensitivity distribution in the derivation of a $PNEC_{oral}$ for consumers (variability of species tested, test duration and endpoint, number of data, etc.) and the identification of suitable'representative prey' organisms.

However, an example of how this might be done extracted from Environment Agency Report (2008) is provided below to illustrate its application.

No Observed Effect Concentrations (NOECs) are reported in the draft lead Risk Assessment Report (RAR). Values that are 'greater than' are unbounded NOECs and their use in an SSD is conservative because the true NOEC will be higher.

According to Figure 4 the lognormal model fit meets all normality and goodness-of-fit statistics at the 1% level. The HC5 (50%) is 28.13 mg Pb kg^{-1} wwt and the HC5 (90%) is 10.43 mg Pb kg^{-1} wwt. Only one, unbounded, value of >25 mg Pb kg^{-1} wwt falls marginally below the HC5 (50%), suggesting that the HC5 (50%) is a robust threshold.

If bird and mammal SSDs are constructed separately, the bird HC5 (50%) is 23 mg Pb kg^{-1} wwt and the HC_5 (90%) is 6.72 mg Pb kg^{-1} wwt, and the mammal HC_5 (50%) is 50.7 mg Pb kg^{-1} wwt and the HC5 (90%) is 5.7 mg Pb kg^{-1} wwt. A log-normal model meets all normality and goodness-of-fit statistics at the 1% level for both SSDs. This suggests that, for some substances at least, it may be possible to use an SSD approach in the effects assessment. Whilst it is likely that an assessment factor would be considered for application to the HC5, a lower one might be applied than when using the lowest reported NOEC. Two tests with low NOEC values have been reported for the American Kestrel, which would be considered as a relevant species for wildlife assessment.

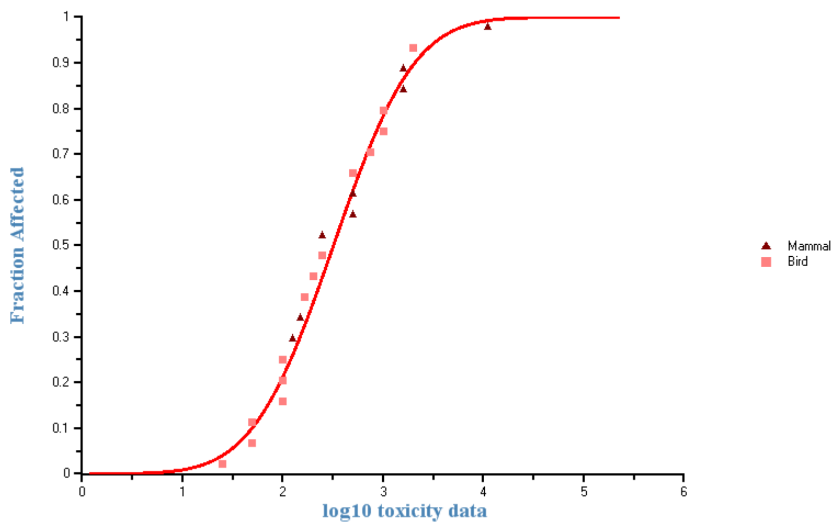

Figure 3. SSD based on mammal and bird oral toxicity data (Peters and Crane, 2008).

Further background information on the use of species sensitivity distributions can be found in the report from the Avian Effects Workshop held in Woudschoten (Hart *et al.* 2001), the publication of

Posthuma et al. (2002) and Section R 10.2.4 of Chapter R 10 of RIP 3.2-2 of the TGD in support of the New EU Chemicals Legislation (REACH).

APPENDIX 5: GLOSSARY

5P-COV	5th percentile cut-off value; the 5th percentile of a species sensitivity distribution.
AA-EQS	annual average environmental quality standard
ADI	acceptable daily intake
AF	assessment factor
AF_{oral}	assessment factor applied in extrapolation of $EQS_{biota.Predators}$
ARA	added risk approach
AVS	acid volatile sulphide
B	bioaccumulative
BAF	bioaccumulation factor
BCF	bioconcentration factor
BioF	bioavaiability factor
BMF	biomagnification factor
bw	body weight
CONV	conversion factor from NOAEL into NOEC
CSTEE	Scientific Advisory Committee on Toxicity and Ecotoxicity of Chemicals of the European Commission
Cb	background concentration
C_{ARA}	concentration of dissolved metal monitored at a site excluding the background concentration
C_{SPM}	concentration of suspended matter
C_{TRA}	concentration of dissolved metal monitored at a site
DDE	dichlorodiphenyldichloroethylene
DDT	dichlorodiphenyltrichloroethane
DFI	daily food intake ($kg_{Food\ (FW)}.d^{-1}$)
dw	dry weight
EC	European Commission
EC_x	effect concentration for X% of the individuals in a toxicity test
EFSA	European Food Safety Authority
EQS	environmental quality standard
EU	European Union
f_{oc}	fraction of organic carbon
FWMF	food web magnification factor
GLP	Good Laboratory Practice
H	hardness
HC_5	hazardous concentration for 5% of the species (based on the SSD)
HCB	hexachlorobenzene
HCH	hexachlorocyclohexane
HELCOM	Helsinki Commission: Baltic Marine Environment Protection Commission
Hg	mercury
ICES	International Council for the Exploration of the Sea
ICME	International Council on Metals and the Environment
ICPR	International Commission for the Protection of the Rhine
K_{ow}	octanol–water partition coefficient
K_{oc}	organic carbon adsorption coefficient
K_p	partition coefficient
$K_{p,susp}$	partition coefficient to suspended matter
LC_{50}	lethal concentration for 50% of the individuals in a toxicity test
log K_{ow}	logarithm (base 10) of the octanol–water partition coefficient
LOEC	lowest observed effect concentration
LOQ	limit of quantification
M	metal
MAC	maximum acceptable concentration

MPA	maximum permissible addition
MS	metal sulphide
$NOAEL_{oral}$	no observed adverse effect level, direct oral dosing tests
NOEC	no observed effect concentration
$NOEC_{oral}$	no observed effect concentration in a toxicity test, feeding tests
$NOEC_{reference}$	reference no observed effect concentration based on a worst case approach
$NOEC_{site\text{-}specific}$	site-specific no observed effect concentration based on local physicochemical conditions
OCP	organochlorine pesticide
OECD	Organisation for Economic Development
OSPAR	Commission for the Protection of the Marine Environment of the North-East Atlantic
PAH	polyaromatic hydrocarbon
PBDE	polybrominated diphenylether
PBT	persistent, bioaccumulative and toxic
PCB	polychlorinated biphenyl
PEC	predicted environmental concentration
PFOS	perfluorooctane sulfonate
PHS	priority hazardous substance
PNEC	predicted no-effect concentration
$PNEC_{oral}$	predicted no-effect concentration for the ingestion of food
$PNEC_{biota}$	predicted no-effect concentration in biota
$PNEC_{secpois}$	predicted no-effect concentration for secondary poisoning
$PNEC_{hh}$	predicted no-effect concentration for the protection of human health
PPP	plant protection product
PS	priority substance
QCAR	quantitative cationic activity relationships
QICAR	quantitative ion character–activity relationships
QS	temporary quality standards, defined during derivation. An overview of temporary standards can be found in Appendix 6
QSAR	quantitative structure–activity relationship
QSPR	quantitative structure-property relationship
RA	risk assessment
RAR	risk assessment report
REACH	Registration, Evaluation and Authorisation of Chemicals
RfD	reference dose
SEM	simultaneously extracted metals
SETAC	Society for Environmental Toxicology and Chemistry
SOP	standard pperating procedure
SPM	suspended particulate matter
SSD	species sensitivity distribution
TDI	tolerable daily intake
TGD	Technical Guidance Document (EC 2003)
TMF	trophic magnification factor
TL	threshold level
TOC	total organic carbon
TOX_{oral}	$NOEC_{oral,bird}$ or $NOEC_{oral,mammals}$ or LC_{50} (as indicative value and not for EQS derivation) in $kg.kg_{food\ (FW)}^{-1}$
TRA	total risk approach
$uptake_{dw}$	daily uptake of drinking water
UVCB	substances of unknown or variable composition, complex reaction products or biological materials
vB	very bioaccumulative
vPvB	very persistent, very bioaccumulative
WFD	Water Framework Directive
ww	wet weight

APPENDIX 6: OVERVIEW OF TEMPORARY STANDARDS FOR EQS DERIVATION

Freshwater	Saltwater	short description	REMARK
TEMPORARY STANDARDS, DURING DERIVATION (QS)			
$QS_{fw,\ eco}$	$QS_{sw,\ eco}$	direct ecotoxicity	
$QS_{dw,\ hh}$		drinking water	standard for saltwater and freshwater is identical
$QS_{biota,\ secpois,\ fw}$	$QS_{biota,\ secpois,\ sw}$	secondary poisoning expressed in biota	sp standard *in* biota is NOT identical for fresh and salt since BMF2 is applied for saltwater
$QS_{fw,\ secpois}$	$QS_{sw,\ secpois}$	secondary poisoning expressed in water	
$QS_{biota,\ hh\ food}$		human consumption of fishery products, expressed in biota	hh standard *in* biota is identical for fresh and salt
$QS_{water,\ hh\ food}$		human consumption of fishery products, expressed in water	this standard is equal for fresh and marine water (only BMF_1) as the top predator (i.c. human) is identical for fresh and marine (has the same trophic position). Is this clear from the guidance?
$MAC\text{-}QS_{fw,\ eco}$	$MAC\text{-}QS_{sw,\ eco}$	standard for short term exposure protective for the ecosystem	
$QS_{sediment,\ fw,\ eco}$	$QS_{sediment,\ sw,\ eco}$	sediment, based on sediment toxicity data (expressed in dry weight)	
$QS_{sediment,\ fw,\ EqP}$	$QS_{sediment,\ sw,\ EqP}$	sediment, based on EqP, expressed in dry weight sediment	
$QS_{sediment,\ fw,\ field}$	$QS_{sediment,\ sw,\ field}$	sediment standard, adjusted for field or mesocosm data	
SPECIFIC TEMPORARY STANDARDS IN METAL QS DERIVATION			

Freshwater	Saltwater	short description	REMARK
$QS_{generic, fw, eco}$	$QS_{generic, sw, eco}$	uncorrected standard for ecosystem	
$QS_{reference, fw, eco}$	$QS_{reference, sw, eco}$	standard for ecosystem for reference conditions	
$QS_{site-specific, fw, eco}$	$QS_{site-specific, sw, eco}$	site specific standard for ecosystem	
$QS_{added, fw, eco}$	$QS_{added, sw, eco}$	standard for the ecosystem following added risk approach – added part only	
FINAL SELECTED STANDARDS (EQS)			
$AA\text{-}EQS_{fwr}$	$AA\text{-}EQS_{sw}$	selected overall standard for water compartment	
$MAC\text{-}EQS_{fw}$	$MAC\text{-}EQS_{sw}$	selected overall standard protective for short term exposure	
$EQS_{biota, fw}$	$EQS_{biota, sw}$	selected overall standard in biota	secpois standard *in* biota is NOT identical for fresh and salt since BMF2 is applied for saltwater
$EQS_{sediment, fw}$	$EQS_{sediment, sw}$

Hence, the views expressed in the document do not necessarily represent the views of the European Commission.

Common Implementation Strategy for the Water Framework Directive (2000/60/EC)

Guidance Document No. 28

Technical Guidance on the Preparation of an Inventory of Emissions, Discharges and Losses of Priority and Priority Hazardous Substances

FOREWORD

In 2000, the European Union Member States, Norway, and the European Commission jointly developed a common strategy for implementing Directive 2000/60/EC establishing a framework for Community action in the field of water policy (the Water Framework Directive). The main aim of this strategy is to allow coherent and harmonious implementation of the Directive. The focus is on methodological questions relating to a common understanding of the technical and scientific implications of the Water Framework Directive. In particular, one of the objectives of the strategy is the development of practical non-legally binding Guidance Documents on relevant technical issues. These Guidance Documents are targeted at the experts who are directly or indirectly implementing the Water Framework Directive in river basins. The structure, presentation and terminology are therefore adapted to the needs of those experts, and formal, legalistic language is avoided wherever possible.

Under the WFD Common Implementation Strategy, a Drafting Group was established in 2010 to produce guidance on the preparation of the inventory of emissions, discharges and losses, as required by Article 5(6) of the Environmental Quality Standards Directive 2008/105/EC. The Drafting Group worked under the umbrella of the CIS Working Group E on Chemical Aspects and was co-led by Germany, France and the Environment Directorate General. The Working Group E is chaired by the Commission and consists of experts from Member States, EFTA countries, candidate countries and more than 25 European umbrella organisations representing a wide range of interests (industry, agriculture, water, environment, etc.).

The Water Directors endorsed the Guidance during their informal meeting under the Polish Presidency in Warsaw (8-9 December 2011).

The Guidance is a living document that will need to be reviewed and improved as experience is gained in its application.

CONTENTS

I. PURPOSE OF THE GUIDANCE

I.1 Introduction and legal requirements

According to Article 5 of the Directive 2008/105/EC on Environmental Quality Standards in the Field of Water Policy (the EQS Directive), Member States (MS) are obliged to establish an inventory of emissions, discharges and losses of all Priority Substances (PS) and pollutants listed in Part A of Annex I to this Directive.

Pursuant to Article 5(6), technical guidelines for the establishment of inventories are to be adopted in accordance with Water Framework Directive (WFD) regulatory procedure. This guidance document aims to help MS establish the inventories and to reduce the burden by focusing on substances that are relevant at the River Basin District (RBD) level. European wide comparability of the results is another objective.

The inventories should give information on the relevance of PS at the spatial scale of the RBD or the national part of an international RBD, and on the loads discharged to the aquatic environment, thus supporting MS in subsequent river basin management and WFD implementation. For the public, the inventories should give greater transparency with regard to existing problems and on the need for measures to address them. Additionally these inventories will be used by the Commission for compliance checking with the environmental objectives of the WFD (WFD, Article 4) on reduction of discharges, emissions and losses for PS and cessation or phase out of discharges, emissions and losses for Priority Hazardous Substances (PHS). These inventories will be an important input for the Commission report according to Art. 7(1) of the EQS Directive on the possible need to amend existing acts, and the need for additional specific Community-wide measures such as emission controls.

Furthermore, the preamble of the EQS Directive (Recital 20) foresees the need to have an appropriate tool for quantifying losses of substances occurring naturally, or produced through natural processes, in which case complete cessation or phase out from all potential sources is impossible.

These inventories are to be compiled for every RBD or the national part of international RBDs and to provide not only yearly inputs but also to include, as appropriate, concentrations in sediment and biota (e.g. helping to substantiate the relevance of a substance for the RBD).

Article 5 of the EQS Directive requires MS to establish the inventory on the basis of information collected under Articles 5 and 8 of the WFD, under Regulation (EC) No 166/2006 and other available data. Each of these information sources is briefly described in the next section.

I.1.1 Information to be used in compiling the Inventory

Article 5 of Directive 2000/60/EC (the WFD) requires MS to provide, for each RBD, an analysis of its characteristics, a review of the impact of human activity on the status of surface waters and on groundwater, and an economic analysis of water use. Reports prepared under WFD Article 5 need to include, amongst other things:

- assessment of the likelihood that surface waters bodies within the RBD will fail to meet the WFD ecological and chemical status objectives;
- identification of significant point source pollution from urban, industrial, agricultural and other installations and activities; and
- identification of significant diffuse source pollution from urban, industrial, agricultural and other installations.

Article 8 of the WFD requires MS to establish programmes to monitor surface water status, groundwater status and protected areas, with the aim of establishing a coherent and comprehensive overview of water status within each RBD. For surface water monitoring programmes must include not only ecological and chemical status in accordance with the requirements of Annex V of that Directive, but also the volume and level or rate of flow as relevant to ecological and chemical status. Chemical status of surface waters is defined by Environmental Quality Standards (EQS), established to protect both environmental quality and human health. For groundwater such programmes are to cover monitoring of the chemical and quantitative status.

Regulation (EC) No 166/2006 concerns the establishment of a European Pollutant Release and Transfer Register (E-PRTR) at EU level in the form of a publicly accessible electronic database and lays down rules for its functioning, in order to; implement the UNECE Protocol on Pollutant Release and Transfer Registers; facilitate public participation in environmental decision-making and; contribute to the prevention and reduction of pollution of the environment. E-PRTR builds upon but also extends the principles of the European Pollutant Emission Register (EPER), requiring the reporting of pollutant 'releases' to water from industrial and other facilities, provided certain specified thresholds are exceeded.

Other available data encompasses monitoring data collected for other purposes (e.g. research studies, compliance monitoring for waste water discharges by Competent Authorities) describing, for example, substance concentrations in water, sediment and biota, and trend information. It also includes information describing the production and use of a substance and, if and when it has been banned or restrictions on its use have been implemented. Given the connectivity between ground and surface water, those substances exceeding national groundwater thresholds can also be considered to be potentially of relevance.

I.1.2 Timetable

MS will establish the first inventories under the EQS Directive as part of the review of the WFD Article 5 analysis of pressures that is scheduled for December 2013. Both point and diffuse sources should be addressed. Article 5 of the EQS Directive requires the compilation update and reporting of the inventory on a regular basis as part of the river basin management process. Table 1 lists the relevant deadlines for the subsequent River Basin Management Plan (RBMP) cycles.

Table 1: Deadlines for the RBMP cycles

Reporting under Article 13 of the WFD	Preparation of the inventory	Publication of the RBMP	Communication to the Commission
1st cycle of the RBMP	--	22.12.2009	22.03.2010
2nd cycle of the RBMP	22.12.2013	22.12.2015	22.03.2016
3rd cycle of the RBMP	22.12.2019	22.12.2021	22.03.2022
……			

I.2. Practical uses of emissions inventories (who will use them and for what purposes)

This guidance applies to the substances contained in Annex 1, Part A of the EQS Directive. However, it is recommended that MS also use it to establish inventories for their national, regional or local specific pollutants (Annex VIII of the WFD).

In practical terms, an emission inventory should be seen as a tool which may be used to:

- assist in establishing and implementing targeted reduction of emissions, discharges and losses of PS eventually leading to the cessation of emissions, discharges and losses of PHS (e.g. by identifying the main sources, their relative share with respect to pollution and, their pathways);
- demonstrate the efficacy of RBMP Programmes of Measures (PoM);
- assess if or to what extent monitored concentrations are caused by natural sources or processes (e.g. geogenic background) or long-range transport processes;
- support the Commission in checking compliance with the environmental objectives under the WFD.

- assist in checking the effectiveness of measures implemented to achieve the reduction and phasing out of emissions required by the provisions of the WFD.
- identify gaps in knowledge and hence where there is a need to develop new strategies/policies.
- assist with the implementation of the Marine Strategy Framework Directive (MSFD).

An emissions inventory can therefore assist in a range of ways with the implementation of the WFD.

This guidance document is targeted at those experts who are directly or indirectly involved in the establishment, at the national level, of the inventories of emissions, discharges and losses. It will also support decision makers. The structure, presentation and terminology are therefore adapted to the needs of these categories of experts and formal, legalistic language is avoided wherever possible.

I.3. General approach and minimum expectations

An inventory of annual emissions, discharges and losses of PS is required at national RBD scale. It should in principle cover all substances listed in Annex I of the EQS-Directive.

The practical usefulness of an inventory in River Basin Management significantly increases with a more detailed analysis and higher spatial resolution (see section III.2 for a more detailed discussion on the spatial scale).

The scale of pressures caused by certain substances might be very different throughout Europe. Therefore a two-step analysis (Figure 1) is recommended, which allows for a prioritisation of resources to compile the inventory.

1) As a first step, an assessment of current relevance of the substances at the RBD level should be undertaken.

The aim of the first step is to identify those substances which are clearly of minor relevance for the RBD at present and in the foreseeable future and to concentrate the efforts of subsequent inventory development on the remaining substances. Consequently, the criteria for this first selection round must not be too strict.

This assessment of relevance should draw upon the information sources identified in Article 5 of the EQS Directive (see Section 1.1), namely the results of the WFD compliance monitoring as well as information on existing restrictions on production and marketing. Using this information a set of transparent criteria should be applied for this initial assessment. A substance should be included for in-depth inventory compilation if at least one of the following possible criteria (when considering data from the last 3-5 years) is met:

- The substance causes a failure of good chemical status in at least one water body

- The level of concentration for a substance is above half of the EQS in more than one water body
- Monitoring results show an increasing trend of concentration which may cause problems within the next RBMP cycles
- PRTR data show releases which might lead to concentrations matching the criteria above
- Known sources and activities causing inputs in the RBD exist which might lead to concentrations matching the criteria above.

This selection criteria and results should be reported in the inventory. For the substances discarded (i.e. for substances of minor relevance) MS should try to provide a basic estimation of emissions, discharges and losses from available data. This is especially important for PHS.

2) As a second step, for the substances which pass the relevance criteria a more detailed analysis using a tiered approach should be performed. It should aim at providing further estimates of emissions, discharges and losses from point and diffuse sources, as well as loads transported in rivers.

The analytical approach chosen (from those in chapter III.4) should be based on the required output information, the available data and practical experience.

As a minimum requirement for the first inventory, point discharges of PS from industrial facilities and municipal wastewater plants (e.g. as required to be reported under E-PRTR) and, a basic or approximate estimation of diffuse inputs, via, for example, the calculation of riverine loads should be provided. The riverine load approach has the advantage of a) being an approach that a number of MS will have already adopted under regional sea conventions such as OSPAR and HELCOM and; b) providing a means of verifying estimates arising from other methodologies.

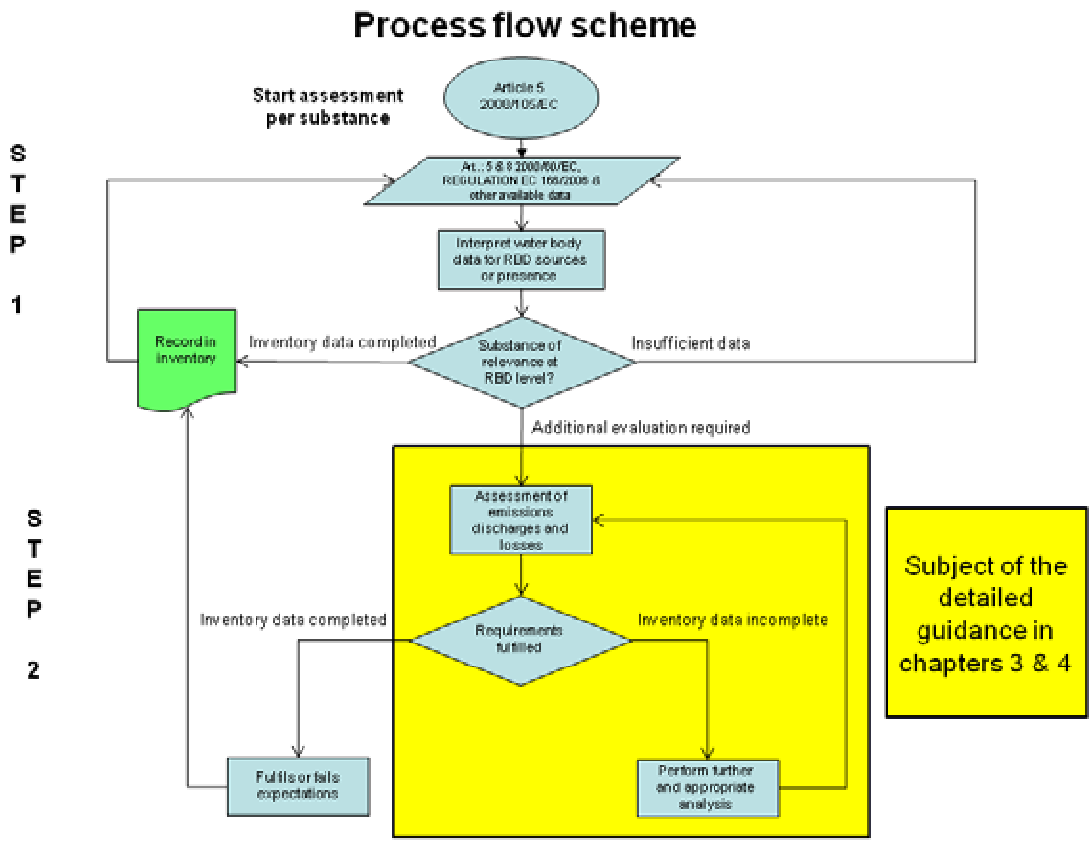

Figure 1: Overview of the 2-step inventory building process

For the first inventory, one year's worth of data is required between 2008 and 2010 (see section III.3 on temporal scale). Since diffuse inputs are strongly and positively correlated with rainfall/river flow (diffuse inputs can increase markedly in wet years) this has to be taken into account.

Where ‘higher tier’ methods are introduced, re-calculation of more basic estimates for earlier reporting dates should be undertaken and reported. In this way, not only will the quality of the original estimate be improved but consistency in methodology over time is maintained.

II. DEFINITION OF TERMS

II.1. Discharges, emissions and losses

The term "discharges, emissions and losses" was used for the first time in the Esbjerg Declaration of the 4th North Sea Conference in 1995[1] with respect to the prevention of pollution by hazardous substances.

The use was in conjunction with the *"generation goal"* which is described as *"the prevention of the pollution of the North Sea by continuously reducing discharges, emissions and losses of hazardous substances thereby moving towards the target of their cessation within one generation (25 years) with the ultimate aim of concentrations in the environment near background values for naturally occurring substances and close to zero concentrations for man-made synthetic substances."*

This somewhat complicated term "discharges, emissions and losses" was chosen in the Esbjerg Declaration to make it clear that all inputs

- coming from land and sea based sources,
- coming from point and diffuse sources,
- reaching the marine environment via direct discharges, riverine inputs or airborne transport,

are addressed and have to be included in the required reduction measures to reach the generation goal.

The requirements of Art. 16 of the WFD regarding PHS also have their origin in the North Sea generation goal and aim to make it operational.

Although some terms (e.g. emissions) have been defined elsewhere in other legislation (e.g. the IPPC Directive[2]) the overall meaning of "discharges, emissions and losses" has not changed. Consequently, in the context of the PS inventory "emissions, discharges and losses" should be used in this broad sense.

Thus, for the purpose of the inventory the term "discharges, emissions and losses" means that the inventory has **to address all inputs of the relevant substances into the environment**, **irrespective of the compartment involved, that are likely to reach surface waters (the main routes of transport into surface waters are described in III.1)**. So, for example, a restriction to point sources only, without a comprehensive justification of why this would be the only relevant input route to the aquatic environment, clearly would not meet the requirement of the EQS Directive.

---

[1]http://www.ospar.org/html_documents/ospar/html/4NSC-1995_Esbjerg-declaration.pdf

In this guidance document, "input" is used as a generic term for the movement of a substance into the aquatic environment.

II.2. Sources

In the conceptual framework of this inventory, all processes and activities that are likely to contribute to the input of pollutants into the environment are defined as sources.

The reader should bear in mind that the principal focus of this guidance is the identification and quantification of anthropogenic sources, although some substances may also have a significant naturally occurring source.

For pragmatic reasons it is useful to distinguish between point and diffuse sources.

A **point source** is a single localized point of discharge of wastewater containing one or more pollutant(s). The most important ones are industrial facilities, waste water treatment plants (although strictly speaking the plant itself is not the source), untreated sewage, waste disposal systems and mining sites[3]. Some of these sources are also modelled as diffuse sources due to data restrictions.

The E-PRTR Regulation (EC) No 166/2006 gives the following definition of **diffuse sources**: *"diffuse sources' means the many smaller or scattered sources from which pollutants may be released to land, air or water, whose combined impact on those media may be significant and for which it is impractical to collect reports from each individual source"*. Diffuse sources include agricultural activities, some urban related emissions, atmospheric deposition, and rural dwellings. Typically, they are more variable in space and time than point sources.

Regarding Plant Protection Products (PPPs) in agriculture, the definition of point source and diffuse source is different from that described above due to the specific temporal and spatial context. "Point source" for PPPs includes any spills of concentrated or diluted PPP during transport, storage, filling, spraying, cleaning, management of residual spray and maintenance. In particular it includes use or handling in areas not covered by approved label recommendations for spraying or guidance/codes of practice for correct filling, cleaning or disposal. It also includes uncontrolled release of an excessive amount of PPP during treatment (overdosing). "Diffuse source" for PPPs is related to undesired movement of PPPs in soil, water or air following application on crops and within areas agreed for use

---

[2]Directive 2008/1/EC of the European Parliament and of the Council of 15 January 2008 concerning integrated pollution prevention and control

[3] The general term mining sites comprises active and abandoned/historic sites. Active modern mining sites operate well-organised waste water treatment and therefore correspond to point sources. In Fig 2 they are considered in the box Industry and in pathway 10. In contrast the discharges from abandoned or historic mining sites may arise from a distinct point, such as waste water treatment, or be scattered and untreated. Emissions from abandoned or historic mining may therefore correspond to pathway 10 or 11.

according to approved label recommendations. These definitions may be relevant to pesticides other than PPPs, e.g. certain biocides, depending upon their mode of use.

Due to the discrepancies in the definitions of diffuse and point sources, whether an input is dealt with as a diffuse or a point source must be documented in the inventory.

II.3. Pathways

Pathways are the means or routes by which specific substances can migrate or are transported from their various sources to the aquatic environment. Following release, substances may be directly emitted to a waterbody or transferred to and stored within environmental media including soil and impermeable surfaces, before entering the aquatic environment. Aerial emission is an important pathway for certain PS and can result in subsequent direct deposition to a waterbody or indirect entry via soil or a sewer system.

II.4. Processes in the river system

In surface waters a wide range of processes occur, e. g. sorption on suspended particles, degradation, biodegradation, biotransformation or bioaccumulation in plants or animals. Retention is a broad term used to describe the outcome whereby loads from sources entering surface water remain there, without for example being discharged to coastal waters. The fractions that are retained have the potential to become mobilised in the future, however, this is not always the case. The extent of retention depends on the physical-chemical properties of the PS as well as on the flow velocity of the river, type and number of particles in the water or the available retention area such as wooded floodplains.

II.5. Riverine load

Riverine loads describe the mass of a contaminant transported per unit of time, typically expressed as kg or tonnes per year. Their calculations have value with respect to establishing a PS emissions inventory for two reasons:

1.) The load for any given contaminant reflects the sum of inputs upstream of the monitoring point at which these are calculated. As such these provide a check or means of validation - the sum of inputs from individual and separate sources should broadly equate to the total riverine load;
2.) Riverine loads can be used to estimate and/or verify the contribution from diffuse sources.

II.6. Emission factor

An emission factor is a coefficient linking the estimated average quantity of emission of a given pollutant during a representative time interval to an easily accessible emission variable, also called characteristic unit (inhabitant, p.e., car, ha of land…) with the following formula:

Estimated emission = number of characteristic units x emission factor

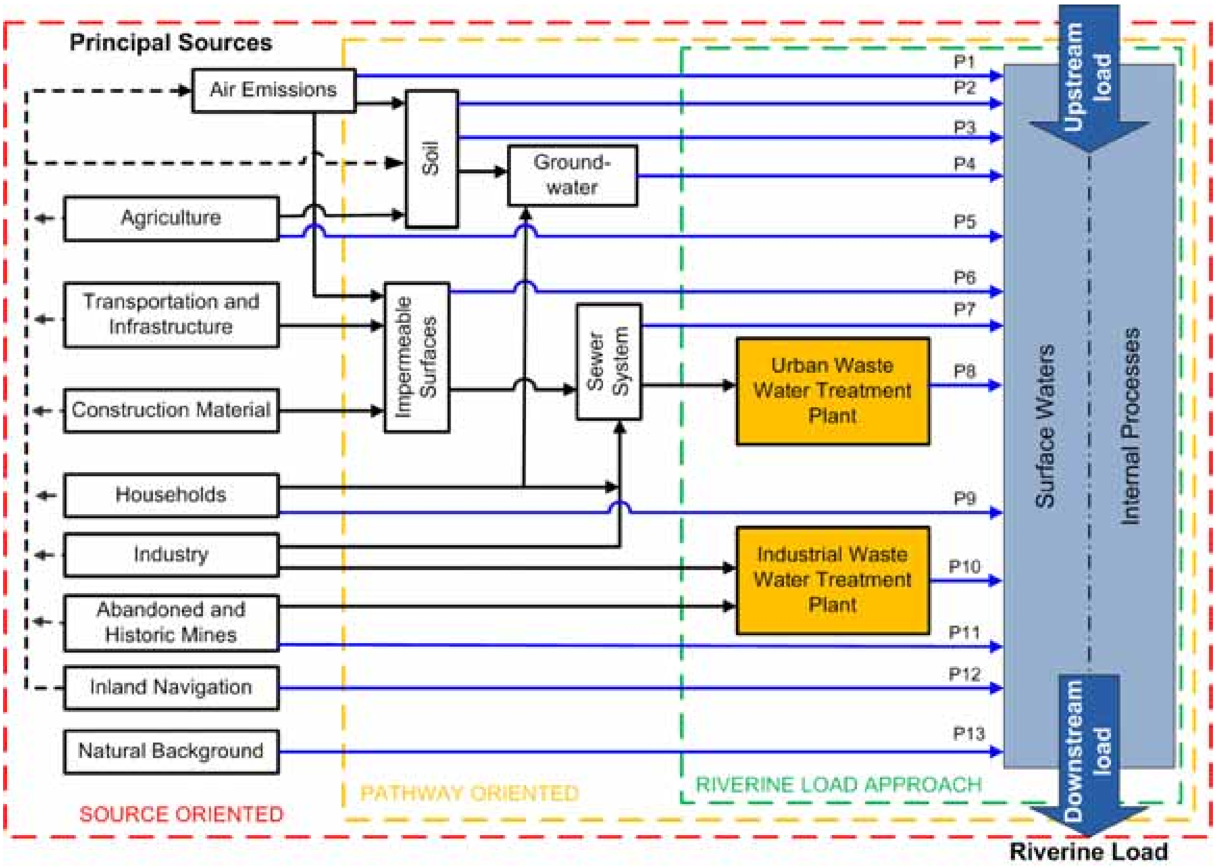
Most emission factors are developed by taking the average measured pollutant quantity, measured at easily accessible points (stack, discharge point…), for a representative sample of the targeted sources, during a representative time interval. The average measured pollutant quantity is related to the extent of the activity for which emission estimation is needed using a quantitative unit, the characteristic unit, for which statistics are easy to obtain from several bibliographical sources (trade associations, national statistics, research institutes databases …).

The application of emission factors will provide information about the average emission of many installations but cannot provide reliable data for a single installation.

III. GENERAL COMPONENTS OF AN INVENTORY

III.1. General working scheme

The principal components of the inventory and their inter-linkages are shown in Figure 2. The main routes of transport into surface waters are shown from left to right.



P1: Atmospheric Deposition directly to Surface Waters

P2: Erosion

P3: Surface Runoff from Unsealed Areas

P4 Interflow, Tile Drainage and Groundwater[4]

P5: Direct Discharges and Drifting

P6: Surface Runoff from Sealed Areas

P7: Storm Water Outlets, Combined Sewer Overflows and Unconnected Sewers

P8: Urban Waste Water Treated

P9: Individual - Treated and Untreated- Household Discharges

P10 Industrial Waste Water treated

P11: Direct Discharges from Mining Areas[5]

P12: Direct Discharges from Navigation[6]

P13 Natural Background

Figure 2: General working scheme of the inventory

[4] This pathway comprises also emissions from contaminated land

[5] A portion of the total emissions from abandoned and historic mining sites is discharged to groundwater. Active mines are covered under "Industry".

[6] Inland navigation also comprises waterway construction materials.

The most important sources for the release of substances into the environment are shown on the left of the figure. Substances may be released to water, air or soil. Direct input routes into surface water are indicated by blue arrows, other transport routes by black arrows.

Substance inputs into waste water should undergo treatment in Urban Waste Water Treatment Plants (UWWTPs) before entering surface waters. Substances emitted indirectly to surface waters may be first temporarily detained in “interface media” like soil or impermeable surfaces, and then subsequently transported to surface waters by other processes (erosion, urban storm water etc.). Some of these intermediate processes may take a very long time (decades and beyond) to reach surface waters. The interface media are shown in the middle part of the figure.

The internal removal, transport or storage processes in the surface water itself (like degradation, sedimentation, re-suspension) are indicated on the right side of the figure. So the quantity to be observed (the load in the river system) is the result of all these indicated processes and their respective time constants.

Due to the complexity of the system and the challenges associated with data collection, different approaches arise with respect to the establishment of inventories. In principle, three broad approaches can be distinguished:

- the riverine load oriented approach, which estimates the observed total load in the river. This information can be used together with a quantification of point source inputs to calculate an estimate of the diffuse inputs.
- the pathway oriented approach, also called Regionalised Pathway Analysis (RPA), models the different transport phenomena for the final input routes to the river system starting from the “interface media”. This approach calculates regionalised emissions for small catchments (termed analytical units) which can be subsequently aggregated to RBDs or sub-units.
- the source oriented approach addresses the whole system starting from the principal sources of substance release. Such an approach includes Substance Flow Analysis (SFA).

The scope of these approaches is indicated by the dashed boxes in diagram. The complexity of the approaches increases from right to left. The different approaches are discussed in more detail in chapter IV; limitations of the different approaches are discussed in III.2.

III.2. Spatial resolution of the inventory

The EQS Directive formally requires a spatial resolution of the inventory at RBD scale or the national part of an international RBD. The current reporting practice for the RBMP requests information on the sub-unit scale to improve pan-European comparability (5000-50000 km²). The inventory is not aimed at waterbody level.

Regarding the usefulness of the inventory for RBMP purposes, e.g. for identifying hot spots (areas with high specific inputs of substances) or estimating the effectiveness of measures, a significantly higher spatial resolution (~100-~1000 km²) is desirable. To support water management at a local scale, an even higher spatial resolution is necessary.

The spatial resolution of substance inputs is determined by the nature and distribution of sources (location of production and consumption sites, including share and type of agricultural land), and the structure and characteristics of transport pathways to surface water (e.g. regional geography and the regional meteorological and hydrological situation).

Point source information can normally cover all spatial requirements, as the inputs are located at the point of discharge, but if emission factors have to be used the spatial resolution is lower, as the specifics of the installation concerned are not covered.

The determination of the spatial distribution of inputs is dependent on the estimation methodology applied. When estimating substance inputs via the monitoring of riverine loads, the area covered by the inventory is by definition the whole catchment upstream of the monitoring station investigated. Neglecting the problems of load monitoring, the observed (measured) loads are the sum of all inputs plus all transport phenomena (remobilization) minus the sum of all retention processes (degradation and intermediate storage processes). Estimated contributions of larger tributaries are only accessible using proxy parameters like area or population share. This is generally only a rough estimate.

When applying the RPA (pathway oriented approach) method the spatial resolution is theoretically limited by the size of the catchments (Analytical Units) used in the emission calculations, which are normally in the range of 100-1500 km². Thus the possible spatial resolution overlaps well with the resolution required for RBMP purposes. However, normally due to limitations in the quality and resolution of required input data, the practical resolution is lower. Often only average values for the whole river basin can be given. As data availability differs significantly for (priority) substances, only a few substances can be covered at present by RPA with a spatial resolution of 100 - 1500 km².

Local models are normally highly adapted to the specific situation of the target areas. The problem then is how the model can allow reasonable generalisation to larger areas (RBDs). This is strongly model dependent.

Substance Flow Analysis (SFA) investigations are limited in their regional scope as the required input data (e.g. production and consumption figures or estimates thereof) are only available from national or EU-wide statistics. In addition, regionalisation of emission factors requires an extensive compilation of analytical results and their corresponding metadata. So, when using SFAs, even regionalisation on RBD level is normally only possible using proxy parameters like population share.

In conclusion, the spatial resolution achievable will be a compromise between the size of the problem, the required information, the availability of data and the resources required. Thus it is likely that the methods used and the spatial resolution achieved will vary between substances.

III.3. Temporal scope of the inventory

The inventories aim to provide information on the yearly inputs of the PS at a certain point in time (reference period). Emissions discharges and losses are not always steady throughout the year and the impact on aquatic environment of peak inputs can be higher than the same quantity emitted at a steady state over time. However this temporal disaggregation is not targeted by the inventory since it is already addressed through the EQS and associated monitoring and compliance checking.

As emission processes, particularly diffuse ones, are strongly dependent on the hydrological situation, interpretation of the results requires a separation and discrimination of the hydrological effects from trends and changes caused by anthropogenic activities. This is especially important when evaluating and interpreting trends which are clearly dominated by hydrological variation. The offered option for PPPs is one possibility to account for these effects.

Article 5(2) of the EQS Directive states that the reference period for the first inventory is one year between 2008 and 2010. For PS covered by Regulation (EC) No 1107/2009[7] on PPPs also the average of the years 2008-2010 may be used. For the updates of the inventories, the reference period is the year before that analysis is to be completed. For PPPs again the average of the three years before completion may be used. The specific 3-year-average option for PPPs is explained in Recital 23 with the *"fact that the losses from the application of pesticides may vary considerably from one year to another because of different application rates, for instance as a result of different climatic conditions."*

Inventories of inputs of PPPs need to consider 3 - 5 years average so as to minimize the yearly variation in emission due to variation of climatic conditions involving variation of pest pressure and so significant difference in yearly use of PPPs. Choice of the years on which to calculate the average needs to consider possible changes in approved uses over the years. It could be, for example, that the approved use of a substance is currently restricted to greenhouse use only, when in previous years the substance was used on cereals. In such cases the average calculation needs to cover years with the same approved usage; separate averages should be provided for different usage periods.

[7] Regulation (EC) No 1107/2009 of the European Parliament and of the Council of 21 October 2009 concerning the placing of plant protection products on the market and repealing Council Directives 79/117/EEC and 91/414/EEC

A similar approach is used in the regionalised path analysis where results are calculated on a yearly basis but published as 3-5 years average values. Another possibility is the calculation of inputs and adjustment of riverine loads using the long-term average hydrological conditions. Alternatively, riverine loads from any given year can be flow normalized.

Look out 	Nominally the **reference period** is the start of the RBMP cycles, providing information at the beginning of each cycle on the effects of the measures taken in the previous cycle. Given the complexity of the emission monitoring and estimation methods, the term "reference period" does not mean that only data generated during the reference period may be used. All data may be used if they are required in order to draw an adequate picture of the emission situation in the reference period. This is particularly important given that the guidance on inventory provisions had not been agreed prior to the conclusion of the period documented in the Directive. The selection of data should be justified by expert judgment and documented in the inventory.

III.4 Tiered Approach

The in depth analysis for the relevant substances can be performed with different approaches.

The approaches described in this guidance document vary in their complexity in order to account for the wide range of information and data sources available across MS. A tiered (or level) approach is presented whereby the complexity increases with each progressive rise in the tier.

Associated with a tier rise is an increase in understanding of sources and pathways, resolution and detail, all of which aids the identification of appropriate measures.

Improvements associated with higher tier approaches include; a greater discrimination of ‘true sources’, for example, the relative contribution of those sources emitting PS to sewers and UWWTPs, rather than the (lower tier) reporting of a lumped treated effluent discharge which does not allow for discrimination of the original source. Similarly, higher tier methods can discriminate original sources within the transport sector such as brake and tyre wear; greater geographical detail (from basin through to waterbody); improved temporal information (from once in a few years to annual or even seasonal); and the use of location-specific emission factors, production data (life-cycle assessment information) and detailed statistical data. Thus the different tiers support a progressively improved understanding of the emission situation and, therefore, the ability to effectively allocate financial resources.

Table 2 summarises the steps / approaches in compiling the inventory, the information required and the increase in output information which may be gained. Step 1 is the check for relevance of a substance. The criteria are described in chapter I.3.

For the relevant substances, the first two approaches of Step 2 (Table 2) must be undertaken in order to meet the requirements of the first round of reporting. It is anticipated that methodologies will generally become more sophisticated with later reporting cycles, however, MS may already choose to adopt a higher tier approach for the first round of reporting. Where methods are improved over time using higher tier approaches (tier 3 and 4), re-calculation of the more basic estimates for earlier reporting dates should be undertaken and reported. In this way, not only will the quality of the original estimate be improved but consistency in methodology over time will be maintained.

Table 2: Scheme of tiered approach for establishing an inventory, indicating complexity and information content

TIER	BUILDING BLOCKS	EXPECTED OUTPUT	RESULTS FOR THE INVENTORY
STEP 1: ASSESSMENT OF RELEVANCE			
	Information sources identified in Art. 5 of EQS directive, see section I.1	Decision of relevance	List of relevant and less relevant substances
STEP 2: APPROACHES FOR RELEVANT SUBSTANCES			
1. Point source information	• Data on point sources • Emissions factors	• Availability of data • Quality of data • Identification of gaps	• Point source emissions • Listing of identified data gaps
2. Riverine load approach	add: • River concentration • Data on discharge • In stream processes	• Riverine load • Trend information • Proportion of diffuse and point sources • Identification of gaps	• Rough estimation of total lumped diffuse emissions • Verification data for pathway and source orientated approaches • Listing of identified data gaps
3. Pathway orientated approach	add: • Land use data • Data on hydrology • Statistical data • …….. • ……..	• Quantification and proportion of pathways • Identification of hotspots • Information on adequacy of POM	• Pathway specific emissions • Additional spatial information on emissions
4. Source orientated approach	add: • Production and use data e.g. from REACH • SFA • Substance specific emission factors • …….. • ……..	• Quantification of primary sources • Complete overview about substance cycle • Information on adequacy of POM	• Source specific emissions • Total emissions to environment and proportion to surface waters

The method of deriving information for the inventory will vary depending upon a range of factors including data availability and available resources. In any given RBD different methodologies will be selected for different substances through a process of identification of relevant and less relevant substances and a subsequent focus on the most important problem substances.

Four levels or “tiers” of emission estimation methods can be distinguished:

Tier 1: Point Source Information:

This tier focuses on point source information. It uses readily available statistical data including point source information reported under E-PRTR. Based on this information, the presence or absence of known point sources can be concluded. The conclusion of absence should be backed up through the analysis of production and use information. If this confirms that the point emission of a substance is negligible, then final confirmation should be provided from the results of emission monitoring, which should be undertaken using appropriate methods. For all relevant hazardous substances this tier is mandatory, as it forms the basis of diffuse sources assessment.

Tier 2: Riverine Load Approach

It is based on concentration (both for the water and the suspended solids phase) and discharge data in rivers considering the basic processes of transport, storage or temporary storage and degradation of substances. The resulting riverine load provides information about the recent status of pollution and if long-term information is available then temporal trends too. In combination with the information gained in tier 1 it allows the allocation of observed loads to point and diffuse sources (a basic source apportionment). If the riverine load is equal to or less than the point source load calculated in tier 1, and the database, especially regarding concentration data, delivers reliable information, then the requirements for an inventory might be met. High pollutant concentrations, an increasing trend, or a high relevance of diffuse sources point to the need for a more detailed analysis using the approaches in tiers 3 and 4.

Tier 3: Pathway Oriented Approach

It uses more specific information about the land use, hydrology and basic transport processes involved. The data requirements are higher than for the lower tiers, but the level of information available for the inventory and management plans is even higher. This tier allows identification of the main sources and regional hotspots of emission and, a holistic overview of emission status, providing specific emissions (e.g. area specific loads, storm water runoff loads). It will, therefore, provide the basis for an accurate inventory. For substances following a ubiquitous emission pattern or for which efficient mitigation measures are not available it might be appropriate to enter the next tier.

Tier 4: The Source Oriented Approach (SOA)

It is based on substance-specific information on production, sales and consumption which to some extent are available through REACH. It allows the drawing of a comprehensive picture of the life cycle of a substance. The benefit of this approach is that the information gained is precise enough to implement not only end-of-pipe solutions but also source controls and precautionary measures.

IV. WORKING METHODOLOGIES

IV.1. General Description of existing methodologies

IV.1.1. Riverine load oriented approaches

Background

Riverine loads describe the mass of a contaminant transported per unit of time, typically expressed as kg or tons per year. Their calculation has value with respect to establishing a PS emissions inventory for two reasons:

- Riverine loads for any given contaminant reflect the sum of inputs to surface water from all sources upstream of the monitoring point at which they are calculated. As such they provide a check or means of verification – the sum of inputs from individual and separate sources should broadly equate to the total riverine load (provided any in-river processing is accounted for).
- Total riverine contaminant loads can be used - provided certain other information is available - to estimate and/or validate the contribution of that contaminant from diffuse sources; diffuse inputs are not readily calculable and typically require the use of estimation tools and models.

Estimation of riverine load

The load of a contaminant transported by a river is estimated by taking the product of the mean flow weighted concentration and the total river flow, expressed by the following formula (OSPAR, 2004a);

$$Ly = \frac{Q_d}{Q_{Meas}} \cdot \left(\frac{1}{n} \sum_{i=1}^{n} C_i \cdot Q_i \cdot U_f \right)$$

Ly = annual load (t/yr)
Qd = arithmetic mean of daily flow (m3/s)
Qmeas = arithmetic mean of all daily flow data with concentration measurement (m3/s)
Ci = concentration (mg/l)
Qi = measurement of daily flow (m3/s)
Uf = correction factor for the different location of flow and water quality monitoring station
n = number of data with measurements within the investigation period

Periods of high river flow typically carry a disproportionately large amount of the annual load of a contaminant. To avoid the underestimation of annual loads it is, therefore, important that water quality sampling strategies are designed to capture periods of high river flow. Sites selected for sampling should be in a region of unidirectional freshwater flow in an area where the water is well mixed and of uniform quality. Both the particulate and soluble load of a contaminant should be quantified. OSPAR, (2004) provides guidelines with respect to concentrations that are less than the limit of detection. These involve the calculation of two load estimations, one assuming that the true concentration is zero and the other assuming that the true concentration is the limit of detection. This approach derives maximum and minimum concentrations within which the true estimate will fall, providing upper and lower bounds for the load estimate. Other approaches are used al well, e.g. using 50% of the limit of quantification. The method used in load calculation has to be transparently documented and reported.

Flow normalisation

Riverine contaminant loads, and in particular certain diffuse source components, vary strongly with rainfall and hence river flow; typically the wetter the year, the higher the loading. Without the application of flow normalisation procedures, natural inter-annual variations in flow can mask or lead to misinterpretation of trends in contaminant loads. Genuine reductions in pollutant inputs attributable to the implementation of measures, for example, can be masked by the occurrence of higher annual river flow during more recent monitoring. Conversely, an apparently declining trend can be incorrectly attributed to the success of measures, but in reality reflects a drier year or years. Flow normalisation addresses this issue and can be undertaken via a variety of methods. Harmonised flow normalisation procedures are given by OSPAR, 2004a.

Estimation of diffuse loads

Riverine loads can be used to calculate diffuse and unknown inputs of PS providing point source information is available. In the most basic approach, the diffuse load can be estimated as the difference between the total load and the load discharged from point sources, as follows:

$$LDiff = Ly - Dp$$

Where, for a given contaminant, LDiff is the anthropogenic diffuse load, Ly is the total annual riverine load, and Dp is the total point source discharge. Such an approach ignores any potential in-river processes such as sedimentation and remobilisation, but provides a useful approximate means of estimating the diffuse load of a given substance.

A more detailed formulation will be necessary where in-stream processes and natural background loads are thought to be significant. The following formula is based on an approach established by OSPAR (2004b) for the calculation of diffuse nutrient loads; in-river nutrient processing is typically significant. The formulation is also applicable to the PS:

$$LDiff = Ly - Dp - LB + NP$$

Where, for a given contaminant, LB is the natural background load of the contaminant, and NP is the net outcome of in-river processes upstream of the monitoring point.

The riverine load approach provides a useful means of estimating diffuse inputs and/or validating modelled predictions. However, diffuse inputs from different sources are lumped into a single value and it is not possible, for example, to distinguish between inputs arising from agriculture and those from urban runoff.

IV.1.2. Pathway oriented approaches including hydrology-driven transfer processes

Pathway oriented approaches are well established and applied in many European RBDs for the quantification of nutrients and heavy metal inputs. Here, understanding the transformation, removal and temporal storage processes taking place between the source of emission and the receiving water body is vital.

As defined in chapter 2, inputs can be caused by point and diffuse sources. Accordingly, point source-pathways are defined by being discrete, having distinct locations and quasi-continuous discharge, e.g. the discharge of municipal waste water treatment plants and industrial plants. Diffuse source inputs influence different pathways and are discharged via different runoff components into surface waters. A differentiation of the runoff components is necessary as substance concentrations as well as the underlying processes may differ significantly for the considered substances.

The current state of knowledge in RPA identifies 13 potential pathways for inputs into surface waters. This is summarized in the general working scheme (cf figure 2). Not all potential pathways are important for all substances under consideration.

To keep track the pathways can be classified into three blocks:

1. pathways depend on point-source
2. pathways depend on diffuse non-urban sources and
3. pathways depend on diffuse urban sources.

The calculation of emissions from point sources can be straightforward, as data on effluent concentration and the amount of treated waste water are available or can be derived from statistical data with the required accuracy.

The inputs caused by diffuse sources are the result of more or less complex interactions with different interfaces, including temporal storage, transformation and losses. These processes have to be integrated into the approaches adequately.

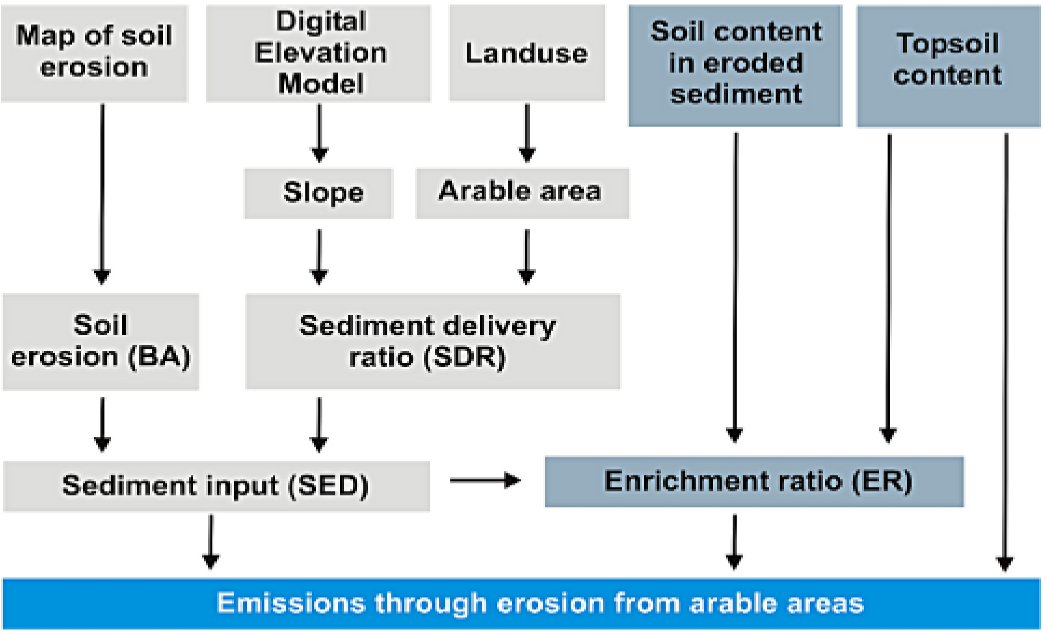


Figure 3: Input data to quantify the emissions from erosion (taken from Fuchs et al., 2010)

Pathways from agricultural diffuse sources include erosion, surface run off, tile drainage, seepage and spray drift. With regard to the transported masses and the complexity of processes involved, erosion is most suitable to illustrate the principles of pathway oriented approaches particularly as PS, including PPPs, can readily attach to soil and eroded sediment (see figure 3).

The initial process of pollutant inputs via erosion is the mobilization of top soil caused by heavy rainfall. At a river basin scale the soil loss from arable land is commonly calculated using an adapted version of the Universal Soil Loss Equation (Wischmeier, W. H., and D. D. Smith, 1960) which considers the slope, rainfall (energy input), soil characteristics, land cover and cultivation as well as active erosion protection measures. In the second step, the proportion of eroded soil entering the surface water is calculated (sediment delivery ratio). Based on a Geographical Information System (GIS)-supported sub model, individual areas within a catchment can be identified where eroded soil reaches a water body, enabling a relationship between sediment delivery and catchment characteristics to be obtained (Behrendt et al., 1999). The slope and the share of arable land have a large influence on the sediment input. During the erosion process, fine particles accumulate in the transported sediment. As pollutants are predominantly bound to finer grains, they also accumulate during the transport process. The enrichment of a substance in the erosion material is described by the enrichment ratio (EnR) which is the ratio between the substance concentration in the top soil and in the sediment reaching the water body. Beyond the initial substance concentration, the grain size distribution of the top soil and the intensity of the classification process are the most important factors influencing the sediment concentration.

Storm sewers and combined overflows are important diffuse pathways in all urbanized parts of a river basin. Up to 40 % of the total heavy metal load or 25 % of the total PAH load emitted into surface waters can be traced back to storm sewer outlet and combined sewer overflows. These pathways account for various sources including air pollution, waste water from industries and households as well as primary emissions from construction material and traffic. For the calculation of annual pollutant loads emitted to surface waters several processes including mixing, transformation and retention, taking place on urban surfaces and within sewer systems, have to be taken into account. The relevance of these processes is highly variable and depends on local boundary conditions. In general a more complex situation can be assumed in combined sewer systems where it has to be considered that a certain portion of storm water is routed to a central waste water treatment plant and that the discharges via combined sewer overflow (CSO) include a variable amount of sewage.

The calculation of pollutant load discharged via storm sewers can be based on a regionalised and area specific surface load (e.g. Cu 204 g/(ha·a)) for any pollutant under consideration. This specific surface load is derived from observed runoff concentrations and precipitation data and it is assumed that it is realised every year independent of the inter-annual variation of precipitation. Regionalisation of specific surface loads can be based on three categories of intensity of urbanisation (rural, urban, urban agglomeration).

For combined sewer systems, the overflow rate and the proportion of discharged wastewater that is mixed up with the stormwater should be estimated. The overflow rate is strictly dependent on the storage volume realised in the catchment and the hydraulic capacity of the waste water treatment plant. For example on average, combined overflows may run for approximately 200 h/a (Brombach et al 1997) and for this time the related sewage load has to be added to the specific surface load.

As illustrated for erosion and urban sewer systems, pathway oriented approaches always require process studies and input data which allow for the formulation of empirical sub models. Due to the fact that these process studies may be limited, the identification of the necessary variables, in a way that enables wide application of such models, may prove challenging. Transfer of a model application from one river basin to another always needs a cross check of the sub-model used.

IV.1.3. Source oriented approaches (SFA, SOCOPSE project)

Substance Flow Analysis (SFA), a source oriented approach, is a method of analysing the flows of a substance in a well-defined system, including through industries producing and using it, households, wastewater treatment plants and all connected media such as soil, air and water.

All the applications and uses of a substance are collated, enabling strategies to reduce the impact of the substance to be developed. Such measures are not necessarily only end-of-pipe as in other approaches but can also encompass source controls such as product substitution. SFA is applied in connection with the early recognition of potentially harmful or beneficial accumulations and depletions in stocks, as well as the prediction of future environmental loads. SFA methods, as we know them today, were first applied by Wolman in the wake of the introducing metabolism studies for cities (Wolman, 1965) .

Basic information on sources was collected during the drafting process of the EQS Directive and made available by the Commission (DG ENV, 2005).

In the SOCOPSE project [www.socopse.se] for example, SFA is used to describe current European sources, fluxes, and endpoints in the environment for selected PSs. This information is used to identify important source categories and to set priorities for emission control measures. Information to construct SFAs can be derived from different sources such as: inventories of goods and their PS concentrations; statistical data on the use of PSs in different economic sectors and; concentration of PSs in raw materials and production data. In cases where data are not available, emission factors, release rates and other statistical information can be used for estimation.

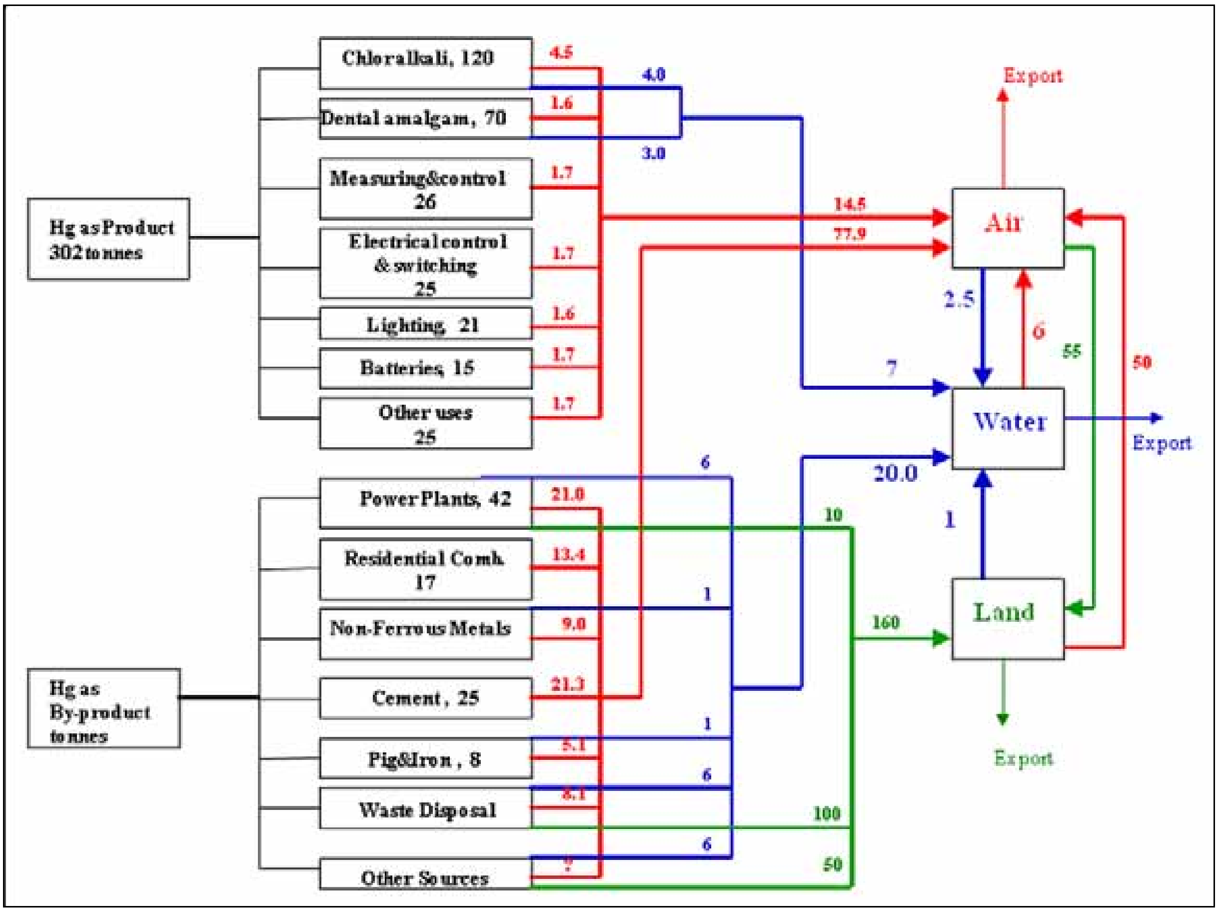

Figure 4: SFA for mercury in Europe in 2000 (numbers in tonnes/year)

Figure 4 shows an example of a SFA for mercury in Europe in 2000 from the SOCOPSE project (NILU, 2009). One advantage of the source-oriented approach is that, if all fluxes are known, it is possible to identify the most efficient emission reduction, because the SFA gives the share of the different emission sources to water, soil and air.

One drawback to SFA is that applicable data are often limited to specific spatial or temporary solutions, which influence the quality of the resulting SFA. Data sets are often only available on a country or EU level. If the perspective is limited to a river basin, proxies often have to be used to illustrate the regional situation. And even though national data may be of high quality because they were compiled accurately, downsizing to the regional level can incorporate errors. Particularly for PSs, use and emission figures can decrease steeply in the space of a few years, so that the corresponding emission factors become worthless. As a result, it is necessary for a SFA to cite information about the time and regional frame for each figure used.

IV.2. Input data needs for the different approaches: building blocks, using existing EU and international data sources

For the generation of an inventory, the EQS Directive requires the use of data obtained by implementing Articles 5 and 8 of Directive 2000/60/EC, Regulation (EC) No 166/2006 and from other available sources. The different data management systems can be operated on regional, national or international level.

Besides the data management systems based on EU-legislation, other data sources can be available from other legal national and international dataflows or based on voluntary data management systems.

Many data are generated for reasons other than fulfilling reporting obligations. For the compilation of an emissions inventory it is of crucial importance that the data are quality checked.

Special attention should be given to the identity of the chemicals concerned as discrepancies can exist between the reporting obligations. Normally for an inventory it is the total emissions of a substance / group of substances that matter, not the species which is used to assess the status, as speciation varies over time.

For example, Annex X of the WFD names brominated diphenylethers as priority substances but sets EQS only for six congeners of pentabromodiphenylether. The E-PRTR however requests emissions data for the sum of penta-, octa- and deca-BDEs. So the E-PRTR data can be used to compile the inventory of brominated diphenylethers, but cannot provide specific information about the congeners.

In the following an overview of possible data sources is provided. In Table 3 the use of data for the different assessment approaches is indicated. This indicative list of data sources should support the generation of the inventory of emissions, discharges and losses. However many data are collected through different data streams and it is of utmost importance to avoid double counting. For that, information coming from different reporting streams should not be simply "joined" but have to go through a critical compilation process to identify data common to the different streams and those that are different.

IV.2.1. Legal data flows

The following legislatively based reporting obligations are the core sources for the data needed for the inventory on emissions, discharges and losses

- Reporting under the WFD (Art. 5 and 8)
- Reporting schemes under the Urban Waste Water Treatment Directive
- Reporting under the European Pollutant Release and Transfer Register (E-PRTR).
- Reporting under the Dangerous Substances Directive

IV.2.2. Voluntary data flows

There are several other dataflow organised by Eurostat/ Organisation for Economic Cooperation and Development (OECD) where the MS are co-operating to gather the information, to develop and apply common definitions and criteria for the quality control of the data, and to verify the data and to provide the information necessary to interpret and report the submitted data.

Further, detailed reporting exercises are organized by the Contracting Parties within the frame of the existing international conventions such as Danube River Protection Convention (DRPC), OSPAR Convention, and the Helsinki Convention on the Protection of the Marine Environment of the Baltic Sea Area (HELCOM) and Stockholm Convention on Persistent Organic Pollutants (POP).

IV.2.3. WISE

The development and the update of the Water Information System for Europe (WISE) have been triggered by the need to streamline and facilitate reporting from the MS to the Commission and to improve its effectiveness. Many reporting obligations are integrated into WISE covering also other water-related Directives, in particular the UWWTD, Bathing Water Directive (BWD), Nitrate Directive (NiD), Drinking Water Directive (DWD) and other mandatory or voluntary reporting to the EU level, in particular submissions to the European Environment Agency (EEA) and EUROSTAT (see Figure 5 below).

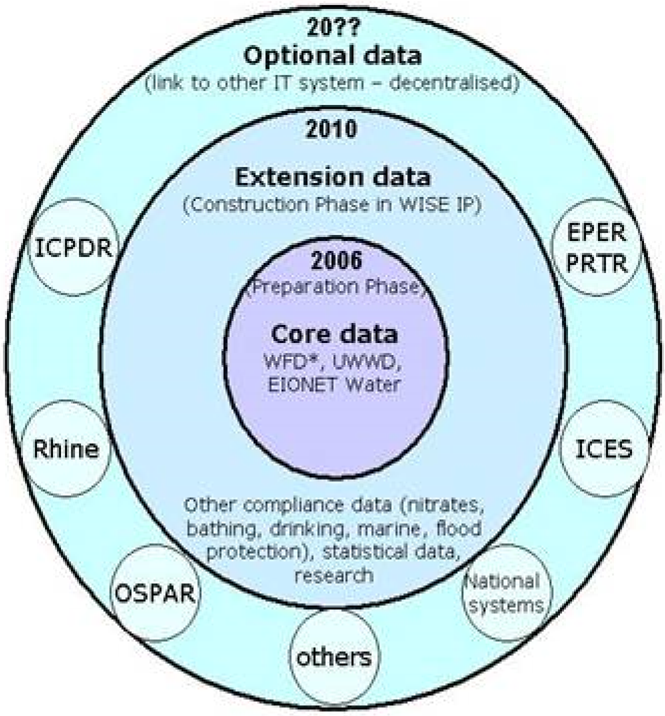

Figure 5: Concept of the Water Information System for Europe (WISE)

The Eurostat/OECD Water Statistics Joint Questionnaire on Inland Water provides national aggregates for load generation and inputs by sector – however data coverage is very poor (in particular for heavy metals and specific organic PS are not included)[8]. It is considered useful for comparison of national estimates for a few pollutants but not a feasible dataflow for the WFD / EQS emission inventory.

State of the Environment (SoE) inputs aim at collecting existing national inventories at RDB aggregation level and are potentially an important dataflow: http://rod.eionet.europa.eu/obligations/632. Data from the 1st year of reporting have been published: http://www.eea.europa.eu/data-and-maps/data/waterbase-emissions, and some compilation documents prepared by the European Topic Centre for Water (ETC/W) are available.

IV.2.4. Additional national/regional dataflows

Additional data sources which may be used for the compilation of the emission inventory are national or regional data management systems (based on legal obligations, for management purposes, for statistical duties, for subsidies or for other reasons), environmental reports or scientific data. These data can have different restrictions in spatial scale, time, coverage, availability or aggregation which have to be considered for their usage for the emission inventory. In the various MS the situation may be different, with more or other data being available from different sources. This chapter contains

[8] http://appsso.eurostat.ec.europa.eu/nui/setupModifyTableLayout.do

many types of data but due to the different approaches and situations in the MS it cannot be completely comprehensive.

Examples of types and sources of data:

- Permit data
- Wastewater and emission monitoring data
- Water quality monitoring data
- Statistical data (inhabitants, connection rates to sewer systems, tourism data, ...)
- Wastewater charges
- Subsidies data on investment and operation of water and wastewater facilities
- Case studies / research data
- Environmental reports
- Other data:
  - hydrological data
  - soil data
  - (hydro-) geological data
  - production data
  - import/export data
  - deposition data
  - agricultural data
  - substance application data

IV.3. Proposed procedure for the compilation of the inventory

As the compilation of the inventory is a demanding task which blends the information from various sources in a structured way, an iterative approach is necessary, which also reflects longer term objectives. Due to data gaps as well lack of time, resources and funds it might not be possible to obtain the results preferred from the water management perspective in the first run, and it might therefore be an option to include tasks to improve the inventory (moving to a higher tier analysis) in the next RBMP.

Based on the discussions in chapters I. 3 and III. 1- III. 4 the following steps are recommended when planning and compiling the inventory:

1. Identification of the "relevant" substances for the RBD

The criteria developed in chapter I 3 are related either to the monitoring results of the last years or the compilation of known pressures and emissions. So this information has to be collected and compiled. As a result of this selection process a list of substances relevant for the RBD concerned is available. MS may opt for certain substances identified in one RBD also to include them in the inventories for other RBDs in their territory with the aim of compiling a national overview.

2. Identification of the information outputs required from the inventory / preliminary method selection (substance specific)

A European-wide estimate of point and diffuse substance inputs can be achieved with the methodologies proposed for the minimum expectations.

As the different methodologies however provide different levels of detail in the results, it is recommended as a second step to identify the information needs for the next RBMP tasks. So for example, when it is likely that the proportion of diffuse inputs is high in the RBD and targeted measures, especially in hot-spots, to reduce these inputs have to be implemented, additional information on location and share of different pathways is required. In such a case, the information which can be extracted from the riverine load approach is normally not sufficient. The information on the share of different diffuse pathways and a spatial resolution to identify hot spots however can be extracted from RPA compilations. For an overview of the information which can be extracted from the different methodologies refer to Table 2. On the basis of the identified needs a substance-specific preliminary method selection should be performed.

3. Survey of available information needed for the selected tiers

The next step is ta compile the information needed for the selected tiers and to check which part of it is available and can be utilised. Important data sources are described in chapter IV 2.

- Point source data can be taken from the E-PRTR system. However, evaluations of the E-PRTR indicate that it may cover only part of the relevant point source emissions. Especially low-concentration inputs from UWWTPs, together with the high volume of waste water from the urban sector, might lead to additional inputs which have to be accounted for. A combined evaluation of the substance invariant information of the UWWT Directive-reporting (size, location, technology and waste water volume) and the use of emission factors may give reasonable estimates. However the derivation of the emission factors requires high-quality concentration measurements and a careful evaluation of these results. This is an area where close cooperation between MS and scientific institutions may be useful.

- The application of the riverine load approach requires data on discharges and on average concentrations of the substances in whole water if available (in the dissolved phase and in suspended solids). This information should be available in the quality required by the Commission Directive 2009/90/EC for most substances at least at the confluence of the most important tributaries and on “border” monitoring stations. For heavy metals a problem could arise from the fact that, unlike for the organic substances, the samples have to be filtered. This may cause a significant underestimation of the transported loads.
- Pathway oriented approaches (e.g. RPA) require:
    - Substance invariant regionalized data on topology, geology, land use etc which can be taken from various maps or statistical sources. If for a RBD an RPA for nutrients already exists (e.g. a MONERIS Analysis) this is a good starting point as it already covers a great portion of the required substance invariant information.
    - Substance-specific concentrations (if possible also regionalised) at the various transfer points are required. A joint compilation of results available in several MS might help.

Source oriented approaches require data on production, consumption use and emission into different environmental media; which might be available from chemical management institutions as well as infrastructure and other statistical data. Furthermore, information on storage and transfer processes in the environment is required. Here, data collected by the authorities for the management of chemicals, PPPs or biocides, national inventories and also international information, e.g. from different OECD activities, are valuable sources of information.

4. Identification of data gaps for the selected tiers and assessment of efforts needed to close the identified data gaps

As a result of Step 3 and the data requirements for the preliminary selected tiers the data gaps will become obvious. It should be also identified which parts of the intended investigations are hampered by the missing data. If the affected parts of the input inventory only affects parts which are very likely to be of minor relevance simpler substitutes for this part can be considered.

Based on these assessments the efforts needed to close the identified data gaps or to provide the substitutes can be assessed.

5. Final decision on method selection (substance-specific) for the current inventory compilation

Steps 2-4 will form the basis for the final selection of the approaches which should be taken for the current inventory compilation. It will become clear which information required from the inventory for the next RBMP tasks will not be available from the first compilation. International coordination / exchange of experiences in an international RBD should be also part this process .

6. **Formulation of tasks for the next RBMP (substance-specific), if improvements necessary in the inventory, e.g. by use of higher-tier approaches**

The data gaps and investigations needed to improve future inventories should be known. The investigations should be included in the next RBMP. This step ensures that the information identified in Step 2 will be available by the time the next inventory is compiled.

7. **Preparation, check and refinement of the substance-specific inventories**

Finally the different approaches should be compiled and checked against each other. This cross-checking, especially against the riverine load approach, provides indications of the completeness and the plausibility of results. At the right spatial scale, source and pathway specific investigations can be compared.

8. **Presentation of the results**

The results can be presented in tables or graphs as well as in maps showing either monitored loads or area / population-specific inputs into surface waters. Information on uncertainties and estimates of errors should be also provided. Key conclusions for water-management purposes, i.e. the proportion of point and diffuse sources, identification of important sources / pathways and thus possible targets for reduction measures should be integrated into the RBMP.

Specific MS examples are given in the annexes of this guidance document.

A reporting sheet for the inventory, aiming at providing information for a pan-European overview is being developed.

IV.4. Interpretation of the results from the different approaches

IV.4.1 Interpretation

As indicated in Table 2 the different approaches provide results at a different level of detail. Furthermore the results are available at different regional scales, based on methodology and regional differentiation of input data / coefficients.

1. **Point source emissions**

These localised emissions are in general reliable; however they should be checked

- if analytical results used for the load calculation show a high percentage of measurements below LOD / LOQ. This may lead to a clear over- or underestimation of those inputs, depending on how these results are taken into account.
- if emission values resulting from the use of emission factors are derived for the installations concerned. Use of emission factors reduces the spatial resolution and may lead to over- or underestimation of emissions from specific installations, although the average for several installations may be correct.

2. Riverine load approach

These results are in summary the loads of all upstream inputs plus the net sum of loads transported from and to internal stores. Depending on the flow conditions this transport may increase or decrease the monitored loads, therefore the result should be corrected for these in-stream processes. The net difference between the observed loads and the point source emissions serves as a basic estimate of all diffuse inputs.

3. Pathway oriented approach

Pathway oriented methods, when they are adapted to the situation in the RBD district, give inputs separated into different pathways regionalised into a network of small, hydrologically connected catchments. So, in addition to the localised point source emissions also localised information on diffuse inputs is available. This allows also for the identification of hot spots.

4. Source oriented approach

Here the data depend strongly on how the underlying model covers the actual situation in the river basin. As most of the production and use data are only available at national / EU level the derivation of regional information is a comprehensive task.

The source oriented method gives information on the contribution of certain sources to the pathway specific loads, however disaggregation is difficult (see Chapter III 2).

IV.4.2 Comparison

Inter-method comparison of the results at the MS level gives valuable information on the plausibility of results.

As point source information and in-stream loads are determined by measurements they are relatively reliable and serve as reference points in the comparisons.

The results of load estimations should normally be higher than the point source emissions. If not this indicates the existence of high internal storage / degradation processes which have to be taken into account, otherwise the estimated diffuse inputs would be significantly too low.

RPA estimations are normally fitted / compared to the loads transported through a high number of gauges / monitoring stations to try to minimize the overall error which normally is within +- 30% range for the individual stations. As an example a comparison of observed vs. monitored load for Nickel in Germany is given in Figure 6.

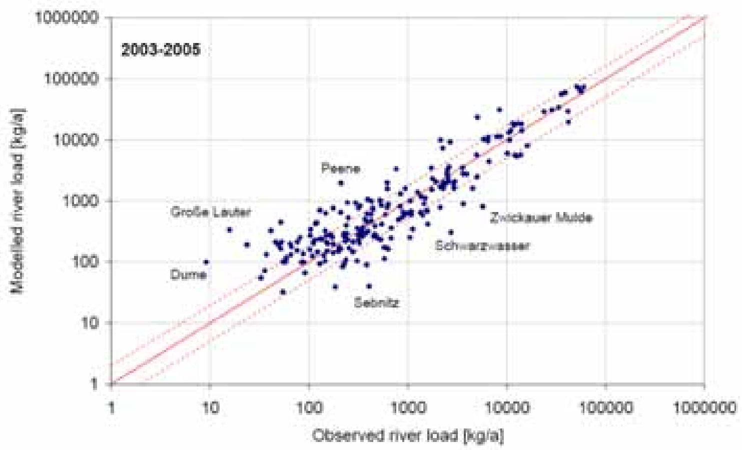

Figure 6: Comparison of calculated and observed loads of nickel using RPA for Germany (Fuchs et al. 2010)

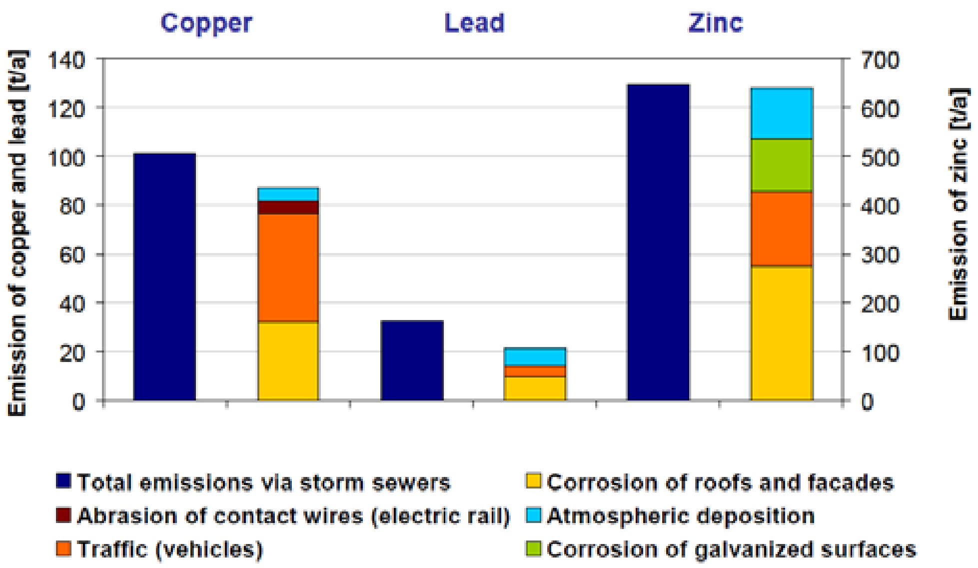
Source based disaggregations can also be compared to the riverine loads.

A comparison of source oriented / pathway oriented results is also possible if the data situation is good and the spatial aggregation level is adequate. Figure 7 shows the comparison between a source specific emission estimation and a pathway specific estimation for the emissions via storm sewers for copper, zinc and lead for the Federal Republic of Germany. Here both results match quite well (figure taken from Fuchs et. al 2010).



Comparison of the calculated emissions from storm sewers for copper, lead and zinc with the source-specific emission approach according to HILLEN-BRAND ET AL. (2005)

Figure 7: Comparison of the calculated emissions from storm sewers for copper, lead and zinc with the source-specific emission approach according to Hillen-Brand et al. (2005)

IV.4.3 Use of results in water management processes

As the objectives of the inventories for river basin management have been defined in the proposed procedure, the results obtained should be compared with the objectives. As mentioned previously, a higher tier approach may be needed for future inventories to improve their usefulness in water management.

If measures for hot spots are planned on the basis of the inventory results, an additional round of plausibility checking should be performed to ensure that the measures are applied at a scale corresponding to the scale of the problem, which could be the result of very specific local conditions not evident from the geographical scale of the inventory.

PREPARATION OF THE GUIDANCE

Mandate for the Drafting Group

This Guidance Document was prepared under the WFD Common Implementation Strategy (CIS) by the Drafting Group (DG) on PS inventory set up in 2010 according to a mandate agreed by the Water Directors at their meeting on 27-28 May 2010 in Segovia.

The DG worked under the umbrella of the CIS Working Group E on Chemical Aspects and was co-led by Germany (Joachim Heidemeier), France (Lauriane Greaud) and DG ENV (Madalina David).

List of participants in the Drafting Group

ANNEXES: COUNTRY EXAMPLES

Austria case study fact sheet

General information

country: *Austria*

title of the project/study:

Emissions of organic and inorganic micro pollutants from Austrian urban wastewater treatment plants

type: Case Study

The Project was worked out for preparatory purposes for a national legal document (ordinance) about an emission register for surface waters.

scope:

- Information gathering: Up to this project only little information in Austria was available about organic and inorganic micro pollutants discharged from urban wastewater treatment plants.
- Selection of present priority and other Substances of national concern

duration: *2007 – 2009*

status: *finalized*

methodology used :

- Analytical analysis of influents and effluents of selected 15 Austrian urban wastewater treatment plants as a first step of the project defining the substances for an in deep assessment in a second step
- Analysis of effluents of 9 Austrian urban wastewater treamtentplant 5 times over a one year period on selected substances (result of step 1)
- Assessement of the fate of substance during wastewater treatment in two urban wastewater treatment plant with mass balance over a 2 week period.

information resources (URL):

The final report of the project is available in German language under

Abstract

INTRODUCTION

The focus on substances in urban wastewater management developed in the last decades from organic pollutants (BOD_5, COD) to nutrients (nitrogen and phosphorus) and within the last years to micropollutants. In the European water policy the relevance of hazardous substances is reflected by the priority (PS) and priority hazardous substances (PHS) in the Water Framework Directive (WFD) (EC, 2000). The knowledge on occurrence and fate of xenobiotics in wastewater has increased in recent years.
The development of a national emission register for surface water from significant point sources (EMREG-SW) (BGBl. II 29/2009) has been already started with the WFD implementation process in Austria. In preparation of the legal basis for this EMREG-SW a comprehensive study was carried out in the years 2007 – 2009 on Austrian urban wastewater treatment plants (UWWTP), with the aim to identify relevant substances and substance groups, which should be monitored regularly in treated urban wastewaters.

METHODOLOGY

Selection of wastewater treatment plants

In a first step the UWWTPs to be sampled had to be selected. The 638 municipal UWWTP with a treatment capacity of more than 2000 population equivalents (pe) (Überreiter et al., 2010) were categorised dependent on their size and the industrial influence. The size was selected as categorisation criteria, because different requirements regarding the treatment efficiency exist for UWWTPs with treatment capacities of less or more than 5000 pe. According to Austrian legislation UWWTPs with a capacity of more than 5000 pe have to remove nitrogen and phosphorus, whereas UWWTPs below 5000 pe have to remove phosphorus and to apply nitrification. A second size class included UWWTPs with a treatment capacity of more than 150,000 pe as these large UWWTP are treating approx 50% of the total generated load (Überreiter et al., 2010).
The second categorisation criteria was the industrial contribution to the generated load. The industrial contribution was determined based on BOD and COD data. For 420 of the 638 UWWTPs data on BOD and/or COD influent load as well as information on the connected population was available. Based on specific discharges to wastewater of 60 g BOD/(cap·d) and 110 g COD/(cap·d) the industrial/commercial contribution to the UWWTP was calculated. Based on these calculation 3 different categories were defined. Category 1 included UWWTPs with industrial/commercial contribution (in terms of BOD and or COD) of less than 25%, which are considered as domestic areas with negligible industrial influence.
The most important categories in terms of generated load are those with an industrial/commercial contribution between 25 and 75% and a treatment capacity of more than 5000 pe. For a first assessment (module 1) 15 UWWTPs were selected out of the 6 categories by considering also different treatments technologies. For this first assessment influent and effluent samples were taken.
In a second step (module 2) the substances identified as potentially relevant were monitored over one year in 9 UWWTP effluents with a 2 months frequency. Additionally 2 UWWTPs were sampled over 2 weeks in order to assess the fate of selected compounds during the treatment. For this assessment influent, effluent and sludge samples were considered.

Applied relevance criteria

The aim of the first screening of 15 UWWTP effluents was to identify substances, for which the emission to the surface waters via wastewater discharges might be relevant and to select the compounds to be subjected to a further monitoring. All substances were excluded i) which were not detectable in none of the analysed effluent samples or ii) for which the maximum measured concentration was below half the EQS. The limited number of samples and the related uncertainty should at least partially be addressed by setting the relevance criteria with half the EQS and the comparison with the maximum measured concentration.
All substances which could not be excluded in the first step were subjected to a monitoring over one year. 9 UWWTPs effluents were sampled every two months. Based on the results of this monitoring those substances are considered as relevant in wastewaters for which i) the mean concentration of all measurements (including also those from the first step) was higher than half the EQS and ii) the average concentration in at least one of the sampled UWWTPs (only second step) is higher than the EQS. The second criterion is applicable only to the substances subjected to the annual monitoring.

RESULTS AND DISCUSSION

Results of the first screening (Modul 1)

The results of the screening of UWWTP influents and effluents (Modul 1) are summarized in table 1.

Table 1: Results of the screening on the occurrence of selected xenobiotics in treated and untreated wastewater.

	Priority Substances, Priority Hazardous Substances and EU-wide regulated substances	**Other substances**
Not detected in influent and effluent	alachlor, chlorfenvinphos, endosulfane, hexachlorobenzene, hexachlorobutadiene, pentachlorophenol, pentachlorobenzene, trichlorbenzenes trifluralin, aldrin, dieldrin, endrin, isodrin, DDT, p'p'-DDT, tetrachloroethylene, tetrachloromethane, trichloroethylene	benzidine, chlordane, 1,2-dichloroethene, 2,5-dichlorophenole, 1,3-dichloro-2-propanole, heptachlor, mevinphos, omethoate, pentachloronitrobenzene, sebuthylazine
Detected in at least one influent sample but not in effluents	anthracene, 1,2-dichloroethane, naphthalene, fluoranthene, benzo(a)pyrene, benzo(b)fluoranthene, benzo(k)fluoranthene	cyanides (easily purgeable), dimethylamine, ethylbenzene, isopropylbenzene, linear alkylbenzene sulfonates, xylene
Maximum effluent concentration below EQS/2	Atrazine, benzene, isoproturon, simazine, C_{10-13}chloroalkanes, lead*	benzylchloride, bisphenol-A, dibutyltin compounds, 2,4-dichlorophenole, phosalone, arsenic
Maximum effluent concentration above EQS/2	Pentabrominated diphenyl ethers, cadmium*, chlorpyrifos, di(2-ethylhexyl)-phthalate, diuron, mercury*, nonylphenole, nickel*, octylphenol, tributyltin compounds, indeno(1,2,3-cd)pyrene**, benzo(g,h,i)perylene**,	Ammonia**, adsorbable organic halogens, chloroacetic acid**, ethylenediaminetetraacetic acid, nitrilotriacetic acid, fluorides**, nitrite**, trichlorfon, copper, zinc,

	trichloromethane**, dichloromethane**	silver, selenium

*…total concentrations were determined **…not considered in the monitoring

According to the criteria mentioned before, the following substances were selected to be monitored in module 2 of the project over one year in two months intervals in the effluent of 9 UWWTPs: Pentabrominated diphenyl ethers, cadmium, chlorpyrifos, di(2-ethylhexyl)-phthalate, diuron, mercury, nonylphenole, nickel, octylphenol, tributyltin compounds, adsorbable organic halogens, ethylenediaminetetraacetic acid, nitrilotriacetic acid, trichlorfon, copper, zinc, selenium, sebuthylazine.

Monitoring xenobiotics in UWWTP effluents (Modul 2)

The screening (Modul 1) was performed in September, which might be beyond the application period of most Plant Protection Products (PPP). Beside the above mentioned substances PPP were measured again twice in May and in July/August (n=18) in order to confirm the observations and conclusions from the screening. The mean values of the investigated plant protection products are clearly below half the EQS and also the measured maximum concentrations are well below the EQS wherefore emissions from UWWTPs are deemed not as relevant sources for surface water contamination and are therefore not suggested to be regularly monitored.
The results of the Monitoring programme are summarized in Table 2.

Table 2: summary on the measured effluent concentrations (n=60)

	Mean [µg/l]	Median [µg/l]	Min [µg/l]	Max [µg/l]
PBDE	0,00021	0,000039	n.d.	0,0037
cadmium	0,056	0,010	n.d.	0,20
DEHP	0,51	0,22	n.d.	6,6
diuron	0,073	0,040	n.d.	0,65
nonylphenole	0,25	0,18	n.d.	1,8
AOX	110	43	2	3300
EDTA	65	43	6,5	310
NTA	45	12	n.d.	410
Cupper	7,2	4,3	1,3	56
Selenium	2,3	0,30	n.d.	32
Zinc	32	31	3,0	72
nickel	5,6	4,1	1,0	41
tributyltin compounds	0,00020	0,00010	n.d.	0,0020

n.d. … not detected

As described before mean values for each compound and UWWTP were determined and compared with the respective EQS (Fig. 1a). Beside cadmium, DEHP and nickel in at least one of the nine sampled UWWTPs the calculated mean effluent concentration exceeds the respective EQS. The mean concentration from all available effluent measurements (n=60 for each substance) exceeds half the EQS for all compounds beside DEHP, nickel and diuron (Fig. 1b). Hence comparable results are obtained by the application of the 2 criteria. For PBDE, nonylphenoles, diuron, tributyltin compounds, cadmium, AOX, EDTA, NTA, cupper, selenium and zinc the impact on surface water quality via the discharge of treated wastewater might be of relevance and those substances are suggested for a regular monitoring.

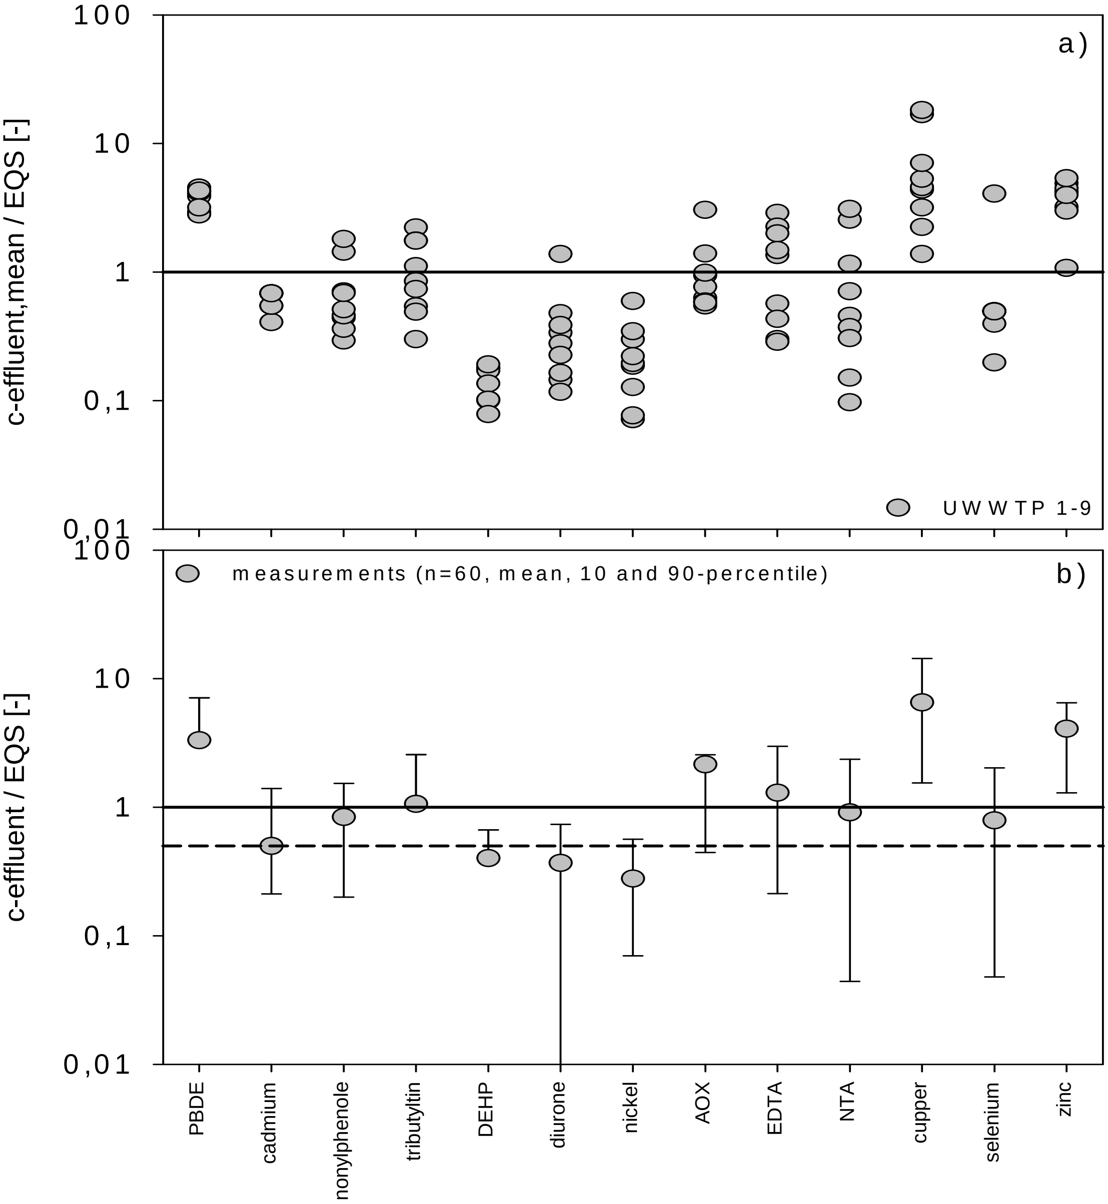

Figure 1: Ratio of mean values of each UWWTP to respective EQS (Fig. 1a); mean value of all effluent measurements compared against EQS and EQS/2 (Fig. 1b)

More details and results are available in the study report. (UBA, 2009).

CONCLUSION

As result of this study the priority substances diuron, cadmium, nonylphenole and tributyltin compounds were selected as relevant for UWWTP effluents for consideration in the Austrian EMREG-SW. Therefore these substances are included in this reporting scheme. UWWTPs with a design capacity above 10.000 pe have to measure these compounds within a six years reporting cycle at least 12 times over one year and report the annual loads in kg/a. For the relevant non priority substances there is no obligation for measurement. For UWWTP above 100.000 pe the annual emitted load can be estimated or calculated with emission factors and reported.

Abstract

The aim of the project series mentioned above was to analyse the emission situation of priority substances in Germany and to come up with suggestions for emission controls. The main focus was on the 33 substances of the WFD and additionally the heavy metals copper and zinc.
The method of SFA was applied to get information about the production, imports/exports, use and pathways to water emission of the substances. Based on this work, emission control measures under particular consideration of the situation in Germany were suggested.
The priority substances are very diverse in their use and formation, emission pathways, share of emissions into water as well as with regard to the quality and coverage of the available information. Therefore the substances were grouped together in several sets which shared some of the aspects cited (e.g. common area of application or origin, similar use/emission pathway, common data sources, comparable abatement possibilities). The groups are Heavy metals and their compounds, Polycyclic aromatic hydrocarbons, Chlorinated compounds – solvents, Chlorinated compounds – mainly intermediate products, Pesticides and Individual compounds with particular significance, see the following table.

Overview of the most important uses and emission sources for the priority substances in Germany

Priority substance	Significant applications in Germany	Emissions
Lead	Storage batteries, semi finished products, alloys; construction industry, vehicles, hunting/fishing/diving sports	Heavy metals MONERIS:
Cadmium	Batteries, (stabilizers, alloys) accompanying element of Zn, fertilizer	- urban/rural areas
Nickel	Steel, Ni-alloys, batteries, Ni-plating, catalysts	- municipal/ind. sewage plants
Mercury	Chlor-alkali-electr., mercury batteries, fluorescent lamps, dental treatment (→crematoria)	- atmospheric deposition, historical pollution, …
PAH (anthracene, fluoranthene naphthalene, PAH)	PAHs are formed in combustion processes; creosote (local emission); tar oil paints (ships, corrosion prevention); anthracene, fluoranthene, naphthalene: dyes, interim product	mainly via atmospheric deposition
1,2-dichloroethane	Interim product in vinyl chloride production	emissions (air and water) from production of basic chemicals and waste treatment
Dichloromethane	industrial solvent and extracting agent, 10% as paint stripper to remove coatings	emissions from use as solvent (metal working), air emissions from open applications (atm. deposition estimated as low)
Trichloromethane (chloroform)	Interim product and solvent	emissions from use as solvent via wastewater and air pathways
Hexachlorobenzene	POP; no production, no use	emissions from use of fog-generating munitions; historical pollution of sediments/sites; by-product
Hexachlorobutadiene	no production, no use	By-product chlorine chemistry
Pentachlorobenzene	no production, no use; (source material for quintocene; prohibited since 1992)	historical pollution/sediments
Trichlorobenzene	Production; used as interim product	
Alachlor	not licensed	
Atrazine	not licensed	
Chlorfenvinphos	not licensed	
Chloropyrifos	license for 2 products until 2015 as PPP; under review as biocide	
Diuron	licensed as PPP, under review as biocide	
Endosulfane (alpha-endosulfane)	not licensed	
Hexachlorocyclohexane (HCH)	no longer permissible for licensing in EU since 2002	historical pollution one point source water direct (manufacturing inorganic basic chemicals)
Isoproturon	permitted	diffuse emissions via farming, increased by illegal/improper use, point emissions from farmyard run-offs
Simazine	prohibited	
Trifluralin	permitted i	
Benzene	large volume interim product, component of carburettor fuel (gasoline)	atmospheric deposition
Brominated diphenyl ether	flame proofing agent; since 8/2004 ban on marketing and use for penta- and octaBDPE (incl. products); decaBDPE in products	diffuse emissions DecaBDPE via imported products
C10-13-chloroalkanes	flame proofing agents, softeners; EU-	diffuse emissions via imported

Priority substance	Significant applications in Germany	Emissions
	wide restriction 2002/45/EC; no production in Germany	products, depot effect
Di(2-ethylhexyl) phthalate (DEHP)	PVC softener	emissions from PVC-processing, sewage plants, diffuse emissions via products and old products
Nonylphenols	Adhesive, varnishes; NPEO as tenside; restriction on use through 2003/53/EC	Emissions via NPEO (tenside); imported textiles; via PPP
Octylphenols	no longer produced in Germany; only very minor use	Emissions via impurities in NPEO
Pentachlorophenol	HSM/fungicide; prohibited since 1989	historical pollution, emissions via imported products, depot effect
Tributyltin compounds	Anti-fouling paints: prohibited through 782/2003 and 2002/62/EC (implementation of IMO ban);	direct emissions during anti-fouling applications; shipyards; low emissions due to impurities in mono-/dibutyltin compounds

For each priority substance a substance-specific data sheet was compiled in order to present the information and data in a compact form. These data sheets contain information on the following issues: Nomenclature and substance features, substance specific regulations, monitoring results, production and application, emission situation, approaches for emission abatement measures and literature. When possible, the findings are summarized in a figure like given for NP/NPEO below.

Figure: Fluxes for the NP / NPEO-use and resulting emissions for D (1999/2000)

Abstract

Introduction

The Directives 2000/60/EC (WFD) and 2008/105/EC (on EQS) of the European Parliament and the Commission ask all Member States (MS) an inventory of emissions of priority substances for all RBDs (EU, 2000 and EP, 2008). This task requires appropriate data and approaches for the description of the current state of surface water bodies and the evaluation of appropriate measures for the reduction of emissions into the surface water bodies to achieve a good ecological state of surface water bodies and to meet the quality standards set.

Based on these requirements the proven MONERIS concept that was developed for modeling of nutrient emissions into the water bodies (Behrendt et al., 2000), was adapted as MoRE system (Modeling of Regionalized Emissions) for pollutant emissions. Besides the technical implementation, a full documentation of input data, model approaches and results as well as transparency and flexibility of the model system have been realized.

Currently, MoRE is realized for Germany's large river basins and their catchment areas outside Germany with a total area of 650,000 km². The area is divided in about 3500 analytical units based on the drainage network. The analytical units can be aggregated to different administrative units, sub-basins or river basins. Given adequate input data, MoRE can be adapted easily to any other river basin or MS. The emissions can be modeled either in individual annual steps or for user-defined periods.

The MoRE system comprises approaches for the emission pathways: municipal wastewater treatment plants, industrial direct dischargers and emissions of historic mining for pathways related to point sources and the following emission pathways related to diffuse sources: sewer systems, surface runoff, erosion, groundwater, tile drainage, direct atmospheric deposition onto water surfaces and inland navigation (Figure 1). Thus, MoRE allows a regional and pathway specific quantification for any given aggregation unit. The modeling approaches and sources of input data are described in detail in Fuchs et al. (2010).

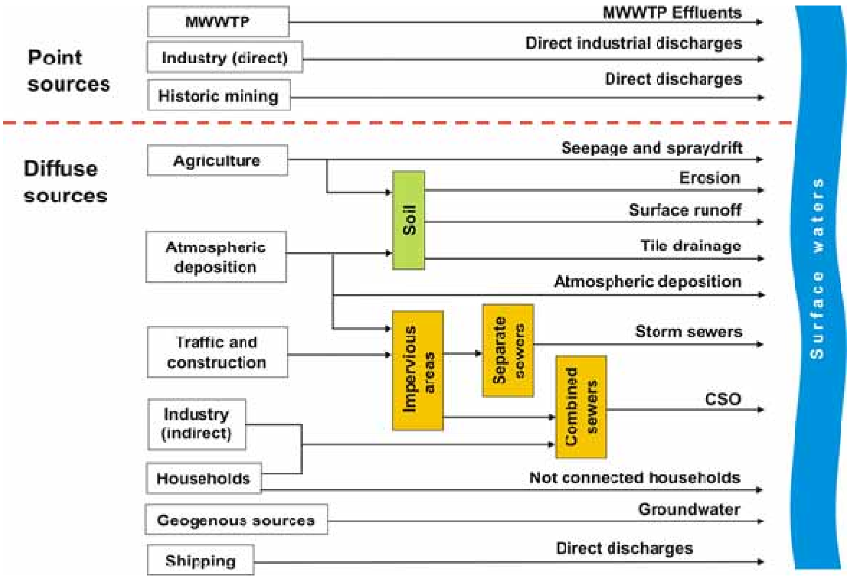

Figure 1: Sources and emission pathways considered (Fuchs et al., 2010)

Model architecture and implementation

This section describes shortly the model architecture with its components and the technical implementation of the MoRE system. Further information is available in Fuchs et al. (2011).

Model architecture

The MoRE system is based on an open source PostgreSQL database and two different graphical user interfaces (GUI): the MoRE Developer GUI and the MoRE Visualizer GUI (Figure 2). The GUIs have been developed for user interaction with the PostgreSQL database. The PostgreSQL database content can be easily read, changed and extended via the MoRE Developer GUI. The modeling can be launched via a calculation engine which is incorporated in the Developer GUI with a dynamic linkage to the PostgreSQL database. Modeling results can be visualized via a GIS-browser (MoRE Visualizer). Users can access the MoRE system either via internet on a multi-user basis or via a single user application for PC.

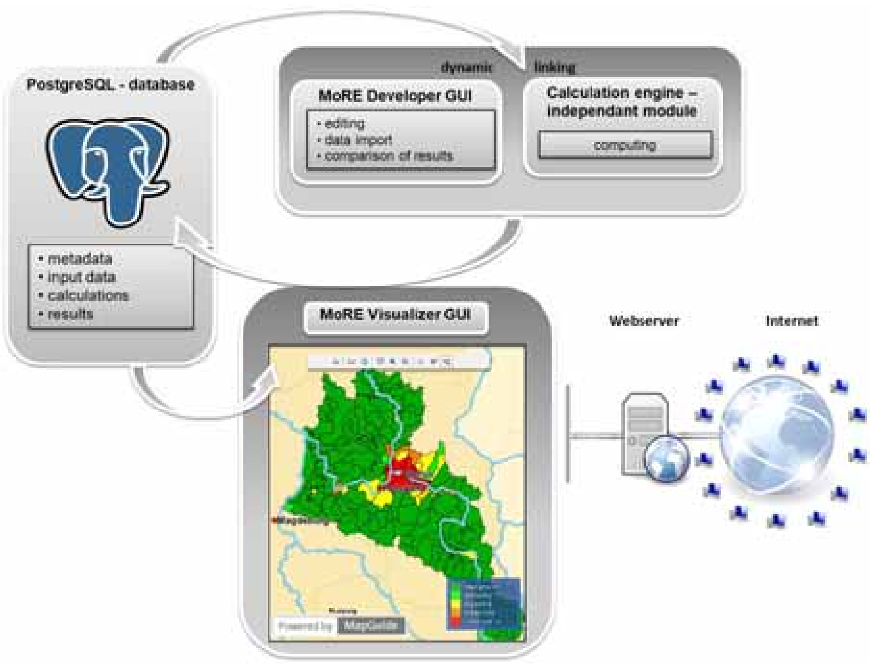

Figure 2: System architecture of MoRE

Calculation engine

One of the main goals of MoRE development was the provision of a flexible modeling tool. New modeling approaches can be integrated in a flexible way using the calculation engine and tested easily in the Developer GUI. This feature is possible because the calculation engine is integrated but unit independent of the database. That means the calculation engine does not include any equations but only the logic structure of the model and doesn't have to be adapted to changes in approaches, as long as the structure of the MoRE database will be maintained. The user does not need to have programming skills.

The database

The fundamental database contains all data and metadata for the spatial and temporal variables and for the model constants. This means, for example, that each record is assigned a unique origin and additional information like pathway specification and substance reference.
Furthermore, the empirical approaches are defined in the database. After modeling, the results can again be written to and stored in the database or exported for further analysis to MS Excel.
The MoRE database contains spatial and periodical input data. Input data is derived either from regionalized datasets like soil maps and hydrogeological maps, land use and population distribution datasets as well as from statistical data like connection rate to sewer systems, share of combined and separate sewer system, storage volume in combined sewer system. Additionally, emission factors like inhabitant specific loads and pollutant loads from impervious areas are implemented as constants. Altogether, the MoRE database contains about 300 variables, 12 million input data and 9 million results.

The graphical user interfaces

MoRE Developer

Using the MoRE Developer GUI, new input data can be added to the database and algorithms for approaches can be readjusted. Additionally, MoRE Developer owns a powerful calculation engine for calculating emissions and river loads for selected analytical units.

MoRE is modular, so that the approaches of individual pathways can be independently adjusted. Thus, alternative input data and modeling approaches can be implemented as variants of a basic variant. The results can be compared to evaluate the quality of the considered input data and approaches.

MoRE Visualizer

The MoRE Visualizer is a browser based application which works via a direct connection with the MoRE database. In addition to the MoRE Developer GUI, the MoRE Visualizer offers the opportunity of presenting and analyzing the computed data for selected aggregation units and periods.
After the selection and visualization of the data, it can also be presented as reports which can be exported to MS Excel.

Availability of MoRE

The MoRE system is Free Software. It is published under the licence AGPL V. 3 which allows free modifications, copying, redistribution and use of the software as long as the same terms also apply to the derivative works.

Exemplary results

Given the example of lead as one of the priority substances, we show exemplary model results. The total lead emissions from Germany account for 263 t/a (Fuchs et al., 2010). It turns out that erosion is the main emission pathway for lead besides sewer systems (Figure 3).

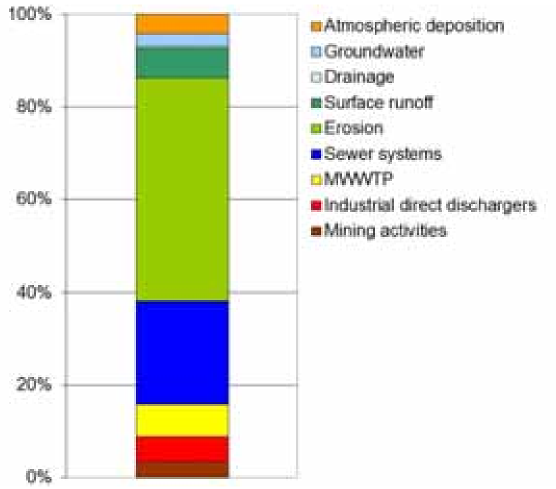

Figure 3: Relevance of the pathways for lead emissions into the RBDs of Germany in the balance period 2003-2005 (Fuchs et al., 2010)

Since MoRE generates regionalized emissions, the total emissions and the emissions for each pathway can be visualized on the level of analytical units. Using this map, one can detect pollution hotspots in river basins or administrative units (Figure 4)

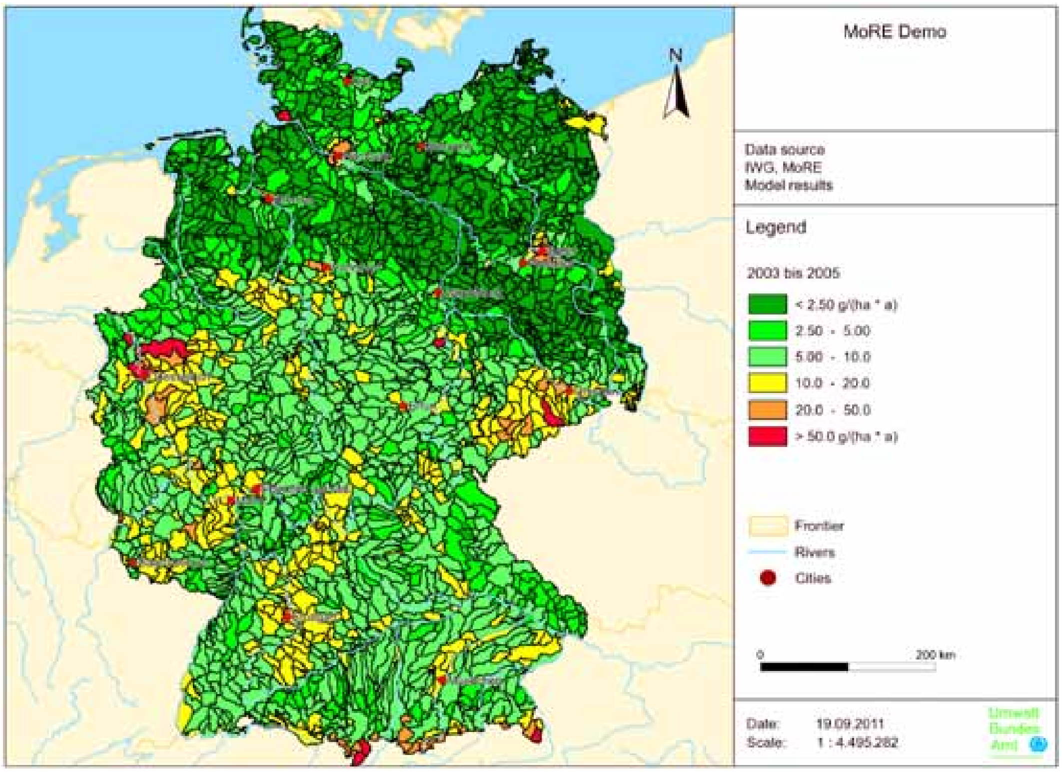

Figure 4: Specific lead emissions from the analytical units of Germany in the period 2003-2005

Conclusions

MoRE system is a flexible and transparent tool for the quantification of pollutant emissions in river basins. It allows a regional and pathway specific quantification for any given aggregation unit. Therefore, MoRE can be highly relevant for the allocation of investments or the implementation of specific measures to mitigate the overall pollutant emission into surface water bodies in order to meet the above mentioned requirements of EU water policy.

Belgium (Flanders) case study fact sheet

General information

country: Belgium

title of the project/study:

WEISS, the Water Emission Inventory, a planning Support System aimed at reducing the pollution of water bodies.

type:

Research project, financed by LIFE+ 08.

The result will be used for administrative practices.

scope:

- Information gathering (e.g. input loads or concentrations)

  Existing monitoring data and estimated diffuse pollution data will be used, supplemented with data from additional research.

- Modelling of inputs

  WEISS will model all the different pathways from source to surface water. Input will be monitoring data, calculated and estimated data.

- Inventory compilation

  The WEISS system will act as an emission inventory and will calculate and report gross and net emissions at a high spatial resolution.

- Assessing relevance of source

  WEISS will integrate all (relevant) emission sources and pollutants and will identify the significant emission sources.

- Decision support

  Assist authorities in their monitoring and reporting obligations. Scenario calculation and planning support.

duration: 2010-2012

status: ongoing

methodology used :

WEISS is a model-based information system handling emission data from diffuse and point sources by means of geographical calculations at a high resolution.

WEISS uses a bottom up methodology in which it combines the advantages of the pathway oriented approach (POA) and the source oriented approach (SOA).

A pure source oriented approach, like Substance Flow Analysis (SFA), analyses all the flows of a substance in a well-defined system, including through industries producing and using it, households, wastewater treatment plants and all connected media such as soil, air and water. The substance flow of WEISS focuses on the end-use of a substance and it's connection to the medium water. Therefore WEISS is less complex than SFA , and has the advantage to report the emission on a high spatial resolution.

The pathway oriented approach focuses on the processes of transport to the surface water. These processes are also part of WEISS, and moreover, WEISS can report on the proportional contribution of sources to a certain transport.

Flemish Environment Agency, Department Water Reporting
A. Van de Maelestraat 96, BE9320 EREMBODEGEM
Mrs Greta Vos (g.vos@vmm.be)

Abstract

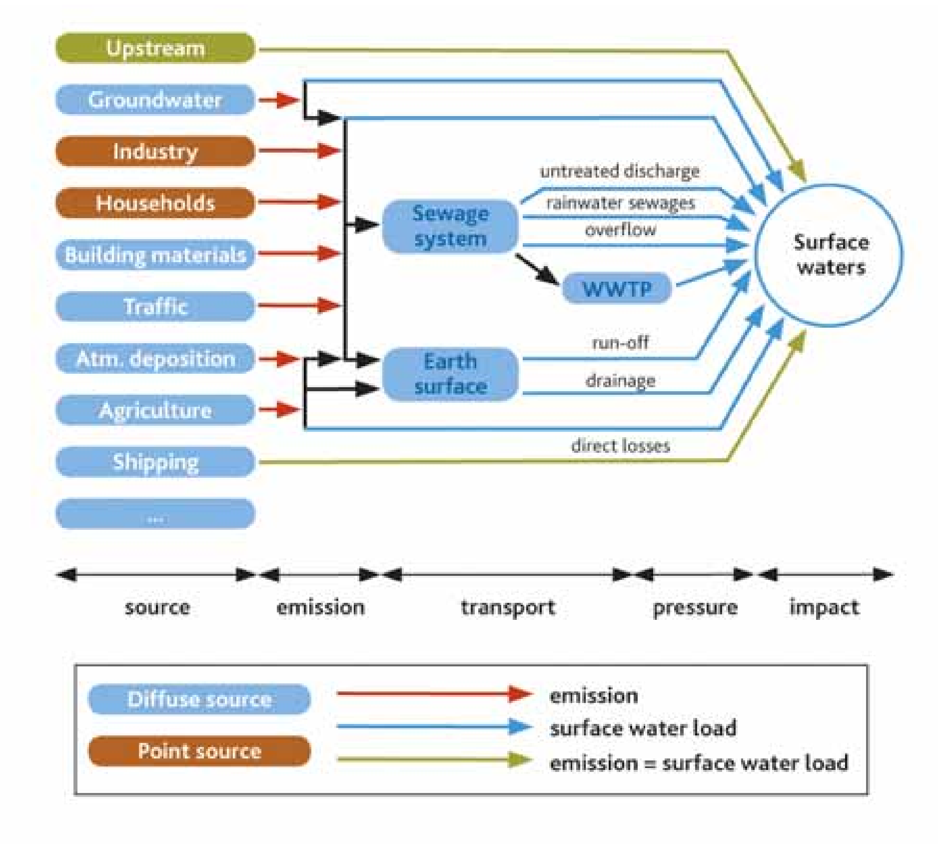
Introduction

Monitoring and reporting the water quality for the Flemish region of Belgium is the responsibility of the Flemish Environment Agency (VMM). To assist in this tasks the WEISS system is currently under development in collaboration with the Flemish Institute for Technological Research (VITO). WEISS is a LIFE+ project that will create a geographically explicit, transparent inventory of emissions towards water for the Flemish region. The project will be realised in 3 years and will be finalised by the end of 2012.

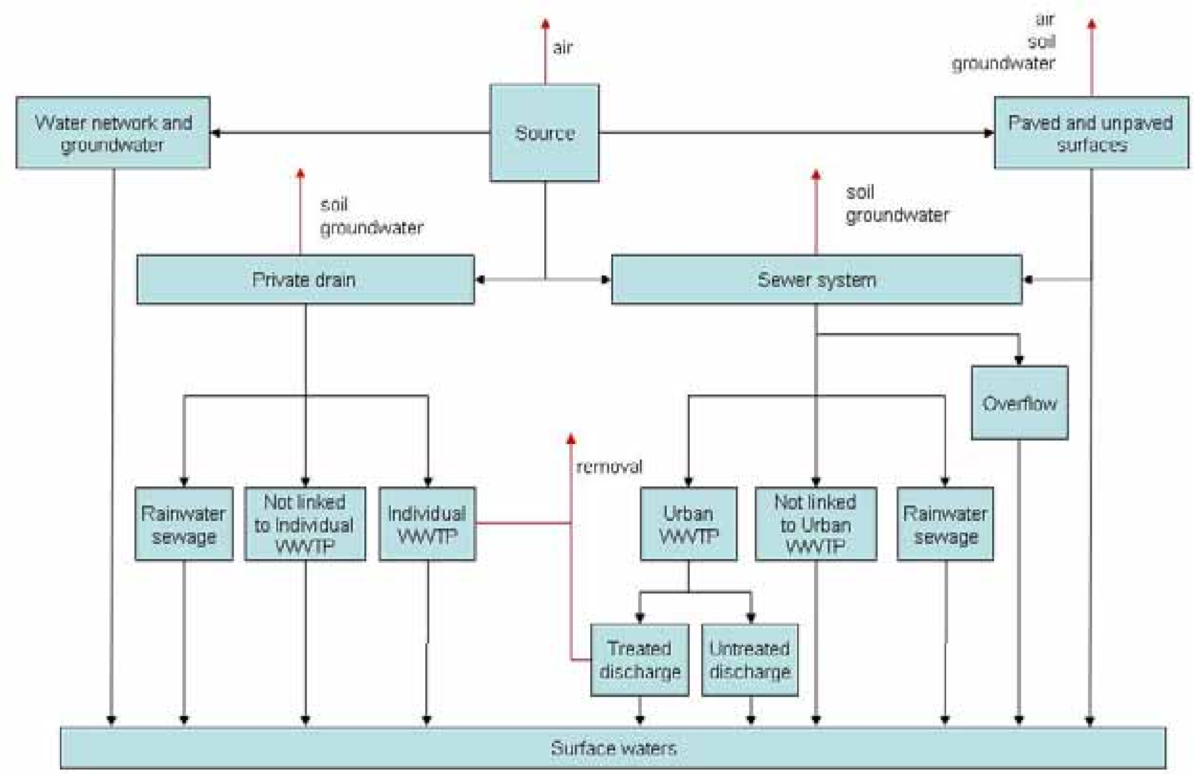
The WEISS system

The WEISS system will integrate all relevant emission sources (both diffuse and point), all transport routes, and a planning support module. This will enable calculation of pollutant loads in distinctive nodes of the pathways, as required for monitoring and reporting (e.g. WFD, E-PRTR, WISE).

Sources and pollutants addressed in WEISS are typical for regions with a high pressure on land use. Pollutants from agricultural, urban and industrial activities will be quantified, with focus on priority substances.



<u>Pathways</u>
WEISS focuses on emissions and their pathways to water bodies. In the flow scheme all the pathways considered in WEISS are represented. Reporting will be possible in each of the nodes.



Flow scheme of WEISS: different pathways from source to surface water

High geographical resolution

WEISS will operate at a high geographical resolution. A resolution of 1 ha is selected for Flanders. The sources are spatially distributed on 1ha resolution maps before calculating the path of the emissions to surface water.

The base resolution can be changed in function of the sources dealt with, the spatial detail desired, the legislative framework, the quality and quantity of the original data and computational constraints.

Bottom-up approach

WEISS will use a bottom-up approach to calculate the emissions for each source and pollutant:

1. Localise the source (EEV) on high resolution map respecting its spatial characteristics (regionalization)
2. Apply Emission Factors (EF) to each grid cell where the source is present
3. Calculate in detail the loads transported via the relevant pathways
4. Summation of the loads for reporting of emissions in entities like water bodies.

In the model this bottom-up approach consists of three consecutive steps:

1. spatial distribution of the source,
2. computation of the pathways and
3. accounting in distinctive nodes of the pathways.

For every step, specific algorithms are applied. They are implemented as part of model blocks stored in a model library. For every emission source the appropriate model blocks are selected and chained to perform the required calculations. This modular approach allows the addition of new sources and new pathways. The accounting module calculates the total pressure and source appointment for a chosen hydrological entity e.g. water body or river basin.

Adaptable

The system will be easily adaptable for use in EU MS or parts thereof and will be freely available to that effect. It will allow determination of the significant emission sources, simulate pathways from source to sink, support monitoring and reporting and assess (policy) measures aimed at reducing water pollution.

Conclusions

WEISS is a transparent emission inventory system with a generic approach that makes it easily adaptable. It uses a bottom-up approach that allows reporting at any geographical scale. The system can start small-scale or with data available at a low level, and can grow over time.

France case study fact sheet

country: France

title of the project: French strategy for monitoring and reduction of hazardous substances discharges to waters from industry and urban wastewater treatment plants

type**:** implementation of a national strategy through a 2 steps process:

- A survey was first carried out on a sample of industrial and urban waste water treatment plants (2876 facilities)
- Use of the outcomes for regulatory purpose (revision of discharges permits)

scope:

- Information gathering: identification of point sources of hazardous substances
- Improvement of E-PRTR reporting on hazardous substances and as the result the quality of the inventory under EQS directive
- Assess the relevance of each source and target reduction measures
- Improve the management of industrial connections to urban wastewater networks
- Contribute to achieve the 2 main objectives of the WFD as far as chemicals are concerned: good status and reduction of emissions of substances.

duration: (start and end date)

The survey started in 2002 and ended in 2008.

Following this survey, 2 ministerial notices have been published and their implementation is ongoing.

- 2009/01/05: notice on the implementation of a specific monitoring of industrial discharges of hazardous substances to waters and their reduction
- 2010/09/29: notice on the implementation of a specific monitoring of UWWTP discharges of hazardous substances to waters

status: ongoing

information resources (URL):

The results of the survey together with the notice 2009/01/05 for industrial discharges monitoring and reduction are available in french on a dedicated website http://ineris.rsde.fr/

The french strategy on micropolluants reduction is summarised in a document that can be dowloaded in french and soon in english at the following link: http://www.developpement-durable.gouv.fr/Les-micropolluants-dans-les.html

At the same link can be downloaded the notice 2010/09/29 for UWWTP discharges monitoring.

Methodology used:

Survey: monitoring of a list of 106 substances in the direct or connected discharges of 2876 plants.

Contact person/organisation:

French ministry for ecology, sustainable development, transport and housing (MEDDTL)

Lauriane Gréaud (lauriane.greaud@developpement-durable.gouv.fr): french strategy on micropolluants reduction

Marine Colin (marine.colin@developpement-durable.gouv.fr): industrial emissions

Vincent Ferstler (vincent.ferstler@developpement-durable.gouv.fr): urban wwtp emissions

Abstract

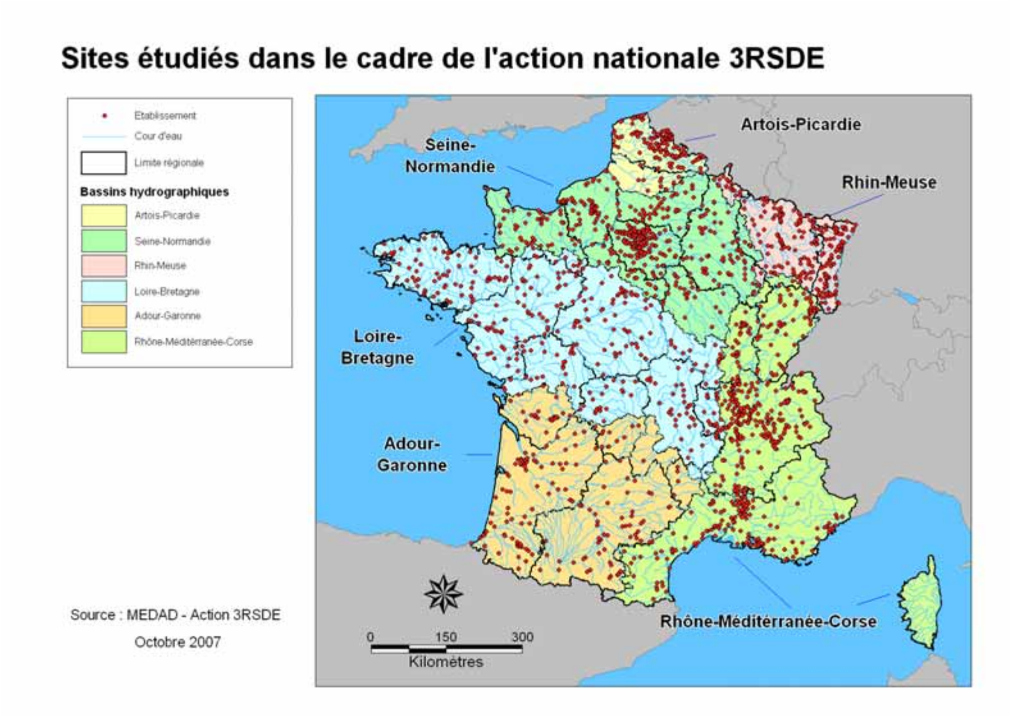
As a part of the global framework for the implementation of the WFD in France, a working programme has been initiated in 2002 which aims at reducing industrial releases of dangerous substances into the aquatic environment. This programme has 4 main steps:

1. Exploratory step: inventory of hazardous substances potentially discharged by industries and UWWTP to waters and identification of the most relevant substances to monitor
2. Improvement of knowledge and data consolidation: transitory monitoring
3. Implementation of a relevant monitoring at the site level
4. Carrying out of reduction actions

1. First step of the reduction strategy of hazardous substances point discharges: the national survey

From 2003 to 2007 took place in France a national inventory of hazardous substances in industrial and urban discharges to waters (called “action 3RSDE”). This action, initiated by the ministry in charge of sustainable development, was based on the chemical analysis of 106 chemicals in discharges from 2876 sites, mostly industrial facilities but also 167 urban wastewater treatment plants (UWWTPs) and 22 power plants. The sample of facilities involved in this action on a voluntary basis is considered representative of the French industry: chemistry, food product, paper manufacturing, surface treatment industry, metallurgy, textile, tanning, glass manufacturing, waste treatment and disposal...

Figure 1: Distribution of the 2876 facilities studied over the 6 French river basins



The list of 106 substances[9] was established considering their toxicity for aquatic ecosystems and because they were subject to EU regulations on the limitation of their discharges to water (76/464/EEC - Dangerous Substances Directive - and 2000/60/EC - Water Framework Directive). Bioassays have also been performed on 10% of the effluents measured in order to begin a study on the possible correlation between chemical and ecotoxicological impacts.

Sampling prescriptions have been determined to be significant of a normal day of activity.

The 21 laboratories in charge of sampling and analyses had to comply with the same technical and quality requirements. Nevertheless, different analytical techniques were used and the associated performances introduced uncertainties in the results. The uncertainties are of course increased for “unusual” substances (not well known on routine basis) and for the low levels of concentrations.

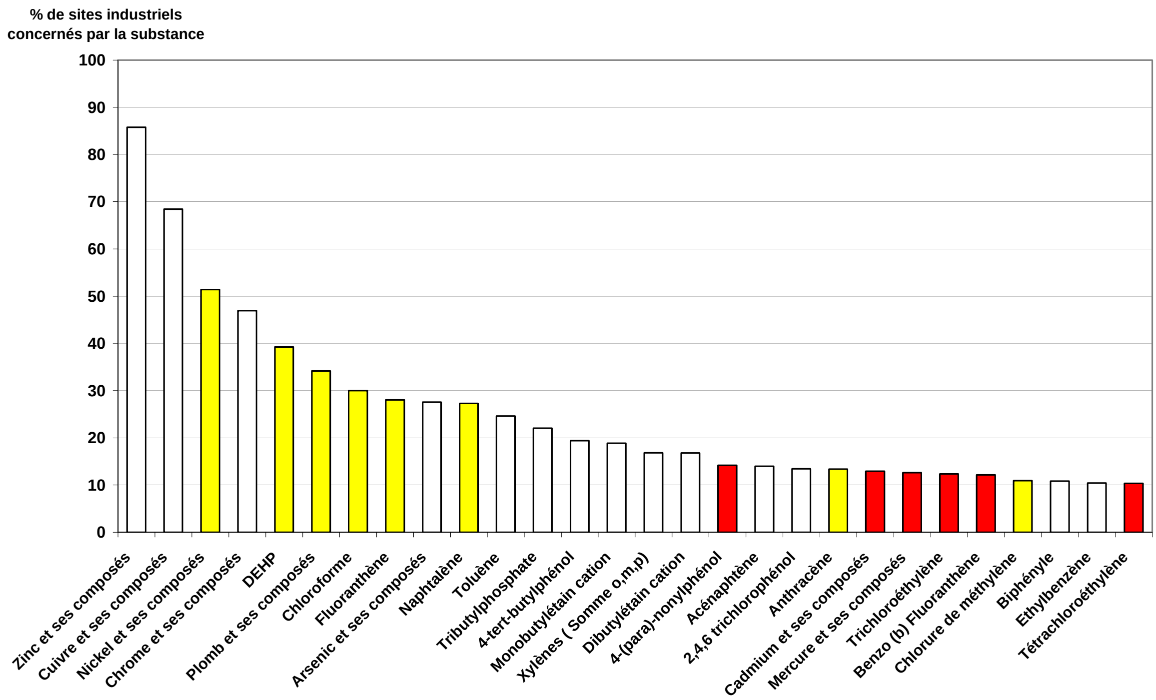
All 106 substances have been quantified at least once, some in more than 30% of the discharges (metals, PAHs, VOHCs, phtalates).

70% of the measured emissions are organic substances. Some substances are quantified in the majority of sites but for 20% of them, a main source is observed.

This action made clear that urban wastewaters are also a source of hazardous substances as most of them (81) have been quantified in at least one discharge.

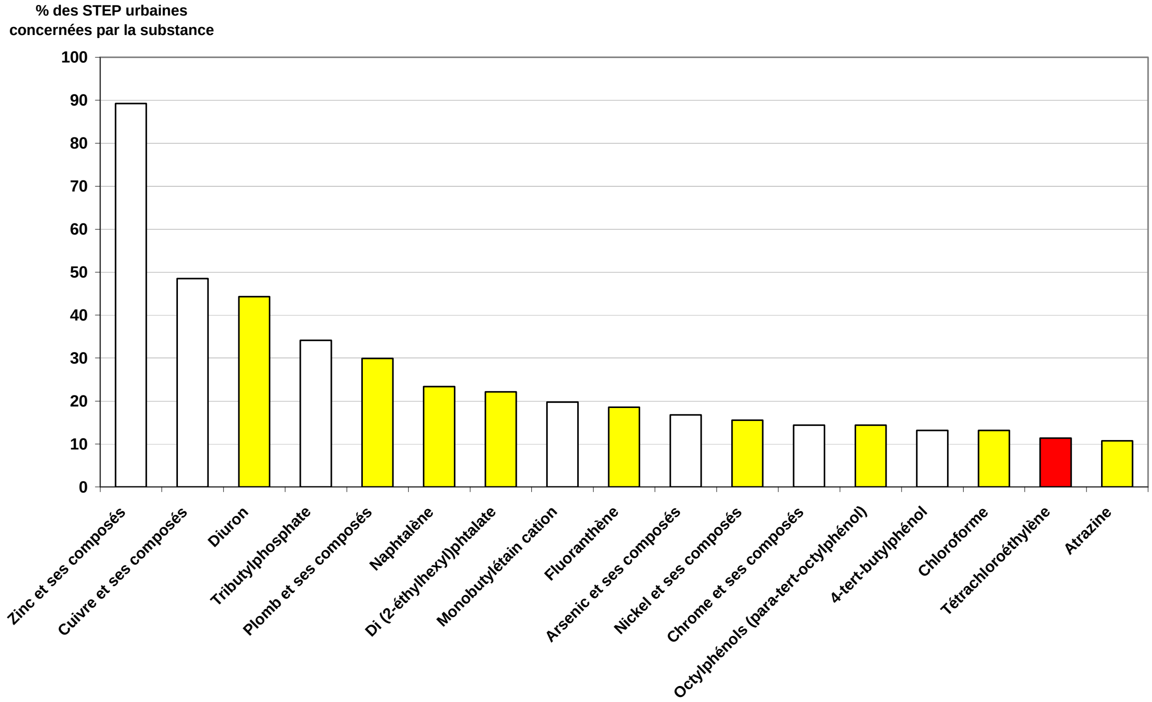
On the following figures, priority hazardous substances are identified in red and priority substances in yellow.

Figure 2: Substances quantified in more than 10% of the industrial discharges studied



[9] The complete results concerning this study can be downloaded (in French) at : http://www.ineris.fr/rsde/doc/docs%20rsde/DRC-07-82615-13836C.pdf . The list of the 106 substances can be found p. 580 to 583.

Figure 3: Substances quantified in more than 10% of the UWWTP discharges studied



The main outcomes of this inventory are:

- A great improvement of laboratories practices on these substances
- A better knowledge of hazardous substances point pollution sources, by the identification of key sectors involved
- Identification of working axes to elaborate appropriate reduction measures

In 2005, the first results of this survey, together with a similar survey carried out on surface waters, have been used to **select the substances of national concern**.

In 2008, negotiations with industrial sector representatives, on the basis of this results, lead to the elaboration of **39 sector specific lists of substances** that should be monitored in their discharges.

2. Second step : implementation of specific monitoring and reduction requirements of hazardous substances

2.1 Requirements for industry

In 2009, a notice from the ministry of sustainable development was published asking for the authorities in charge of delivering discharges permits to revise them in order to include the monitoring and, for some of them, the reduction, of relevant hazardous substances discharges for the industrial facility.

An initial monitoring has to be performed on a monthly basis, for a six month period. The list of substances to monitor depends on of the activities on site (39 sector specific lists established after the national survey).

Based on several criteria (loads, concentration, status of the water body..), some of the substances will be added to the self monitoring programme of the industry and for the ones with higher loads, a reduction action plan has to be established.

The substances entering to the self monitoring obligation have to be monitored on a quarterly basis, for 2 years minimum.

Annex 5 of the notice describes the technical requirements for chemical analysis and sampling. Limit of quantification (LoQ) that must be achieved are established for each substance.

Hazardous substances specific monitoring should be implemented in 2013 for all facilities under permit conditions.

The next step for the local authorities is to revise and ad emission limit values in the permits, according to receiving the water body's allowance (based on EQS).

2.2 Requirements for UWWTP

In 2010, a notice from the ministry was published asking for the authorities in charge of delivering discharges permits to UWWTPs, to revise them in order to include the monitoring relevant hazardous substances.

An initial monitoring has to be performed on a monthly basis during a 4 months period.

For UWWTP above 100.000 eh capacity, the list of substances to monitor is adapted from E-PRTR regulation: implementation in 2011.

For UWWTP between 10.000 and 100.000 eh capacity, the list of substances to monitor is the list of UE priority substances and substances of national concern: implementation in 2012.

Based on several criteria (see above), a regular monitoring of some substances will have to be performed (see table 1). Then, every 3 year, monitoring of a larger list has to be carried out again.

Table 1: Monitoring frequencies for UWWTP

EH	>=10.000 and t<30.000	>= 30.000 and <90.000	>= 90.000 and <360.000	>= 360.000 and <540.000	>= 540.000
Number of analysis per year	3	4	6	8	10

As for industries, this new monitoring requirement will be integrated in self monitoring requirements and permits will be revised.

Annexe 2 of the ministerial notice establishes the limit of quantification (LoQ) that laboratories must achieve for each substance. The technical requirements for chemical analysis and sampling are also described. For example, specific sampling equipment is required.

All these new requirements for industries and UWWTP also include the obligation to report the monitoring results together with the quality data through specific reporting tools. A quality check is performed by the ministry with the help of its technical agencies.

The creation of a national laboratory of reference for water (AQUAREF) has recently been supported by the ministry. This laboratory, which is a consortium of 5 structures, works at improving water monitoring results (natural or discharged waters).
